It is important to observe that before paint or varnish is applied it is essential that the surface be absolutely clean and free from grease. With this object the shells are boiled in a solution of caustic soda, and they are then thoroughly washed in clean water. Any shells which have been improperly varnished are boiled for as long

as three hours, which is sufficient to remove the varnish and render the shells ready for treatment again.

The next two slides are included by permission of the editor of *Machinery*, and are taken from a reprint of articles which appeared in that publication on "High Explosive Shells." The first illustrates the varnishing-room viewed from the stove end, and the second the same room viewed from the preparing end. The procedure, according to *Machinery*, is as follows: "The chamber is wiped out perfectly dry on the bench at the far end of the room. The shells are transferred to the next bench, where the thread guards, termed ferrules, are screwed in. The shells are then pre-heated in the stove, withdrawn, set on the opposite of the bench, where they are filled with copal varnish, which is then poured out. They are now passed to the special bench in the foreground and located nose down to the drain. The surplus varnish falls into a tray inclined in the direction of the varnish tank, into which it flows. The varnished shells are removed on a special trolley and then transferred to the stove. The capacity of the trolley is 120 shells, and the general equipment of the room is adapted for 120 shells at a heat. Baking lasts two or four hours under a temperature of 300° F. According to official regulations, the time under this temperature must not be less than two hours. At the completion of this process, the trolley is transferred to the dispatching end of the building through the exterior doors of the stove. The shells are taken in hand by women who remove the thread ferrules and tap out varnish which may have entered the threads—not forgetting the small hole for receiving the fixing screw."

In conclusion, I should like to refer to the most up-to-date method of painting the bodies of motor-cars. The method is extraordinarily quick, a coat of japan being given to a four-seated car in exactly two minutes. This is done by discharging japan through a flexible tube connected with a overhead tank through a wide nozzle, which is opened by the pressure of the thumb and closed by a spring. The motor body is placed on a bogey with a trough-like tank on three sides of it and a solid iron sheet on the fourth side. On pressing the lever the japan literally pours out of the nozzle on to the work, and it is only necessary to move it very quickly in order to get the whole of the surface covered in the time named. Of course, a great deal more japan passes into the trough-like tank than goes on to the body, but this passes through a screen, and descends into a small tank below, whence it is pumped up to the elevated tank for use again. A few minutes are given for all superfluous japan to run off, and the bogey is then wheeled over to the stove where the body is placed for some hours until the coat is sufficiently hard to enable it to be rubbed down and then to receive a second coat in the same way.

A somewhat similar but improved method of painting motor bodies is largely used in America and is known as the "Aeron." In this process the paint, japan or varnish is forced through a flexible tube, and is discharged continuously through a wide flat nozzle. A trough-like tank is provided into which the superfluous japan flows, but sufficient sticks to the surface to give a good thick and durable coating. In order to prevent the inside of the body being splattered with japan a brush is first used to apply it to the top edges and then the nozzle is passed rapidly over the surface on to which it discharges the japan. The superfluous material which flows into the tank passes through a filter and is used again, being continuously added to that in use. The body is allowed to drip for some minutes, and is then placed in a drying oven specially for the purpose to exclude humidity. The varnish coat dries in rather over four hours and may then be rubbed down lightly either with fine steel wool or pumice stone, when it is ready to receive another coat.

I am indebted to the *Iron Age* of New York for the illustrations and the following details of the process of finishing an aluminium body, for it will be understood that nearly the whole of the materials for the undercoats are applied by means of the "Aeron." The aluminium body is first washed with gasoline applied with a brush, and this is wiped off and allowed to dry. A coat of oxide of iron priming and linseed oil is then given by means of an ordinary sprayer or air brush and the body is then placed in a stove at 115° F. for three hours. It is then ready to receive a coat of coach putty, which is applied by hand, the object being to obtain a level surface. This dries in the air for twelve hours. Then a coat of half white lead and half rough-stuff is sprayed on and the body is stoved at 115° F. for three hours. The next process is to spray on four coats of rough-stuff and to stove each at the same heat for two hours each. Next is applied by hand a coat of rubbing rough-stuff, which is air-dried and then rubbed down with pumice stone. Some additional puttying is then usually required. The body is now in a condition to receive the first coat of colour,

which is sprayed on, and this is allowed to dry in the air for six hours. The "Aeron," or flowing machine, is then employed to put on three coats of colour and varnish or enamel, the first two being stoved at 120° F. for four hours, and the last at 125° F. for four and a half hours. A coat of rubbing varnish is then applied, and this is rubbed down with finely-powdered pumice stone applied by means of a felt pad moistened in water. A final washing-off with clean water and the body is ready for the finishing coat of varnish, which is applied by experts with the usual form of flat varnish brush. The body is then complete, and provided that good materials have been used shows up with that brilliant finish which is so much admired.

Although there appears to be a large number of coats necessary for obtaining the beautiful finish there are, as a fact, fewer than would be required by the old process of applying all the coats by hand. By using the methods described, not only is a great saving of time effected, but the appearance of the finish is improved, while, more important still, the durability is distinctly increased.

In conclusion, I desire to emphasize two important provisions which are absolutely essential to a good finish and speedy work. The first is to provide a room in which the paint and varnish is applied that is well ventilated, free from draughts, and is kept at a uniform temperature. But above all, dust must be absent and the greatest care be taken to exclude it. I have seen painting shops adjacent to the joinery works with but little division between the two. The result, of course, is that specks innumerable settle upon the work, and the finish is spoiled. I would repeat, then, that too much care cannot be taken to eliminate dust.

The second provision is a drying-room, which will facilitate the drying and exclude moisture.

[At the conclusion of the paper a demonstration of the working of the Aerograph was given. Mr. Burdick, the inventor, kindly provided the necessary apparatus, by which coats of paint and varnish were successfully applied to various articles.]

DISCUSSION.

MR. WALTER F. REID, F.I.C., believed that the method of painting by means of a spray was first used at the Chicago Exhibition, as the Secretary of the Society, Sir Henry Trueman Wood, could probably testify. The story he heard was that the painters struck work when the Exhibition was nearly finished, and the man in charge of the fire-engine suggested it should be used for spraying on the paint. The suggestion was adopted, and the strike was broken. At the St. Louis Exhibition practically all the buildings were coated by the spraying method, and an enormous amount of money was thus saved. The method ought to be used to a much greater extent in this country, as it saved a large amount of labour, and effects were obtained with it that could not be produced in any other way. Much time was saved by its use in the painting of shells, and the work was done more accurately, but the author was incorrect in his statement that zinc or ochres might be used as pigments for that purpose. A zinc pigment inside a shell in which picric acid was to be placed would be a source of very considerable danger. Many years ago he worked out the composition of a paint for use in the coating of the insides of shells, which consisted of a tough varnish and contained no pigment at all. It was essential in loading a shell that the picric acid should not come in contact with the steel because it would form picrate of iron, which was exceedingly sensitive, and the varnish protected the metal from the action of the picric acid. The floor-cloth industry, in which he was particularly interested, probably consumed more paint than any other industry, apart from the painting of buildings. Although experiments had been made in the use of paint-spraying for that purpose, he had not heard of any instance in which the method had been practically adopted, and it would be interesting to know if the author had any information on that subject.

MR. CHARLES L. BURDICK said the paint-sprayer with which the demonstration at the meeting was being conducted was one in which the inner nozzle was a pin-valve controlled by a lever, the discharge port being surrounded by a ring of air. That was the only type of spray which had ever been successfully used for painting purposes. Another type of spray was used in the whitewashing machine, consisting of a force-pump with a nozzle which ejected the material in a cone shape. That was quite satisfactory for light material, and it was used at the Chicago Exhibition for whitewashing the buildings, when, owing to insufficiency of time, it was impossible to carry out the intention of painting them. But such an apparatus was not sufficient for handling oil paint, and it did not control the quantity of material used. The pin-valve arrangement with the lever controlled the amount perfectly, so that a golf ball, a lead pencil, or a ship, could be painted by such means.

MR. A. S. JENNINGS, in replying to several questions asked by members of the audience, said it would be necessary for the engineer who designed the plant for a particular piece of work to decide at what distance from the generating plant the spraying machine could be worked. The manufacturers of the spraying machines would give the best advice on that subject to those who

wished to use them. He was much obliged to Mr. Reid for pointing out the erroneous statement made in the paper in regard to zinc. As far as he knew, spraying was not used in the painting of floor-cloth in this country, and there seemed to be an immense field open for a successful application of the method in that direction. He had mentioned in the paper that wind caused trouble in the spraying of gasometers, but he suggested it was possible to construct a cabinet or a protector of a portable nature which would protect the operator while at work. Several spraying machines were on the market and were easily obtainable, their price depending on the size of the plant required. The two essentials controlling the suitability of the paint and varnish used in the apparatus were the specific gravity and the drying properties. Those firms which had made a special study of paints for use in spraying machines had produced excellent results. Over 700 firms making toys had started work in this country in the last twelve months, and there was not the slightest reason why they should not be successful. He recommended that paint-spraying should be adopted in that new industry, the under-coat consisting of a good water-paint and the top-coat of varnish.

On the motion of the CHAIRMAN, a hearty vote of thanks was accorded to Mr. Jennings for his interesting paper, and the meeting terminated.

ENGINEERING NOTES.

The Ljungstrom Turbo-Electric System.—The *Times*, in its engineering summary for the past year, dated the end of January, says use is made in this of the principle of the double-rotation, radial-flow turbine, and in experimental installations the system is stated to have given a demonstration of its suitability for marine machinery. This turbine is claimed to have a low steam-consumption in comparison with other forms, and to be well adapted for the employment of the high superheat with which certain troubles have been associated with some types of turbine. If, as is reported, contracts have been placed for the fitting of this system in several ships now building, some further data derived from actual service should be available at an early date. It is understood that Messrs. Beardmore have under construction at their works a Ljungstrom turbine, in which a mechanical drive will be employed.

Electric Railways in America.—The "James Forrest" lecture before the Institution of Civil Engineers was delivered recently by Mr. H. M. Hobart, and, among other information on the above subject, he drew attention to the continual decrease in the cost of manufacturing electricity as being both a consequence and a cause of the accelerated growth of the electric railway industry. He pointed out that twenty years ago it would have been impossible to manufacture electricity at a cost of much less than 2*d.* a kw. hour, and that ten years ago a price of 1*d.* a kw. hour would usually have been the minimum permitting of any profit. At present there are undertakings that could make a profit in supplying electricity to railways in their district at but little over ½*d.* a kw. hour; and, indeed, during the last two years many millions of units have been delivered on the premises of the Butte, Anaconda, and Pacific Railway at a price of 0·265*d.* Again, fifteen years ago the best generating sets, consisting of slow reciprocating engines direct coupled to dynamos, cost about £30,000 for a 3,000 kw. set, which was considered about as large as could be used to advantage; but now 30,000 kw. steam turbine sets are available at a price considerably below £60,000. Further, the 3,000 kw. set of fifteen years ago consumed some 18 lb. of steam per kw. hour, whereas the present 30,000 kw. set consumes only about 12 lb. The corresponding progress in steam-raising and condensing plant, in conjunction with the requirement of only about two-thirds as much steam and fuel, may be taken, roughly, as at least halving the initial outlay per rated kilowatt installed for these components of an electricity manufacturing plant. Developments in hydro-electric plants have also been very satisfactory, but in districts where coal is obtainable at a low price it is rarely possible for them to supply electricity at a competitive price except for applications with a fairly high load factor. Reference was made to the 11,000 volt lines of the Norfolk and Western Railway, electric operation of the Bluefield division of which was inaugurated in May last with twelve 240-ton locomotives of the split-phase type. This section is twenty-nine miles long, with double track except through the Elk Horn tunnel, in which eastbound trains ascend a gradient of 1·5 per cent. The journey from Vivian to the tunnel, a distance of about fifteen miles, with a rise of about 900 ft., is performed in about an hour with coal trains weighing 2,900 British tons, drawn by two 240-ton electric locomotives, one at the front and the other at the rear. Formerly, with a train of the same weight, three 240-ton Mallet locomotives were employed. The total weight of the trains was therefore 3,620 tons, as compared with 3,380 tons for electric operation, and the speed attained was only about seven miles an hour, exclusive of stoppages for coal and water. Mr. Hobart drew special attention to the elimination of congestion at tunnels. He stated that electric trains maintaining a speed of fourteen miles an hour can be dispatched through the Elk Horn tunnel at the rate of one every three minutes, against six miles an hour steam trains, of less useful weight, every seven minutes. Taking into account the greater useful tonnage of the electrical trains through the

tunnel and the higher speed, he thought it might fairly be stated that any bunching up of tonnage on the division can be relieved by electric operation in about one-third of the time required with steam locomotives.

Australian Transcontinental Railway.—This important connection will be 1,063 miles long, and will save the mails and passengers, which at present go by sea, two to three days in time, according to destination. The country passed through—Port Augusta, South Australia to Kalgoorlie, Western Australia—is fairly easy and bridge work light, but is practically a waterless desert, except for grazing purposes and what it may bring forth in the future as regards mineral wealth. Separate from the above, which we derive from various sources, Mr. W. C. Bell, the Chief Engineer of the Commonwealth Government Railways, reports, in the latest advices, that in Western Australia the route has been surveyed and definitely located for 260 miles. In South Australia the survey is complete throughout, and the route has been definitely fixed for the 428 miles 51 chains between the terminus of Port Augusta and Ooldea. Two hundred and forty miles in Western Australia and 263½ miles in South Australia were ready for platelaying, out of which total of 503½ miles 495½ miles had been done. Very heavy earthworks at the South Australia end are now being approached, but it is hoped that the rails will be laid throughout by the end of the present year.

Swedish Army Oxy-Acetylene Searchlight.—The American Illuminating Engineering Society describes the use in the Swedish army of a pellet of ceria in place of the lime of the oxy-hydrogen lantern, and an oxy-acetylene jet. The consumption is stated to be about 40 litres of acetylene and a like quantity of oxygen per hour, and sufficient supply of these gases to provide for twenty hours burning is carried with the apparatus. It is also stated that searchlights are being used, not only to detect the movement of the enemy, but to blind troops when charging, and to discomfort the pilots of aircraft. Owing to the blinding and confusing effect, it has been found to be impossible to advance troops in the face of strong searchlights, thus affording a practical illustration of the use and effect of glare. In this connection it is interesting to note that the importance of the problem of glaring motor headlights is also being recognised. A series of tests have been worked out which may be used as standard definition of what constitutes a dangerous "glare," and the results will be submitted to manufacturers of headlights with a view of eliminating the trouble. Future headlights are to be constructed according to scientific formulae, by which the far-reaching effect of a searchlight upon the road without glare will b obtained.

The Construction of the Largest Dry Dock in America.—The new South Boston dry dock is to be the largest in the country, being 1,200 ft. by 149 ft. in over-all dimensions. A wide variety of plant, including cableways, locomotive cranes, compressor plant for drills, mixing plants, a variety of floating plant, and, indeed, almost everything but steam shovels, will be used in carrying out the contract. A dredge is already at work on the site of the dock proper, the contractors are expected to bring up one of the biggest dredges on the Atlantic coast, which can handle 150,000 cubic yards of material per month, and which make short work of the 450,000 cubic yards to be dredged from the dock site proper and dumped at sea. Two large areas of land, between which lies the site of the dock and approach channel, have already been made by filling in between recently constructed bulkheads. The rest of this embankment will be made, after the dock is finished, from the material dragged out of the approach channel. This material will also be used to complete the embankment between the dock walls, after heavy bank of rip-rap to be excavated from the dock floor has been placed around the outside of the walls. About 85,000 cubic yards of rock must be excavated all over the dock floor. Considerable saving has been effected in the design by the plan of excavating beneath the walls only enough to secure a solid foundation, a sloping blanket of concrete joining the toe of each wall to the floor concrete of the dock. The contractors will spend the time until the dock site is dredged assembling plant. Then a cofferdam will be thrown across the lower end of the site as indicated, and the water pumped out. Active work on removing the rock will not start before the middle of the spring.

Pneumatic Process for Tamping Railway Sleepers.—Military and munition workers are scarce; therefore it behoves railway men to make use of machinery as much as possible. Compressed air has been used successfully for tamping sleepers on a part of the New York Central and Hudson River Railway. The tamping outfit consists of two pneumatic tampers, 600 ft. of 3-in. hose and an air-compressor mounted on a hand-car. The compressor is driven by a gasoline engine, which also propels the car itself at a speed of from twelve to fifteen miles per hour. The car will carry twelve men, and is equipped with cross trucks, with the aid of which four men can remove the car from the track in less than a minute. Each tamper is fitted with a tamping bar of the ordinary shape, and weighs, complete, 37½ lb. It is stated that the machine is equally effective for stone, gravel, or cinder ballast; that it can be worked to advantage around crossings and switches where hand tamping is difficult or impossible; and that maintenance men prefer it to the

tamping pick or tamping bar. The record showed that two men can average three hundred sleepers per day. A service test was made some time ago to determine the comparative stability of track tamped by hand and that tamped pneumatically. A section of track on the West Shore Railway in New Jersey was selected where the foundation is soft, and it is difficult to maintain the track in good condition. An 800 ft. stretch of track was tamped by machine and an equal length by hand. After six months' observation the machine tamping showed practically only half the settlement of the hand tamping.

Irrigation in the United States.—The total work of the United States Reclamation Service, completed up to the present fiscal year, according to a summation prepared by the service, includes 9.592 miles of canals and branches, the excavation of eighty-nine tunnels with an aggregate length of more than 25 miles, the building of 4,622 bridges with a total length of 19 miles, the construction of 82 miles of railway and the erection of 1,068 buildings, such as power-houses, pumping-stations, offices, residences, and store-houses. Dams of masonry, earth crib and rock embankments have been constructed, with a total volume of 12,200,000 cubic yards. The available reservoir capacity at the time of the summation was, approximately, 6,500,000 acre-feet, or sufficient to cover the States of New Jersey and Delaware to a depth of 12 in. Culverts built number 5,714, and total 36 miles in length. There are now in operation 298 miles of pipe line and 85 miles of flumes. Waggon roads have been built to an aggregate length of 784 miles, many of them in what were inaccessible mountain regions.

OBITUARY.

P. N. Muthuswami Naidu, B.A.—Mr. P. N. Muthuswami Naidu, of Madras, who was only elected a Fellow of the Society in November last, died on February 3rd. Mr. Muthuswami Naidu, who was for long in business at Madras, was one of the earliest graduates of the Madras University. In later life he took a prominent part in educational and other public movements in the Presidency. He was instrumental in establishing the local branch of the Y.M.I.A., and was a member of its managing committee. He was secretary of the South Indian Chamber of Commerce, and founded the Lakshmi Hindu Balika Patashala, a free school for girls at Saidapet. He had travelled in Europe, America, Japan, and China.

The Hon. Sir Chinubhoy Madavlal, Bt., C.I.E.—Sir Chinubhoy Madavlal, who had been a life member of the Society since 1900, died at Ahmedabad on March 2nd. Sir Chinubhoy's grandfather established the first spinning-mill in Ahmedabad, and he carried on the tradition of his family by taking a prominent part in the development of the textile industry in the Bombay Presidency. He was a member of the Legislative Council of the Governor of Bombay, and Chairman of the Ahmedabad Millowners' Association. He was the founder or supporter of many scientific and educational institutions in the Presidency, and enjoyed a very high reputation as a leading member of the mercantile community and as a philanthropist. His public services were recognised by his being made a C.I.E. in 1907, a knight in 1909, and a baronet in 1913. He was the first and, so far, the only Hindu to be created a baronet.

GENERAL NOTES.

Production of Zinc.—In his recent presidential address at the annual meeting of the Institute of Metals, Dr. G. T. Beilby urged that more attention should be paid to the industrial side of metallurgy. Before the war it was taken for granted by British users of zinc that there would always be an ample supply of this metal. It must have been an awakening to those optimists when the price of zinc ran up many times its normal value. He strongly urged that zinc-smelting should be established in Great Britain at the first opportunity. As to the German monopoly of metal-magnesium, there was no reason why this metal should not be produced on a large scale and at a comparatively low price.

Gypsum in Canada.—The gypsum industry is one of the most important and one of the oldest of the mining industries of Canada. In order of magnitude amongst the world's gypsum producers, Canada ranks third. The chief producing provinces are Nova Scotia, New Brunswick, Ontario, and Manitoba; but a small amount is also obtained in British Columbia. The output of these various provinces during 1913, according to the Annual Report on the Mineral Production of Canada for 1913, was as follows:—

	Tons.	Value in dollars.
Nova Scotia	404,801	479,515
New Brunswick	103,954	279,395
Ontario	62,315	208,029
Manitoba	65,100	479,500
British Columbia	200	1,300

The gypsum industry of Canada consists chiefly in quarrying the crude gypsum, and in shipping it in that condition to the United States, where it is calcined, and in part shipped back to Canada as a finished product.

Export of Dried Apples from the United States in War Time.—The influence of the war on the destination of shipments of dried apples from the United States to European ports has been very marked. During the five

fiscal years ending 1914, the average annual quantity of this description of fruit amounted to 35,137,000 lb., to the value of $2,815,000 (£563,000), as compared with a maximum of 53,665,000 lb. in 1912, and a minimum of 21,804,000 lb. in 1911. Since the outbreak of hostilities these figures have increased nearly 21 per cent. above the average of the five previous years, and amounted for the fiscal year 1914–15 to 42,589,000 lb., to the value of $3,271,000 (£654,200). The following shows the percentage of these exports shipped to the various European countries during the two periods—in order of their importance:—

	1909-14.		1914-15.	
Germany	47·7	per cent.	·25	per cent.
Holland	27·4	,,	12·20	,,
Belgium	5·5	,,	*Nil.*	
Denmark	3·7	,,	42·00	per cent.
Sweden	3·2	,,	25·40	,,
Norway	4·5	,,	·90	,,
Great Britain	3·4	,,	12·00	,,
Other countries	4·6	,,	7·25	,,
	100	,,	100	

From these figures it appears that, whilst the exports to Germany have declined from 47·7 per cent. to practically *nil*, those to the neutral countries of Denmark and Sweden have increased tenfold (from 6·9 to 67 per cent.). It would be interesting to know how much of this enormous increase finds its way ultimately to Germany.

MEETINGS OF THE SOCIETY.

Ordinary Meetings.

Wednesday afternoons, at 4.30 p.m.:—

May 3.—Professor W. B. Bottomley, M.A., F.C.S., F.L.S., "Bacterised Peat."

May 10.—Sir Francis Taylor Piggott, M.A., LL.M., Chief Justice of Hong-Kong, 1905–1912, "Contraband and Blockade." Dugald Clerk, D.Sc., F.R.S., Chairman of the Council of the Society, will preside.

May 17.—George Percival Baker, "Hindu Hand-painted Calicoes of the Seventeenth and Eighteenth Centuries, and their Influence on the Tinctorial Arts of Europe." Sir William Martin Conway, M.A., F.S.A., F.R.G.S., will preside.

May 24.—John Collett Moulden, A.R.S.M., M.Inst.M.M., "Zinc, its Production and Industrial Applications." (Peter Le Neve Foster Prize Essay.)

Indian Section.

Thursday afternoons, at 4.30 p.m.:—

April 27.—James MacKenna, M.A., I.C.S. (Deputy Commissioner, Myaungmya, Burma, and designated Agricultural Adviser to the Government of India), "Scientific Agriculture in India."

May 18.—Sardar Daljit Singh, C.S.I., "The Sikhs."

June 1.—Professor Wyndham R. Dunstan, C.M.G., M.A., LL.D., F.R.S., "The Work of the Imperial Institute for India." The Right Hon. Lord Islington, G.C.M.G., will preside.

Colonial Section.

Tuesday afternoons, at 4.30 p.m.:—

April 11.—Sir Daniel Morris, K.C.M.G., M.A., D.C.L., D.Sc., F.L.S., "The Forest Resources of Newfoundland." The Right Hon. Sir William MacGregor, G.C.M.G., C.B., will preside.

May 2. — The Right Hon. Sir William MacGregor, G.C.M.G, C.B., LL.D., D.Sc., "Some Native Potentates and Colleagues."

Fothergill Lecture.

Monday afternoon, at 4.30 p.m.:—

Edward A. Reeves, F.R.A.S., F.R.G.S., Map Curator and Instructor in Surveying to the Royal Geographical Society, "Surveying, Past and Present." Three Lectures.

Syllabus.

Lecture III.—April 10.—*Modern Instruments and Methods of Geographical Surveying.* Advance made in recent years—Difficulties of obtaining accurate measurements—Circumstances that determine character of survey—Theodolites—Base line apparatus—Triangulation, with recent examples—Traverses with theodolite and tacheometer or subtense instruments — Plane-table, its use in topographical mapping, and recent improvements —Determination of heights—Photographic surveying—Astronomical observations for fixing positions.

The lecture will be illustrated with lantern-slides.

Cantor Lectures.

Monday afternoons, at 4.30 p.m.:—

J. Erskine-Murray, D.Sc., F.R.S.E., M.I.E.E., "Vibrations, Waves, and Resonance." Four Lectures.

Syllabus.

Lecture I.—May 1.—*Periodic Motions.* Definitions and modes of production—Stable and unstable equilibrium — Inertia, gravity, and elasticity — Pendulums and spring oscillators of various kinds —Torsional vibrations, balance wheel—Corrugation of rails—Musical instruments—Complex vibrations and the quality of a tone—Vibrations on large scale, seismic tremors, vibrations of ships and buildings, lightning.

LECTURE II.—MAY 8.—*Waves in Ponderable Matter.* Transverse and longitudinal waves in solids and liquids — Methods of production and propagation — Polarisation — Wind waves — Ship waves—Tides and seiches—Cloud waves—Independence of wave trains—Superposition of harmonic motions—Sound waves—Submarine bells—Voice, phonograph, and gramophone.

LECTURE III.—MAY 15.—*Waves in the Ether.* Free and conducted—Light, heat, and electric waves — Alternating currents — Telephonic transmission—Wireless telegraphy—Submarine cables —Inductance, capacity, and resistance—Limits of known wave-lengths—Röntgen rays—Light—Heat —Reflection, refraction, and diffraction of wave motions—Stationary waves—Attenuation and distortion of travelling waves.

LECTURE IV.—MAY 22.—*Resonance.* Mechanical and electrical—Superposition of periodic impulses—Universal importance of the selective absorption of wave motions—Mechanical resonance or revibration — Screening of vibrations, absorption, and filtration — The acoustics of buildings — Sound resonators—Absorption of light waves—Coloured glass — Vision and photography — Absorption of electrical power by resonance—Tuning in telegraphy.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, APRIL 10...ROYAL SOCIETY OF ARTS, John street, Adelphi, W.C., 4.30 p.m. (Fothergill Lecture.) Mr. E. A. Reeves, "Surveying: Past and Present." (Lecture III.)

Cold Storage and Ice Association, at the ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 7.30 p.m.

Brewing, Institute of (London Section), Imperial Hotel, Russell-square, W.C., 8 p.m. Dr. A. Fernbach, (*a*) "The Mechanism of Alcoholic Fermentation"; (*b*) "Some Observations on Malt Mills."

Surveyors' Institution, 12, Great George-street, S.W., 5 p.m. Mr. W. R. Davidge, "Principles of Town-Planning."

Electrical Engineers, Institution of (Local Section), Mining Institute, Newcastle, 7.30 p.m. Mr. D. W. M. Thornton, "The Nature of Electrical Insulation."

TUESDAY, APRIL 11...ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 4.30 p.m. (Colonial Section.) Sir D. Morris, "The Forest Resources of Newfoundland."

Electrical Engineers, Institution of (Scottish Section), 207, Bath-street, Glasgow, 8 p.m. Mr. D. M. Macleod, "Branches from E.H.T. Circuits."

Royal Institution, Albemarle-street, W., 3 p.m. Professor F. Keeble, "Modern Horticulture. Lecture III.—Old and New Methods of Forcing."

Colonial Institute, Hotel Cecil, Strand, W.C., 8.30 p.m.

WEDNESDAY, APRIL 12...Naval Architects, Institution of, at the ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 11 a.m. 1. Address by the President. 2. Sir P. Watts, "On the Work of the Load Line Committee." 3. Mr. W. S. Abell, "Some Questions in Connection with the Work of the Load Line Committee."

3 p.m. 1. Mr. C. H. Lees, "The Laws of Skin Friction of a Fluid in Stream Line and in Turbulent Motion along a Solid of Great Length." 2. Mr. G. S. Baker, "Skin Friction Resistance of Ships and our Useful Knowledge of the Subject." 3. Professor T. B. Abell, "Experiments to Determine the Resistance of Bilge-Keels to Rolling." 4. Colonel G. Russo, "An Experimental Tank reproducing Wave Motion."

7.30 p.m. 1. Engineer-Lieutenant W. P. Sillince, "A Brief Summary of the Present Position of the Marine Diesel Engine and its Possibilities." 2. Mr. J. D. Young, "On the Co-ordination of Propeller Results." 3. Mr. T. C. Tobin, "Note on Maximum Propulsive Efficiency of Screw Propellers."

Electrical Engineers, Institution of (Yorkshire Section), Philosophical Hall, Leeds, 7 p.m. Mr. G. Wilkinson, "Electrical Heating: its present position and future development."

Automobile Engineers, Institution of, at the Surveyor's Institution, Great George-street, S.W., 8 p.m. Major B. W. Shilson, "From Engine to Axle."

Japan Society, 20, Hanover-square, W., 3 p.m. Dr. W. L. Hildburgh, "Some Japanese Minor Magical Practices connected with Travelling."

THURSDAY, APRIL 13...Naval Architects, Institution of, at the ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 11 a.m. 1. Sir A. Denny, "Sub-division of Merchant Vessels: Reports of the Bulkhead Committee, 1912-1915." 2. Mr. J. F. King, "Strength of Watertight Bulkheads." 3. Mr. A. T. Wall, "Some Effects of the Bulkhead Committee's Reports in Practice."

3 p.m. 1. Mr. J. Reid, "Notes from a Collision Case." 2. Mr. M. G. de Gelder, "Shipyard Cranes of the Rotterdam Dockyard Company."

Child Study Society, 90, Buckingham Palace-road, S.W., 6 p.m. 1. Dr. C. W. Kimmins, "An Account of Speed Tests of different kinds of Handwriting." 2. Mrs. Grainger, "An Experiment in Handwriting." 3. Miss Golds, "A New Method of Handwriting."

7.30 p.m. Annual Meeting.

Royal Institution, Albemarle-street, W., 3 p.m. Dr. W. H. Hadow, "English Music in the Tudor Period. Lecture III.—Songs and Instrumental Pieces."

Optical Society, at the Chemical Society, Burlington House, W., 8 p.m. 1. Mr. S. D. Chalmers, "Practical Workshop and Laboratory Measurements." 2. Mr. T. F. Connolly, "Focometry."

Electrical Engineers, Institution of, Victoria-embankment, W.C., 8 p.m. Discussion on "The Present Position of Electricity Supply in the United Kingdom, and the Steps to be taken to Improve and Strengthen it."

Historical Society, 7, South-square, Gray's Inn, W.C., 5 p.m. Mr. G. P. Gooch, "Germany and the French Revolution."

FRIDAY, APRIL 14...Royal Institution, Albemarle-street, W., 5 p.m. Professor Sir J. J. Thomson, "The Genesis and Absorption of X-Rays."

Teacher's Registration Council, Caxton Hall, Westminster, S.W., 6.30 p.m. Address by the President of the Board of Education on "The Future Development of Education in relation to Science and Commerce."

Astronomical Society, Burlington House, W., 5 p.m.

Physical Society, Imperial College of Science, South Kensington, S.W., 5 p.m.

Mechanical Engineers, Institution of, at the Institution of Civil Engineers, Great George-street, S.W., 6 p.m. Mr. W. Clemence, "Theory and Practice in the Filtration of Water."

SATURDAY, APRIL 15...Royal Institution, Albemarle-street, W., 3 p.m. Professor Sir J. J. Thomson, "Radiations from Atoms and Electrons." (Lecture VI.)

London: Printed by WILLIAM CLOWES & SONS, LTD., Duke Street, Stamford Street, S.E., and published for the Royal Society of Arts by G. BELL & SONS, LTD., York House, Portugal Street, W.C., in the Parish of St. Clement Danes, in the City of Westminster.—April 7, 1916.

Journal of the Royal Society of Arts.

No. 3,308. VOL. LXIV.

FRIDAY, APRIL 14, 1916.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICES.

COLONIAL SECTION.

Tuesday afternoon, April 11th, 4.30 p.m.; THE RIGHT HON. SIR WILLIAM MACGREGOR, G.C.M.G., C.B., LL.D., D.Sc., in the chair. A paper on "The Forest Resources of Newfoundland" was read by SIR DANIEL MORRIS, K.C.M.G., M.A., D.C.L., D.Sc., F.L.S.

The paper and discussion will be published in subsequent numbers of the *Journal*.

FOTHERGILL LECTURES.

On Monday afternoon, April 10th, 4.30 p.m., Mr. EDWARD A. REEVES, F.R.A.S., F.R.G.S., Map Curator and Instructor in Surveying to the Royal Geographical Society, delivered the third and final lecture of his course on "Surveying: Past and Present."

On the motion of the CHAIRMAN a vote of thanks was accorded to Mr. Reeves for his interesting course.

The lectures will be published in the *Journal* during the summer recess.

JOURNAL.

The Government limitations on the importation of paper and paper-making materials have rendered it necessary to restrict the *Journal* to the smallest possible size. For the present, therefore, its contents will be confined as far as possible to a report of the actual proceedings of the Society, and it may be necessary occasionally to publish reports of the meetings a little less promptly than has always been the practice.

It is hoped that the Fellows will appreciate the necessity of such restrictions, and it is also hoped that the *Journal* may be able to expand to its normal size at an early date.

PROCEEDINGS OF THE SOCIETY.

COLONIAL SECTION.

A meeting of the Colonial Section was held on Tuesday, March 28th, 1916; DUGALD CLERK, D.Sc., F.R.S., Chairman of the Council of the Society, in the chair.

The paper read was—

NEXT STEPS IN EMPIRE PARTNERSHIP.

By PERCY HURD,

Joint author with Mr. Archibald Hurd of "The New Empire Partnership: Defence, Commerce, Policy."

"We have arrived at the hour of our supreme trial and of our supreme opportunity." These words of Mr. Hughes, Prime Minister of the Commonwealth of Australia, may be taken as my text.

In our eagerness for wealth we have neglected security. Drifting complacently along the line of least resistance, with no particular care but our own ease, we have forgotten how that ease was won for us by our forefathers, and we have shut our eyes to the truth that eternal vigilance is the price of freedom. Thus we have come very near to the edge of the precipice—how near many of us do not yet realise.

"Never again," we are saying with united fervour, and "never again" is echoed back to us from every part of the Empire; but it is not words that are necessary, it is deeds—deeds of statesmanship worthy of the deeds of the men who are fighting for us, and for our children and theirs; deeds in pursuit of a high ideal.

And this is the ideal: To live under our own institutions, as free men, in home, nation, empire, and to ensure a like freedom for other peoples.

To overthrow this ideal of ours and establish a world dominion based upon force, Germany has organised a military and economic autocracy

of undreamt-of power and efficiency. To maintain our ideal we, too, must organise. Haphazard methods and drift will no longer do.

"A MERE DISORGANISATION."

Sir Robert Borden, the Prime Minister of Canada, has declared the British Empire to be "in some respects a mere disorganisation." One can fancy how heartily the professorial German would accept that definition. It is true, he would say, and therein lies the death sentence of England and England's Empire. He would argue the matter out with his usual precision. He would tell us that to be a "mere disorganisation" may have sufficed in former days and in former rivalries between such ill-devised Empires as that of our Elizabeth and Philip of Spain, and those of our early Georges and the Grand Monarque. But to-day—No. Kultur has arrived with its gospel of highly-developed and centralised organisation and untiring efficiency. Kultur as exemplified in the German Empire has met at every point the seemingly ill-organised and disjointed thing which we call the British Empire, but which is no Empire on any known model of the past—and Kultur must prevail.

We know that the German professors are hopelessly wrong in their diagnosis and their prophecy; but we are bound to admit, and we do well to profit by the admission, that the triumphs of Kultur as a purely material force have been many and striking. Had the strategic instinct of Prussia been guided by spiritual insight, ruin would not now be staring Germany in the face, and we of the British Empire should not be taking a new lease of life as we now are.

Take the sphere of applied science as an illustration. What tribute to the efficiency which is one of the products of German Kultur could be more arresting than the frantic efforts we have been making to undo in nineteen months of war the mischief of a complacent dependence upon Germany for essentials of our national and Imperial life? Too lazy or pre-occupied to attend to our own vital business and develop our own magnificent heritage, we found ourselves in the opening stages of the conflict labouring under a handicap which, had the German permeation gone on unchecked for another ten years, must have landed us in the gravest difficulties if not disaster.

For want of German dyes our great textile and other industries were brought near to a standstill; it was German carbons and magnetos which fed and ran our naval searchlights; deprived of optical glass, which we had allowed enemy countries to monopolise, many of our gallant soldiers have had to go into battle ill-equipped; and it was upon German chemicals and drugs that our medical services had come to depend for the purposes both of peace and war.

Contrast our land problem with that of Germany. Only under stress of war and the peril of our dependence upon imported food are we beginning to remember that British official statistics class as "farm lands" 3¾ million acres euphemistically declared to be "under grass," but producing little or nothing in the way of food for man or beast. The scientific methods of Kultur have turned similarly poor German lands into thousands of smiling homesteads. Apply the methods of Germany and Holland not only to these 3¾ million acres, but to the 12 million other acres of British heath and other so-called "waste" land, and you would make this country far more self-supporting, prosperous and happy, a far fitter nursery of our race.

The abundant metals of our own Empire, which we left unheeded, have become in the hands of German Kultur the means of sending to their death thousands of the flower of the youth of British countries. It is with the help of their own Australian spelter ores that German and Austrian armies have killed and maimed Australian boys in Gallipoli; the nickel and hematite ores of Canada have made their contribution to the murderous power of Krupp's among the Canadian troops in Flanders; and the wolfram resources of India have been used to overthrow the cause for which India has poured out her young life and wealth. It is the work of Kultur that has brought it to pass that, as the Solicitor-General confessed in the Admiralty Prize Court last September, the German octopus had before the outbreak of war thrown out its tentacles so successfully that the base metals of the world, and especially of the British Empire, were at the mercy of three great and highly-organised German concerns of Frankfurt and Halberstadt; and it is to Kultur expressed in a hundred other ways that Germany owes at this moment the astounding, even if infamous, war machine and the industrial and political organisation which have put Austria, Turkey and Bulgaria under her domination and are maintaining her stupendous fight against the world's three most powerful Empires.

Can you wonder that Kultur, which has accomplished so much on its material side, and which two years ago seemed so certain of win-

ning all it wished by the sheer force of efficiency and the quiet work of permeation—can you wonder that the disciples of German Kultur should have spurned the right of England to rule one-fourth of the world's surface by means which to the methodised German brain seems so planless and illogical ?

AND YET——

Let me put the case to you as it strikes the impartial and detached American. I quote from that influential American journal, the *St. Louis Republic.* It says—

"Whenever Germany and France, with their highly centralised and logically wrought-out Governments, have contemplated the fabric known as the British Empire they have smiled smiles of disdain. If ever there was an instance of 'muddling along' through decades, and even centuries, taking things for granted, avoiding issues, extemporising expedients, and working always for the object immediately in view, with scant reference to any principle of outward consistency, it is supplied by the history of the making of the British Empire. This is a strange gathering together of Crown Colonies, Dominions, Protectorates, a Commonwealth, Dependencies, and India. India is directly ruled by the Crown. Jersey, Guernsey, and Isle of Man are governed under their own laws, but certain officials are appointed by the Crown. Canada and Australia are both self-governing, but the Senators in Canada are appointed by the Governor-General, while those of Australia are elected. There is a Secretary of State for India in the King's Cabinet. And all gradations of self-government may be found in the more than ninety units of the British Empire.

"This fearful and wonderful fabric has no central body. There is no 'Bundesrath,' or Imperial Council. No collective action of its units is possible. The relation to them of the Mother Country is illogical, ill-defined. To the foreigners accustomed to the federation of the American States or of the units of the German Empire the Government looks planless and ineffective.

"All of which," adds our American critic, "is preliminary to the observation that there is not at the present moment any more effective institution in the whole world of political fabrics than the British Empire. Whatever its machinery lacks appears to be supplied by its spirit. The defects of its body are made up for by the unity of its soul. The fact cannot be gainsaid that England, who does not begin to be as logical as Germany or as systematic as France in matters of government, has, nevertheless, the knack of making men step out of their own free will to die in her defence. She has the gift of keeping alive, across tumbling seas, round half a world, the undying bond that unites the heart to home. She has shown herself indifferent to the possession of the taxing power over her Colonies—but what matters it ? Those Colonies willingly tax themselves to send her warships, and their sons seize their rifles in time of strife to go to her aid. She has the wisdom so to train and guide the swarthy children of alien races, and even the foes of yesteryear, that they put their living bodies between England and England's enemies. She has a fearfully muddled theory of government, but her practice of government lays hold on the deepest thing in the soul of men."

To that I would make this addendum in the words of an experienced Empire administrator, Sir Charles Lucas—

"The Empire, which is not a machine-made conquest but a growth, sown in all sorts of odd ways, and nourished by all sorts of odd sentiments and reasons, does not crush out life or stifle freedom, but increases life and enlarges freedom. Whatever his race or creed, a man in distant lands may be more, and not less, himself because he is a British subject."

OUR PROBLEM.

In these two passages lies my keynote, and the problem I wish to set before you is how this strange creation, the British Empire, this so-called "disorganisation," this seeming chaos which is no chaos, these ninety units in all manner of stages of self-government—Dominions, Crown Colonies, Protectorates and Dependencies—how we are to find the means of perpetuating their unity and how we are to carry into every sphere of the political, social and commercial life of these scattered and diverse communities the oneness of purpose and ideal for which the men and women of the British family in all the four quarters of the world have been willing to sacrifice their all during the past terrible nineteen months.

For that is my starting-point—the British Empire has to-day arrived at the stage of partnership. And—for us most significant and momentous fact of all—it is a partnership in the cause of freedom. You do not start with a clean sheet upon which to map out the future of the Empire and fashion some beautiful Empire fabric which shall burst upon the world at some dramatic and glorious moment. The fabric is being quietly fashioned from day to day under the pressure of necessity and common interests, and it is only by taking full account of what is happening before our eyes, if we will but see it, that we can hope to make our influence felt.

We have been so engrossed in the business of fighting that most of us have perhaps overlooked

the lengths to which this partnership of the British Empire has already gone. I lay stress upon this present partnership because it is ever the way of British progress to let what shall be follow as naturally as may be from what is; to adapt rather than to reconstruct; to make the future an ordered sequel to the present and the past.

While British Ministers Hesitated.

First there springs to the mind the partnership of fighting men, the comradeship of the battlefield, the battleship, the hospital, and, let me add, the desolated home. It has been one of the glorious aspects of a war that has been in some ways so inglorious, and it has been one of the chief props of our minds in this time of stress. For our encouragement along the paths into which the partnership of Empire may lead us if we have but the faith of our forefathers, I beg you to note the spirit and quick decision with which the Dominions ranged themselves by England's side when the hour for action had struck. In the fateful closing days of July and opening days of August, 1914, our own Ministers stood trembling upon the brink. To Germany they said that we must not be thought to be out of the pending conflict; France, our desperately anxious ally, they told that we must not be thought to be in it. The incident recalls the phrase of Caroline in a London play of the moment. She is troubled by the fact that she does not know her own mind. "Don't let that worry you," she is told. "The British Empire is governed exclusively by gentlemen who suffer from the same complaint."

However, it is no part of my business to attempt to criticise this halting of British Ministers between two opinions—the historian must do that upon far fuller information than we now have; but I am concerned to seek comfort in the fact that there were no hesitations among our partners overseas. They saw at once that liberty was at stake, nothing less—their own liberty and the world's liberty. While the British Cabinet inclined first one way and then another, urgent telegrams were reaching Downing Street from the Ministers of the Dominions, pressing for guidance that they might throw their whole weight into the scale in the most acceptable way; and before the German and Austrian official mind had abandoned the expectation that Canada and other British Dominions would remain neutral, if indeed they did not welcome deliverance from the so-called British yoke, fully-equipped Dominion forces were actually crossing the seas to come to our support, and New Zealand and Australian battleships were taking their place in the British battle line.

Anzac and Langemarck have since been added to the imperishable roll of the heroism of our race. General Botha and General Smuts were our indomitable foes a few years ago; we see where they stand to-day. Our Empire has not been spared its rebellions in our modern history; the sons of the former rebels are now among the staunchest of the men in khaki. Among these rebellions were the Papineau rising in Quebec and Riel rising in the North-West. A Papineau is now in hospital after fighting valiantly in the Canadian Expeditionary Force in Flanders, and it was only last month that a soldier's death claimed Sniper Riel of the Winnipeg Rifles, but not before he had himself placed twenty-nine Germans to his credit.

It is to such things as these that our children will point when they seek proof of the inherent rightness of the British way of Empire, and let us especially remember that these men, having faced death for liberty and British institutions, are the men who in every corner of the King's Dominions here and overseas will have a preponderating voice in the fashioning of our future. Empire partnership, we may be sure, will have quite a new meaning for them. Hitherto Empire has meant for a great part of the peoples of the Empire little more than after-dinner oratory and the occasional waving of flags. To the man of the Canadian prairies, or the Australian sheep farmer, the Empire must henceforth mean far more than a mere question of the King's effigy upon a postage stamp or a signature at the bottom of a writ. It is a possession and trust for which his son has fought and maybe died—a trust to which he dare not be false, and which he will not allow his leaders to neglect.

The Armies of the Empire.

A British Member of Parliament, seeking the other day to point the moral of this co-operation on the fields of battle, forecast a centralisation of the armies of the Empire under the supreme control of Whitehall. I know of nothing less likely. It would run directly counter to the great body of Dominion sentiment and practice as evolved during the past two decades and accentuated by the experience of the present war. The example of Australia will, I hope and believe, be followed in other parts of the Empire and by means of the cadet system and national

military system the whole of the youth of each nation will be trained to defend their country. Australia has, I hope, taught us that this strengthening of the defensive power and physical and moral character of the nation can be secured with no danger of an excessive militarism. But there will continue to be not one but several armies raised and trained in each section of the Empire, each reflecting the aspirations and social conditions of its own community.

Our next step in Empire land defence policy is, I believe, quite different—namely, a far closer co-ordination of system and method in ways which the present war is proving to be most effective, a much greater intimacy for staff and administrative purposes and a more adequate and continuous representation of Dominion opinion upon the Imperial Committee of Defence. General Smuts has taken the place of General Smith-Dorrien in command of a British force. It would be good news that a similarly high command had been given to some of the Canadian and Australian officers who have proved their high quality in combat, and to us who look on as laymen it may seem that the time has come to take fuller and more direct advantage of their experience and power of initiative in the general direction of British operations in the field. The seeds of a closer co-operation in future years have already been sown. In the Imperial General Staff there reside great possibilities. There is no need for a rigid standardisation. Each Dominion must continue to be a law unto itself in military matters; but the more the Imperial General Staff becomes really Imperial, and is linked with General Staffs in the Dominions, the more effective will be the co-operation of our armies in the field as a compact force, reflecting the spirit of the race and losing nothing by reason of its wide distribution.

The Navy.

The evolution of the naval policy of the Empire may very well take a different line. As seen from the British standpoint, the obvious moral of the war would seem to be that the little navy, like the little nation, is likely to fare ill under modern conditions. Admiral Cradock's fleet went down before the superior force of Von Spee, and Von Spee had to submit to the same fate when he encountered the ships of Admiral Sturdee. We take pride in the fighting pluck of the Australian Navy, but, as Mr. Hughes said the other day, " there was only one 'Emden.' " The security of the ocean highway has been maintained because the Great Fleet has effectively prevented the emergence of enemy ships from Kiel Harbour. General Botha drew the right moral when he declared, after his land victory: " Were it not that the British Navy kept the seas clear, it would have been absolutely impossible for us to achieve what we have done."

This example suggests the key to our future naval policy. No conceivable Canadian Fleet in North American waters, and no Australian Fleet in the waters of the far Pacific, would have saved Canada or Australia in August, 1914. Their fate was decided in the North Sea by the mobilisation of the Grand Fleet under Admiral Jellicoe thirty hours before war was actually declared. In another crisis it may be in the Mediterranean, the Pacific or the Atlantic that the fate of the Empire will be put to the test; but wherever it is, there must also be the immediate striking force which gives the Empire its mastery of the seas. If we in England read the naval lesson of the war aright, there must be not several navies, but one navy for securing instantly and on the very first threat of war those conditions at sea without which the Empire cannot exist and cannot use its armies. That is the basic naval principle—unity for concentration at the point of danger before danger actually exists. In these Empire matters there is no question of compulsion—the controlling force is reason, sympathy and good fellowship in a great cause. It is a matter for each Dominion to say how far it accepts the principle of naval unity, and how far it desires to act upon it. There would, of course, remain full scope for the development of the local naval resources of each Dominion, and there is also, as it seems to me, everything to be said for Mr. Churchill's proposal of an Imperial Squadron made up of ships of each section of the Empire and representing the Empire successively in every sea. It would also be most natural to constitute a representative Imperial Navy Board visiting the Dominions as circumstances might suggest, showing the flag in the outer seas, and working in close association with the Board of Admiralty and the Naval War Staff for the common naval purposes of the Empire.

Air Supremacy.

But this war has developed a new menace to our security—the menace of the Zeppelin, the aeroplane and the seaplane; and to the supremacy of the sea we must now add the supremacy of the air. It is surely significant of the adaptability

and unity of purpose of the peoples of the Empire that some of the most intrepid of the airmen now wearing the King's uniform are boys from Toronto and Winnipeg. Many of our aeroplanes are gifts from overseas communities, and a recent message from Australia told us that the Commonwealth had decided to send a flying squadron to the front from Australia.

There are those who dream that this war will be the end of all wars. History does not, alas! point that way, nor does the fact that the greatest of neutrals, guided by the chief of her pacifists, Mr. Woodrow Wilson, is preparing a five-year programme for the creation of a navy equal to that we possessed before the war, and an army costing 36 millions sterling a year. And as for ourselves, we shall probably have to repeat what the Imperialist Cromwell said to his Parliament in 1649, when he declared: "You have accounted yourselves happy in being environed with a great ditch from all the world beside. Truly you will not be able to keep your ditch, nor your shipping, unless you fight to defend yourselves. If you shall think this is a time of sleep and ease and rest . . . I have this comfort to Godward: I have told you of it."

Overseas Industrialism and the War.

I pass from the partnership of men of war to the partnership in materials of war, and here I touch upon an aspect of the conflict which must profoundly affect our future policy. We have hitherto thought of the Dominions as primitive countries, wide spaces from the used fragments of which come the wheat, meat, wool, timber and metals of our daily needs—foodstuffs and raw materials—which they have exchanged for the manufactures of this and other countries.

But see what nineteen months of war have done. Take the case of Canada. Before the war not a single shrapnel shell was made there, and in the whole Dominion only one small factory was turning out war material of any kind. To-day there are factories in every province from Atlantic to Pacific, engaged night and day for the war needs of the Allies. The results of the driving power that has brought Canada to her present place as an industrial war force are almost beyond belief. Major-General Sir Sam Hughes, the Canadian Minister of Militia, told the House of Commons at Ottawa on January 25th, that already Canadian factories had turned out 22,000,000 shells, which required in manufacture over 800,000,000. lb. of steel, 45,000,000 lb. of brass, 22,000,000 lb. of copper. and 10,000,000 lb. of cordite. An army of 90,000 skilled mechanics had been trained in industrial work, in addition to the army of 250,000 trained for fighting. More than 1,100,000 shells per month are now being shipped to Great Britain, and the cash value of the orders, representing new wealth to Canada, already totalled over $350,000,000.

You have only to go to one of the fortnightly gatherings of the Canadian Exporters Lunch Club here in London to realise the impetus given to the iron and steel and other industries of Canada by these special war activities. In addition, there have been established lead, cordite, zinc, brass and copper industries in various parts of Canada, which will furnish employment hereafter for at least 30,000 more skilled workmen. Thus it comes about, as the Minister said, that Canada is now in a position to furnish zinc to Great Britain and Russia at 15 cents per lb., as compared with 42 cents per lb. charged by the United States. Yet only a few months ago every bit of Canadian zinc was secured from the United States. Canada supplies 85 per cent. of the nickel of the world, the nickel production which no longer depends upon naval armament or martial requirements. Nickel steel in various forms is used in a wide range of industrial operations, as well as in the manufacture of ordnance and projectiles. Large quantities of plate were used in connection with the reconstruction of the Quebec Bridge, and nickel has entered into all sorts of railway materials, marine engines and propeller shafts, and a thousand and one lines of the manufacturing trades. Hitherto these Canadian nickel ores have been refined in the United States and this country. Under the encouragement of the Canadian Government, the International Nickel Company of New Jersey is now establishing a refining plant in Canada.

Some of the best of the British submarines were built on the banks of the St. Lawrence, and many millions of pounds' worth of war orders have been placed in Canada on behalf of the Allies for textiles and woollens, boots and shoes, harness and saddlery, rifles and ammunition and hardware, to say nothing of tinned meats, canned foods and other manufactured products. Indeed, we have it on the authority of the Hon. J. D. Hazen, Canada's Minister of Marine, that, on account of the Imperial Government alone, shipping from Canada has to be provided for 125,000 gross tons of munitions

and war supplies per month, or approximately 1½ million tons per annum. And this from a country which eighteen months ago was classed as mainly agricultural and primitive.

The comparative remoteness of other Dominions has left them less influenced as yet by this new wave of industrialism; but the situation that has developed in relation to the spelter ores of Australia is full of meaning and of warning. Only now, in the midst of a struggle for all that we hold dear in life, do we realise that it is not our war machine, but the war machine of our enemy that has derived the chief benefit from the illimitable metal resources of many parts of the Empire.

Before the war Australia fed Krupp's and other German enemies to the extent of £3,500,000 worth of lead and zinc ores, crude copper, tin and lead annually; Britain, the Mother Country of Australia, took a second place. Indeed, the German agencies which controlled Australian metal for the benefit of Germany's war machine were situated here in London, and carried on their work under the protection of British laws. After not a little difficulty with British Ministers and British law officers, this German control of Australian metal resources is being ended. That it should ever have existed constitutes, as has been said, "the gravest reflection upon British enterprise, capacity and common sense." Australia is taking the necessary steps to "cut every German fibre out of her industrial life." She is also, in the phrase of Mr. Hughes, "learning lessons in economy of labour that will remain a permanent possession." Instead of exporting her metallic ores to Europe, as she did before the war, her lead she is treating in Australia itself, and 90 per cent. of her copper output is being turned into copper goods on the spot.

This is what Canada and Australia are doing to strengthen their industrialism, and, learning from the bitter experience of this war, the imperative duty is now laid upon us all to apply our legislation, our administration, and our business faculties to the great work of developing the resources of every part of the Empire, not in the interests of our proven enemy and the enemy of liberty and civilisation, but in the interests of the Dominions and the Empire as a whole, and our proven friends among the nations. We shall be false to the trust placed in our hands if we neglect this insistent duty, and if we perpetuate the criminal folly of building up our industries upon a foundation controlled by the enemy.

A more Self-supporting Empire.

Amid the preoccupations of war the British public has little realised the extent to which the self-governing British peoples overseas have thrown their all upon our side in the present struggle. Although independent in fiscal matters, and completely in control of their own trade, the Dominions have from the outset of the war adopted every device to give England and the Allies the sole benefit of their production. In one issue alone of the *Board of Trade Journal* 130 pages are occupied with the export prohibitions of British Dominions, Dependencies and Protectorates, and their general purpose is to bring to our aid the full advantage of overseas food products such as wheat, meat, sugar and dairy produce; raw materials such as wool, leather and metals; and manufactured goods such as metal-working machinery and various textiles.

In this spontaneous and far-reaching co-operation we see the partnership of Empire in actual operation. In it we may also find an irresistible argument for increasing a commercial association which is immune from political entanglements and the rival interests of neutral, even if friendly, States, and by means of which even under stress of war the power of the Empire is immeasurably strengthened. In the full war year of 1915 the overseas Empire contributed 272 million pounds' worth of food and raw materials to the side of the Allies. Despite all the impediments of war and such embarrassments to overseas production as the curtailment of banking facilities, the cessation of borrowings for railway and other extensions of settlement, and despite the mobilisation of men and industry for the war purposes of ourselves and the Allies—despite all these war conditions and allowing for increased prices, we see that the British Dominions and Possessions have together been able to sell in the United Kingdom considerably more of their produce than in the record year of peace, 1913. There is no need of British homes and factories which our own Empire cannot provide, and with mutual forethought and organisation very much of the 370 millions pounds' worth of foodstuffs and materials of industry which we bought in 1915 from foreign lands can be obtained from within our own territory. The British Empire should be made far more self-supporting than it now is, and in making it so we have the comforting assurance that by buying more largely from within the Empire we are adding to the stability, progress and purchasing power of those who are our

comrades in the tasks of Empire and our best customers for British manufactured exports.

The Dominions Royal Commission.

What, then, are the next steps of Empire partnership in respect of trade ?

A first and urgently necessary step is to take stock of these Empire resources. There has been in existence for four years a Dominions Royal Commission, representative of the United Kingdom and the Dominions. It has done useful work, but we turn to its reports in vain for the facts as to the German control of Empire metal resources and the means of its eradication. Neither the Commission itself nor the Ministers who appointed it seem to have taken its task very seriously. Instead of finding in the war a fresh incentive, the Commission blandly informed the world in December, 1914, that it had "decided to suspend its sittings until the conclusion of peace." We shall be deaf indeed to the moral of our present difficulties if the Commission or some better-equipped body is not immediately set to work to prepare the way for a far-reaching policy of co-operation in developing our unmatched resources for the benefit of our own peoples.

Had we had an Imperial Development Commission representative of the whole Empire working under a vigorously minded Imperial Minister of Cabinet rank, and in cordial co-operation with the Development or Conservation Commissions of England, Ireland, Canada, and other parts of the Empire, we should not to-day be lamenting the scandal of British and Dominion resources neglected or allowed to pass under control of the enemy. Take an illustration from India to which attention is called in to-day's *Times*. It could be amplified from almost any part of the Empire. A single small district of Burma is capable of supplying more than half the world's annual requirements of tungsten—the tungsten whose self-hardening properties are needed for the making of machine tools, heavy guns, and armour-plate. Yet before the war we left this essential material to be developed by Germany; German interests controlled the whole output of the industry. A vigorous new Lieutenant-Governor, Sir Harcourt Butler, has now given an entirely new aspect to the business. He has cut out the German cancer, the German interlopers have vanished, and the *Times* tells us that this British district hums with British and native life.

Administrative and Fiscal Preferences.

The administrative preference which has been one of the most welcome features of the British management of this war should be continued and extended. A very few years ago it was impossible to get the Admiralty to look at coal and timber and meat from the Dominions; they were newcomers, and it was just habit rather than malice which shut them out from tenders for the British Navy in favour of the corresponding products of foreign lands. The comradeship of Canada, Australia and New Zealand upon the battlefields of Flanders and Gallipoli has jerked the departments out of their old cosmopolitan grooves, and reminded them that Empire products are *our* products, while foreign products are not. It must be our business to keep them jerked out. Quality and price being duly considered—New South Wales, I see, is allowing a 10 per cent. differentiation in favour of British over foreign products in its purchases of supplies—it should be the business of Empire Governments, municipal bodies and business houses and private citizens to see that their choice is for Empire over foreign goods. We are thus helping our friends and weakening our enemies, and building new barriers of defence for the principles of civilisation which we live to uphold and promulgate.

Mr. Runciman has set an example and made a beginning in his embargo policy. Finding it essential to secure, for the necessaries of life and war, tonnage space now occupied by goods which in this time of stress may be regarded as less necessary, the President of the Board of Trade is seeking to curtail the importation of bulky goods such as paper and paper-making materials, fruits, tobacco, furniture woods and so on. Many difficulties lie in the way, but it is at least satisfactory that in recognition of the family idea in trade the fruits of Australia, Canada and South Africa are exempted from this shipping embargo. We should see to it that the same principle is applied to the wood pulp of Canada, the paper of Newfoundland, the woods of Australia, and every other commodity with which the embargo policy deals.

In a few weeks' time the British House of Commons will have an opportunity of encouraging Ministers to carry the same principle into the sphere of finance. Mr. McKenna may have to raise another 100 millions sterling from taxation, and if necessity leads to an enlarged British import tariff, we should be spared a repetition of the unfortunate precedent of the Budget of 1915, when dutiable imports from the

Dominions were made liable to the same taxation as those from foreign lands. This is not how Canada, Australia, New Zealand and South Africa treat British goods, and now that the conditions of war and British revenue necessities have compelled a change in our fiscal system, we can no longer afford to reject the repeated demand of all the Ministries of the Dominions as made at each successive Imperial Conference since 1902. That repeated demand is that the Motherland should do as the Dominions do and recognise the Empire family through the medium of "preferential treatment to the products and manufactures of the Colonies, either by exemption from or reduction of duties now or hereafter imposed." May we also hope that in his forthcoming Budget, with its probable increase of income tax, Mr. McKenna will recognise the injustice and folly of duplication of taxation on the same income within the Empire. This is not the time to drive British capital into foreign lands.

The Cabinet.

In the sphere of policy as in defence and commerce the trail of Empire progress is being blazed for us by war conditions. The Imperial Committee of Defence, which we owe to Mr. Balfour's initiative, has been more than justified in the fierce testing time of this war, and when the war is over it must become far more expressive of the power of initiative and efficiency which the armed forces of the Dominions are now known to possess. The Imperial Committee of Defence with its Dominion members grew out of the Imperial Conference; so the exigencies of the war relationship of the States of the Empire are evolving a new means of intimacy through the medium of the Cabinet. On July 14th, 1915, Sir Robert Borden attended a meeting of the British Cabinet upon the invitation of Mr. Asquith; during his recent visit to Ottawa, Mr. Hughes, the Prime Minister of the Commonwealth, was sworn in as a member of the Canadian Privy Council and attended the Canadian Cabinet at Ottawa; and this month, again upon the invitation of Mr. Asquith, Mr. Hughes attended the British Cabinet. Unknown though it is to the constitution, the Cabinet is the supreme executive power in the British State, and it is through this agency of the "King in Council," that is to say, the Committee chosen by the Prime Minister and called the Cabinet, that the sovereign power is exercised. The House of Commons has been told by British Ministers that this entrance of Dominion statesmen into the inner chamber of the Imperial executive is not to be regarded as "an isolated incident, but as carrying out the general trend of policy which is proceeding further in the same direction."

Who can say how far this development may lead us? This first step, taken so quietly, has been heralded as revolutionising the theory and practice of the system by which this country has been governed for more than a century and a half, but it is obviously illogical and incomplete. As I have endeavoured to explain in detail elsewhere, the British Cabinet is, so to speak, a Standing Committee of the British Houses of Parliament, and its authority rests upon its responsibility to the British Parliament, and through that Parliament to the British people. Dominion Ministers may sit as occasion demands in the British Cabinet, but they cannot share the responsibility of British Ministers to the British Parliament and peoples; it is to the Parliaments and peoples of their own Dominions that Dominion Ministers are solely answerable. Why not, some ask, an Imperial Parliament representative of the whole Empire? Such a Parliament would require a central Imperial Exchequer — it would require much else. Whether it will come in the future years no man can say. Who, indeed, would set limits to our future co-operation? But whatever be the ultimate constitutional relations of the States of the Empire we may be sure that they will grow out of existing conditions and immediate needs; and when any actual scheme for an Imperial Parliament and a centralised Imperial Executive in Downing Street is tabled and examined from the point of view both of this country and the Dominions, it does not seem to me that it is likely to deal satisfactorily with the infinitely subtle and varied relations, the constitutional, economic, and political elements, which make up the British Empire at the present time. That Empire is a growth rather than a creation out of hand, and a growth it is likely to remain.

What we have to face is that, as Sir Robert Borden has said, "we are moving away from the day when the foreign relations of the Dominions as parts of the Empire can be left to be determined in a species of trust by which the statesmen of the Mother Country, perhaps more or less in consultation with us, can settle these policies"; and we may say with the Canadian Prime Minister, that "those whom these questions concern must always reckon with the inborn feeling in the Canadian breast

that a British subject living in this Dominion must ultimately have as potent a voice in the government and the guidance of this world-wide Empire as the British subject living in the United Kingdom. Whether our home is in the British Islands or in Canada, we must be equals before the King. The full privileges, as well as the full duties and responsibilities, of citizenship are the right of the Canadian people," and let us add, of the peoples of all the self-governing Dominions.

The Heart of the Problem.

Mr. Samuel, a member of the British Cabinet, said the other day that "the Mother Country is very ready to admit the Dominions into a share in decisions of policy as soon as they desire such admission." It may be accepted as a step forward that the Prime Ministers of the Dominions are now made privy to the inner councils of the British Government, and, if the Ottawa precedent is followed, to the inner councils also of the Governments of other Dominions. At the Imperial Conference of 1911 Mr. Asquith flatly refused to contemplate any sharing by the Dominions in the authority of the Government of the United Kingdom in such grave matters as the conduct of foreign policy, the conclusion of treaties and all relations with foreign Powers. That is now dead history, and it is Mr. Asquith who has made it so.

What, then, is the next step? How are we to meet the demand of the Dominions to be given a larger share in the guidance of Imperial affairs? My suggestion is—keep your eye upon the Cabinet and the development of the Cabinet principle, here and in each self-governing part of the Empire, rather than upon any of the proposals we have had for an Imperial Parliament or an Imperial Senate. The Cabinet of each part of the Empire is of course amenable to the Parliament of that part of the Empire, but it is not Parliament but the Cabinet which settles the matters upon which the Dominions wish to have their say. We have a Cabinet in Downing Street which, under war conditions, has become non-party in character, and includes Dominion as well as British members; we have also a committee of the Cabinet, the Imperial Committee of Defence, in which British and Dominion Ministers together consider questions of defence, and at times foreign policy—as, for instance, the Anglo-Japanese Treaty. Through this dual agency—the Cabinet and its adjunct the Imperial Committee of Defence—the States of the Empire have found a means of co-operating both in council and in executive action without impinging upon the control of its own affairs by each State within the Empire. New spheres of co-operation are now being opened up—the mutual development of Empire resources and inter-Imperial trade, partnership in relations with our Allies and the enemy, and so on. Surely the time has come when these new inter-Imperial affairs should be lifted out of party conflicts as defence and foreign policy have been. The way will then be clear for an extension of the methods of intimacy in executive council which we have found to work well in the sphere of defence. If the Dominions desire to make their High Commissioners members of the Dominion Cabinets as Sir George Perley is a member of the Canadian Cabinet, they might, as members also of the British Cabinet, maintain the needed executive link in the absence of the Dominion Prime Ministers. It would be easy to criticise any such arrangement, but it might serve our present purpose, resting as it would do upon a basis of goodwill, mutual respect and understanding.

Our New Relations.

The new intimacy in executive council will soon be put to new tests. Partners in war, the Dominions are also to be partners in the negotiation of terms of peace. Concessions of vital interest to the Dominions will no longer be made behind their backs. I think especially of the conquered German Colonies in South-West Africa and in the Australasian sphere of influence.

In other directions the old order has passed away. On January 10th the British House of Commons unanimously adopted the following resolution upon the motion of Mr. Hewins:—

"That, with a view to increasing the power of the Allies in the prosecution of the war, His Majesty's Government should enter into immediate consultation with the Governments of the Dominions in order, with their aid, to bring the whole economic strength of the Empire into co-operation with our Allies in a policy directed against the enemy."

That resolution will, I believe, become historic, for it has been the herald of the Conference of the Allied Governments, which is now about to meet in Paris, and at which we may expect the foundations will be laid of the new economic relationship of the chief States of the world. For the first time in our history we accept as the basis of our policy, and accept

with the general assent of Parliament, the economic solidarity of the British Empire. In treaties, in tariffs, in trade, and in finance we have in the past spoken with many voices and have often worked at cross-purposes. In future we mean to speak with one voice to the outside world—to our Allies, to friendly neutrals and to the enemy who is no longer to be allowed to use the goodwill of other nations as a means of plotting for their overthrow and enslavement.

This new Empire solidarity must find expression in many directions. The treaty system of the Empire based upon the most-favoured-nation clause had been proved before the war to be entirely inapplicable to the national status of the younger Britains overseas. It was already in the melting-pot. In the new order the Dominions must stand as fully-accredited partners in all treaty negotiations with foreign States, and it will be strange if the States of the Empire, negotiating thus together with other Powers, do not wield a far greater influence than would be theirs in any such separation of interests as we were drifting towards before the war. Our diplomatic and consular services, like our treaty system, must be made to correspond with the new Empire conditions. The navigation laws of the Empire, our dangerously anti-Imperial cable system, our haphazard means of controlling movements of population—these are among the other matters which must hereafter be viewed from the new Empire angle.

In working out these problems we shall inevitably change the character of our attitude towards those parts of the Empire which are not autonomous and with foreign nations which stand in intimate social or commercial relationship with us. India has assumed an entirely new place in the mind of the Canadian, the Australian, the New Zealander, who have fought side by side with the magnificent King's soldiers from that great dependency. Also a Canada which is a fully-equipped partner in the British Empire, and holds half a million men of proved efficiency in the art of war in its most deadly modern form, cannot be the same Canada to the United States as it was before the war. That it will remain a friendly and neighbourly Canada in its attitude towards the great English-speaking community across the Atlantic is, I believe, beyond any shadow of a doubt; but the new differentiation of national ideals which the war has set up on the North American continent must have profound and far-reaching consequences.

In the pursuit of the new path of Empire partnership our statesmen and the statesmen of other lands—and especially the men of the departments who feed the minds and guide the actions of statesmen—will have to recognise, far more fully than many yet do, that the old order has passed away beyond recall. Secure we must be as an Empire, and the price of security must be paid in the abandonment of many old dogmas and predilections. Many of us will say with Mr. Rhodes, when he was reproached with a changed mind, "Yes, I changed as quickly as I could, for I found I was wrong."

Summing-up.

There I must leave this fascinating theme. It would be easy to indulge in speculations as to the more remote means by which these great ends are likely to be attained. It pleases some among us to fashion beautiful Empire fabrics and dream beautiful Empire dreams. My immediate purpose is to indicate the *next* steps in Empire partnership, feeling certain, as I do, that the surest line of advance is from what is to what shall be. These next steps, as I see them, are clear and full of promise. There can be no such thing as finality of method in the development of an Empire such as ours. We move step by step as the need arises, and we may well take comfort in the knowledge that even in this time of severe trial we are adapting ourselves, both in thought and method, to what is no less than a revolution.

May I remind you of these next steps in a few bald sentences, and if they seem dogmatic, as they are not meant to be, please put that semblance down to the necessities of time and space?

1. No centralisation of the armies of the Empire under the supreme control of Whitehall is possible or desirable, but our co-operation on the battlefield should now ensure a far closer co-ordination of system and methods of military administration and a more adequate and permanent representation of the Dominions upon the Imperial Committee of Defence and in places of command. Moreover, every self-governing community is hereafter likely to seek greater security in some form of national military training after the manner of the Australian cadet system and our own Public School O.T.C.'s.

2. Realising that not only our Empire, but also our conception of civilisation, has been saved by an instantly omnipotent and therefore necessarily centralised Navy, it is probable that the

Dominions will desire to take a far more direct and proportionate share in the naval defence which they see to be their bulwark as well as ours. A representative Imperial Navy Board visiting the Dominions as occasion may suggest, and working in close association with the Board of Admiralty and Naval War Staff, would provide the Dominions with a share in naval administration and control; an Imperial Squadron would represent the Empire successively in every sea; and each Dominion would provide its own additional local naval force as its circumstances made necessary.

3. In the creation of the new third arm of defence—the defence of the air—the Dominions are also taking an increasing share.

4. After the war each Dominion should be encouraged to supply a proportionate share of the materials of defence, so that our forces may be able to count upon the industrialism of the whole Empire, even to a greater degree than in the present war.

5. As a necessary sequel to the means by which we are pursuing the present war, the finances of the States of the Empire are far more closely intertwined than they have ever been before, and a differentiation of taxes upon Empire as distinct from foreign investments should provide greater mutual financial support.

6. By every conceivable means of co-operation—governmental, legislative and commercial—the resources of the Empire should be developed for the benefit of the peoples of the Empire, rather than the peoples of foreign lands. The Dominions Royal Commission should be strengthened and reconstituted to take immediate stock of these resources and point the way to their development. It might be made an Imperial Development Commission to include India and other dependencies as well as the Dominions, and thus be representative of the whole Empire, work under a Minister of Cabinet rank and in cordial co-operation with the local Development or Conservation Commissions such as exist here and in Canada. The efforts of the Dominions and India to eliminate the foreign control of their metal and other products should be resolutely and consistently supported with a view to their use in Overseas and British industries rather than in those of our potential enemies. In the external purchases of the spending departments of each section of the Empire an administrative preference should be given to goods of Empire origin, and a substantial Empire preference upon import duties should be made an integral part of the fiscal system of the United Kingdom, as it already is of those of the Dominions.

7. As a natural accompaniment of this new commercial solidarity, the cable system of the Empire must be developed and more completely freed from foreign control, after the manner of the jointly-owned Pacific Cable.

8. The navigation laws of the Empire are also capable of adjustment to fit the new conditions, somewhat on the lines which successive Australian Governments have advocated at the Imperial Conference.

9. Men as well as money being the chief essentials for the development of overseas resources, the land settlement problem after the war calls for practical co-operation between the Home and Dominion Governments. The scheme which Lord Shaughnessy, the President of the Canadian Pacific Railway, is now initiating in the Canadian West offers much guidance in this matter.

10. The treaty system of the Empire had manifestly broken down before the war under the pressure of the new needs of the Dominions in their overseas trade. The war has brought an entirely new set of factors into play. The cosmopolitanism of the most-favoured-nation method is doomed, and in replacing it by the old English method of concession for concession means may be found for bringing in the Dominions as fully-accredited partners in all future negotiations with foreign Powers.

11. The haphazard and irregular character of the fiscal and treaty-making functions of the States of the Empire has been one of the main causes of past difficulties with foreign States, as, for instance, with Germany and the United States, and the removal of this cause of friction may open the way to more intimate, united and mutually advantageous relations between each autonomous part of the Empire, and those foreign Powers whom we desire to call our friends.

12. The diplomatic and consular services must be broadened and, may I say, purified of their alien character, to represent the wider requirements of the new Imperialism, and the public here and overseas must be taken far more into the confidence of the diplomatists in respect of the foreign relations of the Empire. Much of the past secrecy of diplomacy is as unnecessary as it is pernicious.

13. These developments affect, for the most part, matters which are the subject of executive rather than Parliamentary action, and hence the paramount importance of the wider Imperial

status which is being given to the Cabinet, supported by such representative bodies as the Imperial Conference, upon which India should now be represented, and the Imperial Committee of Defence.

14. Any notion of an Imperial Parliament, with a central Imperial Exchequer, an Imperial Zollverein, or other rigid political or economic uniformity, centralised in London, is not within our present range of vision. No Dominion will abandon or whittle away its control over its own tariff and internal affairs. But the closer association of the States of the Empire in defence, mutual tariff and other preferences, joint treaty relations with foreign countries, united efforts to encourage production and improve communications and so on, requires a closer co-ordination of executive methods. Through the Imperial Committee of Defence we have found a means of executive intimacy in defence and in a measure also in foreign policy. Why not also in the economic unity of the Empire which, like defence and foreign policy, should now be removed from party controversy? As the day-to-day associations of the Governments of the Empire develop, so will the interrelation of those Governments increase with possibilities of closer organic union, the exact character of which it is not possible as yet to divine.

THE WIDER HORIZON.

In one year of war we have learnt more than a decade of peace could have taught us of the art of "getting into the closest possible touch with one another." We all now see that in this unity of purpose and action our strength lies. We no longer fear, as many of us did in days not long past, that the time was approaching when, as in the case of every other Empire that the world has known, decay and ultimate dissolution would bring ruin to the work of centuries. We have become imbued with a new sense of the far-reaching mission we have to fulfil together. Without boasting, we may now claim with Sir Wilfrid Laurier that we answer to a "higher destiny," and, in the words of Sir Robert Borden, "it has once for all been borne in upon the minds and souls of all of us that the great policies which touch and control the issues of peace and war concern more than the peoples of these islands." Our public life has a wider horizon, and it must be made wider still. From the blood-soaked mud of Flanders and ravines of Gallipoli the message of Empire has gone to the humblest village of England, the loneliest shack of the prairie and the range, and the politician here or overseas who is deaf to the new impulse and fails to make it the inspiration of his words and action will, I hope and believe, write his own inglorious epitaph.

[The discussion on this paper will be published in the next number of the *Journal*, Friday, April 21st.]

BARBADOS SUGAR CROP.

The Barbados cane crop for 1915 showed an estimated production of sugar amounting to 22,000 tons of dark crystals, 15,000 tons of centrifugal muscovado, 200 tons of muscovado, 30,000 puncheons of syrup, and 16,000 puncheons of molasses.

The average local price has been 14*s*. 10*d*. for crystals, 13*s*. 7*d*. for centrifugals, and 12*s*. 4*d*. for muscovado; syrup, 10*d*. per gallon, with 2*d*. additional for package; molasses, 7½*d*. per gallon, with 2*d*. additional for package.

On account of extreme drought during the early part of the growing season, the production is about 8,000 tons below the average.

According to a report by the United States Consul in Barbados, the weather conditions at the time of writing were exceptionally favourable for the crop to be harvested this year, and with continued good weather the island should produce nearly double the one last harvested.

TIMBER IN BRAZIL.

Brazil is a country of vast variety in timber, and it is calculated that there are more than 5,000 species yielding useful wood, of which at least forty are first-class woods.

M. Gouzaga de Compos, a Brazilian expert, gives the total forest area of Brazil as 58 per cent. of the total area, but this estimate includes damaged forests. All the States possess timber of superior quality, but as yet the timber trade has not been much developed, owing to difficulties of transport, costly rates, and a lack of good ports for quick loading and shipping.

The chief exports are from the south of Brazil by the ports of Paranagua, Rio de Janeiro, and Santos. In 1911, only 821 tons were exported, and in 1912, 1,492 tons. According to a recent report by H.M. Legation at Rio de Janeiro, the thickness and impenetrability of the Amazon forests has so far prevented the export of the valuable woods abounding in these regions.

Lumbering regions are practically confined to the south, where the South Brazil Lumber Co. has set up several saw-mills along the Brazil Railway line. With the exception of that at Tres Barres, which has the most up-to-date appliances, these are of a somewhat primitive character. At Sanges and Calman it is expected that modern mills will be established before long.

The most valuable woods in the south are the Imbuya and the Parana pine. The former resembles mahogany, is a very hard wood, and is used for furniture at São Paulo. It also supplies sleepers for the Brazil Railway and other lines.

The straight trunk and freedom from limbs of the Parana pine make it easily handled by the mills, and it has very hard knots containing a great quantity of resin, which is used for pitch on the railways. Unlike other pines, it does not yield turpentine in sufficient quantities to make this a marketable commodity. The wood is sent to Curityba, São Paulo and Rio de Janeiro for building purposes.

No steps, adds the Legation report, have yet been taken, except by the Parana Government, and possibly also by far-seeing private proprietors, to regulate lumbering operations. Dr. Pedro de Toledo, the ex-Minister of Agriculture, proposed a Federal service in 1911, but his scheme has not yet been voted on by Congress. The railways show no discrimination in cutting down, for fuel purposes, large areas of valuable forest. The peasant in the interior burns quantities of valuable timber in order to cultivate a few hectares of land.

OBITUARY.

Colonel Sir Colin Campbell Scott-Moncrieff, K.C.S.I., K.C.M.G.—Sir Colin Scott-Moncrieff, who died in London on the 6th inst. at the age of eighty, was elected a member of the Society in 1895. He served as a Member of Council from 1903 to 1910, and was a Member of the Indian Section Committee from the time of his election on the Council down to the present date. He took the chair at the reading of Mr. Archibald Colquhoun's paper on Bosnia and Herzegovina, in February, 1909, and on several occasions spoke in the discussions on Indian and Colonial papers.

He went out to India in 1856 as a second lieutenant in the Bengal Engineers, from which regiment he retired as colonel in 1883. His main work in India was connected with the Irrigation Department of the North-West Provinces. He was also Chief Engineer in Burma. On leaving India he was appointed Under Secretary in the Public Works Department at Cairo, in which capacity he had charge of the Egyptian irrigation works. The chief work of his life was the completion of the Nile Barrage, and it is with this that his name will always be associated. After leaving Egypt he served as Under-Secretary for Scotland from 1892 to 1902. He was made a K.C.M.G. in 1887, and a K.C.S.I. in 1903.

Major John Fenwick Dickson.—Major John Fenwick Dickson, of Houston, Texas, U.S.A., died on March 5th, in his eighty-fourth year. He was born in Ireland in 1832, and emigrated to America in 1850. For some years he was connected with the locomotive works of several railways, and in 1869 he went to Texas to take over the management of the railway line then known as the Southern Pacific—a short line afterwards merged into the Texas and Pacific, the terminus of which was at San Diego, California. In 1887 he started the Dickson Car Wheel Company, which has since developed into an enterprise of considerable importance, and is stated to be one of the finest wheel foundries in the United States. He was also connected with the lumber industry, and with other branches of business, and was reputed to be one of the leading industrial men of Texas. Major Dickson became a Fellow of the Society in 1913.

MEETINGS FOR THE ENSUING WEEK.

Monday, April 17...Geographical Society, Burlington-gardens, W., 8.30 p.m. Mr. H. W. Fox, "The Development of Rhodesia from a Geographical Standpoint."

Actuaries, Institute of, Staple Inn Hall, Holborn, W.C., 5 p.m.

Tuesday, April 18...London Society, at the Royal Society of Arts, John-street, Adelphi, W.C., 5.30 p.m. Mr. W. R. Davidge, "The Development of London."

Petroleum Technologists, Institution of, at the Royal Society of Arts, John-street, Adelphi, W.C., 8 p.m. 1. Address by President, Professor J. Cadman. 2. Mr. E. H. C. Craig, "Kerogen and Kerogen-Shales."

Statistical Society, 9, Adelphi-terrace, W.C., 5.15 p.m.

Civil Engineers, Institution of, Great George-street, S.W., 5.30 p.m. Annual General Meeting.

Zoological Society, Regent's Park, N.W., 5.30 p.m. 1. Mr. R. I. Pocock, "On the External Characters of the Mongooses (Mungotidæ)." 2. Major H. Muir Evans, "The Poison-Organ of the Sting-Ray (*Trygon pastinaca*)."

Wednesday, April 19...Meteorological Society, 70, Victoria-street, S.W., 7.30 p.m. 1. Mr. E. V. Newnham, "The Persistence of Wet and Dry Weather." 2. Professor H. H. Turner, "Discontinuities in Meteorological Phenomena."

Microscopical Society, 20, Hanover-square, W., 8 p.m. 1. Professor B. Moore, "Early Stages in the Evolution of Life." 2. Mr. F. M. Duncan, "Studies in Marine Biology." 3. Mr. J. W. Purkiss, "Some Suggestions regarding Visual Efficiency in the use of the Microscope and other Optical Instruments."

Literature, Royal Society of, 20, Hanover-square, W., 5.15 p.m. Professor W. de la Mare, "Truth to Life."

Labour Co-partnership Association, Central Hall, Westminster, S.W., 3 p.m. Mr. F. Maddison, "Co-partnership after the War."

Concrete Institute, 296, Vauxhall Bridge-road, S.W., 5.30 p.m.

A Fellow of the Society is anxious to purchase Vols. I. and II. of the *Journal of the Royal Society of Arts*, published in 1852 and 1853. Anyone having these volumes to dispose of, should communicate with the Secretary, Royal Society of Arts, Adelphi, W.C., stating the price for which he is willing to sell them.

London: Printed by William Clowes & Sons, Ltd., Duke Street, Stamford Street, S.E., and published for the Royal Society of Arts by G. Bell & Sons, Ltd., York House, Portugal Street, W.C., in the Parish of St. Clement Danes, in the City of Westminster.—April 14, 1916.

Journal of the Royal Society of Arts.

No. 3,309. VOL. LXIV.

FRIDAY, APRIL 21, 1916.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICES.

NEXT WEEK.

THURSDAY, APRIL 27th, 4.30 p.m. (Indian Section.) JAMES MACKENNA, M.A., I.C.S. (Deputy Commissioner, Myaungmya, Burma, and designated Agricultural Adviser to the Government of India), "Scientific Agriculture in India."

In the absence of Mr. J. MacKenna, the paper will be read by Sir Steyning W. Edgerley, K.C.S.I., K.C.V.O., C.I.E., Chairman of the Indian Section.

Further particulars of the Society's meetings will be found at the end of this number.

EASTER HOLIDAYS.

The office of the Society will be closed from the 21st inst. (Good Friday) until the following Wednesday morning, the 26th inst.

JOURNAL.

The Government limitations on the importation of paper and paper-making materials have rendered it necessary to restrict the *Journal* to the smallest possible size. For the present, therefore, its contents will be confined as far as possible to a report of the actual proceedings of the Society, and it may be necessary occasionally to publish reports of the meetings a little less promptly than has always been the practice.

It is hoped that the Fellows will appreciate the necessity of such restrictions, and it is also hoped that the *Journal* may be able to expand to its normal size at an early date.

PROCEEDINGS OF THE SOCIETY.

COLONIAL SECTION.

A meeting of the Colonial Section was held on Tuesday, March 28th, 1916; DUGALD CLERK, D.Sc., F.R.S., Chairman of the Council of the Society, in the chair. The paper read was "Next Steps in Empire Partnership." By PERCY HURD.

The text of the paper was printed in last week's *Journal*. The following is the discussion on the paper:—

DISCUSSION.

MR. W. A. S. HEWINS, M.P., M.A., in opening the discussion, said that the British Empire consisted of the United Kingdom, the great self-governing Dominions, India, and the great Crown Colonies and Protectorates, in which there was every kind of civilisation, representatives of every race and religion, every form of Constitution known to man, and every stage of political evolution. At the present time all its myriads of activities were united in a common cause against the enemy, one of the most stupendous facts in its real significance that could possibly be imagined. Attention should be concentrated all the time on the action of the men of the Empire rather than on any theories that might be held about the future constitution of the Empire. Everything turned upon the attitude of the Empire, and what it did in the present state of war. It was perfectly clear that, in view of the resolution adopted by the House of Commons, a new phase of development altogether had been reached in the contemplation of an economic alliance between the British Empire and its Allies; but obviously it was necessary to know what the Empire meant to do itself before entering into final arrangements with other countries. Whatever decisions the Home Government arrived at must be on lines which appealed to the great self-governing portions of the Empire, and when that was done he thought it would be found that the new facts which emerged would put a new complexion upon most of the problems which had to be solved. If it was decided to terminate the German control of the metal resources of the Empire, it meant most important modifications of the whole economic system of Germany, and a shifting of the economic power in Europe. The Empire had fully made up its mind to terminate once for all German control of its resources. When the organisation

of the Empire for the purposes of war, in association with its Allies, was taken in hand in a practical sense, not only would great Imperial problems have to be faced, but to a very large extent the future development of the civilised world. He believed the peoples of the Empire were equal to that task, although he had very little confidence in the people of the past two generations, who had been in command for the last fifty years and had allowed principles to be adopted and acted upon which, in view of the evidence forthcoming from the war, would have wrecked the British Empire. But he believed in the young men and young women of the Empire, and had the greatest confidence in what they would effect in the future, in view of the stupendous feats of organisation which had been performed by them in the conduct of the war. If tables were made showing the course of the economic development of trade, agriculture, and finance, and they were reduced to curves, wonderful fluctuations extending all over the world would be seen; but behind those curves of development there was a great silent power which was moulding events, but which was not at present thoroughly grasped. In spite of all the blunders of the past sixty years of a deliberate policy against the interests of the Empire, that great movement had gone on steadily and silently, under the impulse of unseen forces, and was leading to a more complete organisation of the Empire on the broad features of the English principle which had been known for hundreds of years. Many people who talked about the Empire took a slightly too materialistic view of the matter. The British Empire was not a great association for increasing mutual wealth, or even for illustrating certain political principles of organisation. The very form of the Empire, the different grades of organisation and of political evolution, and the plane above plane of social structure, pointed to something still higher. There was an ideal, and it was in those permanent fundamental principles of justice, fairness, and integrity that the ultimate end for which the British Empire really existed was seen. If the British Empire as a whole got under what he would call German influence, and took the great material forms of wealth as the aim for which it lived, he did not believe it would have any other end than that which he trusted would be reached by the present German Empire. The materialistic forms of organisation, wealth, resources, and man power, had to be put in their places as mere instruments with which the individuals who composed the Empire secured those higher ends without which life was not worth living.

The Hon. F. W. Young, LL.B., Agent-General for South Australia, thought that a broader Imperial outlook amongst all classes was urgently needed at the present moment, so that the future they had to meet might be more fully appreciated, and the necessary decisive actions taken to make that attitude effective. Although he had been in this country for only a comparatively short time, he had been impressed with its immovability. There was to some extent a want of virility of thought and action if the country, as the great centre of the Empire, was to reap the full fruits of everything within the Empire. He discovered that, after the war had existed for twelve months, those interested in copper in South Australia experienced great difficulty in selling that commodity in Great Britain, but after many negotiations a satisfactory alteration of the position was obtained, the final statement which reached him being that the reason South Australian copper had not been purchased was that the Home Government had been able to procure plenty from America. That betrayed a want of outlook in the official world which would, if continued, kill the possibilities of the Empire as Imperialists would like to see them develop. He appreciated that it would be wiser to concentrate their minds at present on the steps that should be taken towards a closer union than to contemplate too seriously the final end in the shape of some rigid Constitution. He believed the immense strength of the moment was due to the looseness of the past. The British people seemed to resist the rigidity of Constitutions, with the result that there was at present a Constitution in this country which it was almost impossible to put on paper. But, with all its faults and muddling, it had to be realised that the people under that Constitution had achieved wonderful things, and that fact should not be ignored in regarding the future. Having behind them and before them the common blood, language, and traditions, if a closer, common interest in defence and in trade were associated with them, a great deal would be accomplished towards effecting the closer union desired throughout all parts of the Empire. The author had referred to the double income tax question, and the attitude of the Exchequer towards it since 1896 at least. At the last Imperial Conference in 1911, the Lords of the Treasury submitted some reasons why the present system of taxation should not be altered, one being that a citizen of Australia, for the time being resident in Great Britain but still having wealth in Australia, was *pro tanto* a citizen of two countries, and it was, therefore, not inequitable that he should pay two taxes. That was the kind of outlook that had to be abolished if a move forward was to be made on Imperial lines. Australia produced one-fifth of the world's supply of zinc and lead, and it was not sufficiently realised that Great Britain was not dependent upon the rest of the world for its metals. Everyone had made up his mind that the German control of the minerals in the Empire was to cease entirely, but it was necessary to go one step further and see that the British Empire took up effective control of those metals, because the mines had to be worked, the men employed, and the produce turned to good account. Therefore, if the German and Austrian manufactories were

shut down it would be necessary to start new manufactories in the British Empire. They were very important industries from a peace point of view, but they were vital to our existence in time of stress. It was to be hoped that the lesson of the present moment would not be lost, and that the people of the Empire would, regardless of past beliefs, adopt a vigorous outlook in regard to all the problems concerned, and do what was felt to be necessary. Only on those lines could they expect to go ahead, as they ought to, as the British Empire.

MR. JAMES SWINBURNE, F.R.S., thought the question of the commercial position after the war was very pressing, because at the present time there was a general tendency towards a reversion to Protection. The Dominions had every facility for producing metals, wool, food, and live-stock; but practically all of them objected to taking imports, and therefore adopted what they called Protection, *i.e.*, they made it difficult for imports to get into the country, thereby stopping exports. By hindering exports their people were turned on to do things which they did badly, and were taken away from things they could do well. As a result, they were not growing as fast as they would if that were not the case. The old idea used to be that a country ought to export, and take in no imports but gold, but as Australia was a gold-producing country it was an example to show the fallacy of the argument. Australia had only as many cattle as England, and three times as many sheep. Surely she should grow very much faster. It was of the utmost importance that the Dominions should grow very fast, because it was undesirable that all the population should be found in one corner of the world. If the British Empire was to be still more powerful, Australia should be so large and powerful that she could hold her own if necessary against any future enemies in her own part of the world. He suggested that Australia was not going the right way to help herself in that respect, because by cutting down her imports, and thereby cutting down her exports, she was injuring herself and other countries as well—for instance, England. A large amount of frozen meat was obtained at present from Argentina which ought to be obtained from Australia and New Zealand, but that was impossible if those countries refused the imports that must enter in exchange for those commodities. He did not think the question of how Germany was to be dealt with was the problem that had to be considered; the real one was how we were going to deal with ourselves. A course ought to be shaped so as to make the Empire grow as fast as possible. Once it was realised that Protection, as it was called, was not protection at all, but the throttling of external trade, it would be apparent that the word "Protection," as used in that sense, was absurd. The words "Preferential" and "Reform" were also in the same category. One hundred and fifty years ago Adam Smith pointed out the absurdity of the idea that exports should be encouraged and imports discouraged. In the old days people objected to machinery because they said a machine did the work of twenty men and thus caused unemployment. The fallacy there was that people thought employment was a good thing and production a bad thing, whereas it was exactly the reverse. This was the most important popular economic fallacy in existence, and was the fundamental argument of the Protectionist. It would be impossible to get an indemnity out of Germany if imports were objected to, because the only way the Allies would get an indemnity would be in the form of imports. The more the Germans dumped goods into this country, the more we should get in the way of an indemnity. Dumping was a splendid thing for the countries that received the goods, and very bad for the countries sending them. He did not believe any Acts of Parliament would be of use in helping trade; they always injured it. The only thing that could be done was to be more efficient in our manufactures, both in the Dominions and in England. Some of the Dominions had laws against the entry of black men into their countries. He would like to see not only the Dominions but the whole of the Allies make a law extending that from the people who had black outsides to the people who were black inside. The Germans ought to be kept out of the Empire as much as possible; but apart from that he believed the real solution of the difficulty was to increase our production in every possible way, and stop any kind of legislation that tended to reduce it.

SIR FRANCIS PIGGOTT, LL.M., late Chief Justice, Hong-Kong, observed that the premiers of the Dominions claimed to take a share in the policies which tended to peace or war in the Empire, but how that problem was to be dealt with was another matter. He agreed with the author that it was necessary to get rid of all the little pitfalls that existed, but it must be remembered that, when dealing with the creation of a new Constitution to admit the Dominions into the councils of the Empire it must be written down, and before that could be done it would have to be ascertained what the British Constitution was. At the present time, however, there were no two books on that subject that were in agreement. It was a problem so full of difficulties that it would require a lengthy discussion for its elucidation. Referring to Mr. Young's remarks on the subject of double income tax, he referred to another illustration from his own experience. In 1887, at the time of the first Imperial Conference, he suggested that judgments in the Colonies and in different parts of the Empire should be executed in other parts of the Empire, just as Scottish and Irish judgments were executed in the Kingdom. The Dominions agreed to the suggestion, but nothing had been done in that direction for thirty years. There were innumer-

able numbers of minute problems of that nature which awaited solution and which were all essential parts of the great general problem.

Mr. James Roberts, M.A., LL.B., advocated the formation of an Imperial Cabinet, with the object of advising His Majesty in all matters which were not exclusively the domestic concerns of the United Kingdom. This Cabinet, he considered, should consist of a definite number of members, half of whom might be British and the other half Dominion representatives. If this plan were adopted, should a General Election take place at home, foreign affairs would automatically be removed, to a very great extent, from the sphere of party politics, because only half of the composition of the Imperial Cabinet would be changed, and uniformity of policy would thus be obtained. The numbers of the representatives of the respective Dominions would necessarily be fixed, but in all other respects the filling up of their seats in the Cabinet should be left to themselves. For they might prefer to send delegates from their Governments, and continue the practice of excluding foreign affairs from their elections. The British half of this Cabinet would include the British Ministers of Foreign Affairs, War, and the like Imperial offices. In such a scheme the difficulties attending a single Imperial Parliament would be avoided, and it could be brought into operation forthwith without legislation, by making the nominees of the Dominions members of the Privy Council.

The Chairman (Dr. Dugald Clerk), in moving a vote of thanks to the author for his most interesting paper, said it must particularly be borne in mind that the British Empire had attained its present position notwithstanding all the "muddlement," the illogical arrangements, and want of a written Constitution, to which Mr. Hurd had called attention. There could be no doubt that one of the greatest strengths of the British Empire was that it had no written Constitution. British law was as much judge-made law as Parliament-made law, and there was a tremendous flexibility in the British method, due to what might be called a want of method. The Constitution of the United States, which was a written one, was at present the greatest stumbling-block to the advance of America. It was a definite written document, with cast-iron provisions, made many years ago, which did not in any way fit the conditions at the present time. As a result, American lawyers were always endeavouring, with great dialectical ingenuity, to get out of their own Constitution, and a great many of the things now done by the American Executive were done outside of the Constitution. The British Constitution was the result of a long organic struggle; the British Empire was like a complicated organism, which it was very difficult to understand. The French legal code looked very beautiful, but French justice was not as good as English justice, and German was still worse. Germany had carried method to a degree of madness. The curious thing to his mind about most things German was that the German came with great precision to an erroneous decision. The German very rarely indeed came to a correct decision. A German first of all made a very fine logical statement, but wound up with a conclusion, generally speaking, in direct opposition to the statement. That was how the Germans managed to persuade themselves, firstly, that the British Empire was a thing of straw; secondly, that the people in it were cowards; and, thirdly, that German science and industry were the most glorious things in the world. People in this country, as in all democratic countries, did not hesitate to say what they thought of each other, and outsiders thought that, because we said we were going to the dogs, that was really the case. As a matter of fact, at the end of the war England would be the strongest country in the world.

Sir William Duke, K.C.I.E, seconded the motion, which was carried unanimously, and Mr. Hurd acknowledged the compliment.

The Chairman expressed the thanks of the Society to Mr. MacLaren Brown, of the Canadian Pacific Railway, for the use of the diagrams with which the paper was illustrated.

Mr. Hurd, in acknowledging the vote of thanks, especially welcomed the suggestive speeches of Mr. Hewins, Mr. Young and Sir Francis Piggott, and added: As Mr. Hewins has so well said, there is underlying and inspiring this Empire movement an idealism as fine as anything that has ever animated the nations of the world. It is for us to live up to that idealism. In our public and departmental life here in England we needed the invigoration and initiative which comes to us from contact with these younger Englands overseas, and the Dominions on their part had shown by their splendid comradeship in the trials of war how highly they valued the high traditions of justice and freedom which have their source in these little islands.

JAPANESE ENTERPRISE IN KOREA.

A report on the various enterprises undertaken and carried out in Korea by the Japanese during the three years following their annexation of that country has recently been made by Count Terauchi, the Governor-General of Korea, to the Emperor at Tokio. Included in this publication are the more noteworthy of the proclamations and instructions issued by the Governor-General during this period. Among the topics that are touched upon, says the United States Consul-General at Seoul, are the cultivation of cotton, stock farming, sericulture, the production of rice, and the regulations intended to increase efficiency in handling goods at the custom-house.

Count Terauchi's statement refers to the fact that Japanese migrating to Korea have been steadily increasing in numbers since the annexation. In 1910 the Japanese living in the peninsula numbered only about 146,000, forming some 43,000 households. In June, 1913, the figures had increased to more than 264,000 and 75,000 respectively, showing increases in the interval of three years of more than 118,000 in population and 32,000 in households.

In former days Japanese residents in Korea mostly congregated in the open ports and vicinity and engaged in the import and export trade, or in retail business on a small scale. After annexation, however, when peace was generally restored in the interior, and travelling and habitation by Japanese became safe, the number of Japanese settling in important places outside the open ports and engaged in mining, agriculture, fishing, transportation and other lines of business steadily increased.

Especially noteworthy is the fact that Japanese engaged in agriculture, an industry which requires much time before substantial profits can be obtained from it, have changed their method of conducting it. Formerly, Japanese buying paddy and dry fields in Korea aimed at obtaining incomes by renting them to Korean tenants, or reaping profits by reselling them. Now those undertaking agricultural industry themselves are gradually increasing.

Besides, as a result of the efforts put forth by the Oriental Development Company, under Government directions, to encourage the emigration of Japanese farmers, the number of those farmers living in Korea has greatly increased. Thus, at the time of annexation the total number of their households was about 2,130. These figures increased to 2,960 during the following year (1911), and further increased to 4,380 during 1912, showing an increase to more than double those in the year of annexation.

In former days it was usual for Japanese fishermen to come to Korea only during the fishing season, but in recent years many have settled permanently in localities along the coast and are engaged in their business in partnership with Korean fishermen.

Further, in all branches of industry, such as agriculture, technical industry, and commerce, Japanese undertaking these employ many Koreans as their business assistants and workmen, and there are also to be found many instances in which Japanese and Koreans are jointly undertaking business.

Cotton can be cultivated with advantage in all parts of Korea, but cotton of native species has been found not quite good enough for spinning purposes. In consequence, measures were taken to improve it. At the same time, it being recognised that cotton of the American upland species grows well in South Korea, the former Korean Government, under direction of the Residency General, put forth efforts for encouraging its cultivation in that part of the peninsula by establishing at Mokpo a temporary station for the experimental cultivation of American cotton. After annexation, in order to promote its cultivation by Korean farmers still more widely, the station was converted into a branch of the model agricultural station at Suwon, and experts with experience in the cultivation of cotton were appointed to offices of prefectures and districts suitable for the cultivation of upland cotton.

Further, guilds of cultivators of cotton were formed; farmers showing themselves specially zealous in the cultivation of upland cotton were publicly rewarded by the presentation of agricultural implements, and the produce of places having difficulty of disposing of it was made saleable by the cultivators being given subsidies toward the cost of transportation. In these ways the cultivation of upland cotton was most vigorously encouraged with a very satisfactory result.

Thus, whereas in the year when annexation was carried out the area of land devoted to the cultivation of upland cotton was about 1,000 cho, and its cultivators numbered less than 20,000, in 1912 the area increased to about 6,500 cho, and cultivators to 77,000, while in 1913 the area reached 14,000 cho (one square cho = 2·45 acres). As to the amoun of cotton exported to Japan, while it was only valued at about 250,000 yen in 1910, it increased to 920,000 yen in 1913.

Like other branches of the agricultural industry, sericulture was also formerly in a very undeveloped condition. Silk cocoons produced in Korea were inferior in quality and diverse in variety. The mulberry leaves used were also very inferior in quality, and mulberry orchards were limited in area. In short, the condition of the sericulture industry in the peninsula was anything but satisfactory. In order to raise it, therefore, measures were first taken to cause the model agricultural station and provincial nurseries to rear and distribute among Koreans seedlings of the best varieties of mulberry trees imported from Japan. Subsidies were also granted to people forming mulberry orchards, so that the cultivation of these seedlings might be encouraged and the area of mulberry orchards enlarged.

Koreans soon found that leaves of Japanese mulberry trees were superior in every respect when compared with those of Korean trees, and the number of people cultivating them steadily increased. In 1912 the total area of orchards planted with Japanese mulberry trees reached about 1,600 cho throughout the peninsula. Also, in order to do away with the variety of native silk cocoons, the model agricultural station was charged with the task of selecting species best suited to the climate of Korea. The result was that three varieties of spring breed, one variety of summer breed, and one variety of autumn breed were selected, and eggs obtained from these five varieties of silkworms by the

model agricultural station were distributed among provincial offices, which then undertook, through various sericultural organs, the distribution of the eggs among individual people engaged in sericulture.

As silkworms hatched from these eggs were found to be very strong in resisting diseases and their cocoons were excellent in quality, the hatching of silkworms from eggs of the improved species rapidly became general, and the demand for cocoons spun by them also greatly increased, while the price quoted was three times that given for cocoons of the native species. As people in general outside agricultural people can engage in the sericulture industry with comparative ease, those undertaking it increased in number remarkably, and the total crop obtained in 1913, including spring, summer, and autumn breeds, amounted to as much as 35,400 koku, whereas that obtained in 1909, the year preceding annexation, amounted only to 11,900 koku (koku = 4·96 bushels).

Cattle are indispensable to the agricultural industry in Korea, and occupy a prominent position in the list of items of the export trade of the country. Great attention was paid to the improvement and increase of the breed. Further, in all local centres people were induced to organise cattle guilds among themselves, and to these experts were appointed to teach them the method of increasing their stock. The slaughter of cows in calf was restricted. By means of these measures, without depending on foreign breeds, the improvement and increase of the native breed best adapted to the soil and climate of Korea were undertaken and the result obtained was very satisfactory. Thus, whereas the total number of cattle in Korea was 628,000 in 1909, and 703,000 in 1910, the year of annexation, it increased to 906,000 in 1911, and to 1,040,000 in 1912. Now, Korean cattle being in great demand at Vladivostok and in other parts of Siberia, as well as in Japan, there is little doubt that they will become one of the most important products of Korea.

The encouragement of afforestation is what is most closely connected with the improvement of the agricultural industry. In Korea, in consequence of the ruthless felling of trees and the denudation of mountains, floods or drought frequently occur, and not only the agricultural industry but roads and railways suffer much damage. In order, therefore, to eradicate the evil the authorities early undertook to encourage afforestation among the people.

In 1908 the Residency General caused the Korean Government to provide regulations for the administration of forests in general, as well as for the management of State-owned forests, and thus fixed a general policy with regard to afforestation work in this peninsula. After annexation, in 1911, in order to complete the adjustment of forests and foster in the minds of the people at large the love of forests, the old regulations were abolished and new forestry regulations and some minor regulations relating thereto were promulgated.

At the same time strenuous efforts were put forth to encourage afforestation work. First of all, after due investigation of State-owned forests, those most needing protection were selected and their areas fixed, special offices for supervising them being created.

As for those State-owned forests the retention of which as such was considered unnecessary, it was arranged that these should be leased to private persons undertaking afforestation, and that if they succeeded in their work, the forests should be transferred to their possession.

In July, 1913, there existed throughout Korea 319 nurseries, including one maintained at State expense, 270 maintained by local revenue, and 48 maintained from proceeds from the Imperial donation fund. In these nurseries seedlings of pine, acacia, chestnut, poplar, and a few other trees were reared and distributed free. There are also not a few similar institutions established and managed by private persons and companies, and these contribute in no small degree to the spread of afforestation work.

In 1911, Arbour Day was established in Korea, April 3rd, a great national holiday, being fixed upon, and 4,650,000 young trees were planted on that day by officials and private persons throughout Korea. In 1912 there were 10,160,000 young trees planted, and 12,430,000 in 1913. The steady increases in figures will show how people in general are becoming cognisant of the benefit of afforestation.

INDIAN INDIGO.

The *Agricultural Journal of India* contains an interesting report by Mr. and Mrs. Howard of the progress which has been made in the improvement of indigo in Bihar in 1914. The principal value of the plant lies in the amount of indican contained in its leaves, though the by-product seeth, which consists of the plant residues after extraction of the indican, is an excellent manure. Indigo is a leguminous plant, and, as with all other similar crops in India, its well-being depends on the aëration of the root nodules. The essential points about these nodules are two. In the first place, they contain bacteria which have the power of assimilating the free nitrogen of the atmosphere, and working this up into materials from which the indigo plant makes the proteid it requires, and also the indican in its leaves. In the second, the food of the bacteria in the nodules is supplied by the plant, and for this purpose substances of the nature of sugar are passed down from the leaves into the nodule to feed the bacteria.

Leguminous plants, if grown in soil rich in nitrates, do not form nodules, but absorb the nitrates direct in the same manner as other plants do; and it must also be borne in mind that the

parts of the root which absorb water and minerals also require air, and will not work in the absence of oxygen.

The root nodules, consequently, develop most successfully when the plant is grown on somewhat poor land. When the soil contains little nitrate, the nodules work at high pressure to supply the proteids required by the plant; large amounts of the nitrogen and oxygen of the air are used up, and the leaves become rich in indican.

The activity of the root nodules reaches its maximum when the plant is ready to flower; and it is said that if the crop is allowed to flower the yield of finished indigo falls off and the colour suffers.

As regards the supply of air round the nodules, this is easily secured in Bihar during the earlier part of the season, provided that the soil is deeply cultivated and well broken up; but if there is a very heavy rainfall, so that the soil gets packed and the air spaces filled up with water for any length of time, the activity of the whole root system is stopped, no further indican can be formed, and the plant falls back upon the reserve indican stored in its leaves. From this it is clear that the first aim of the planter must be "to run the whole nodule factory to its highest pitch. Not only is the yield of indigo thus increased, but the condition of the finished product is improved and good colour results."

GEOLOGICAL NOTES ON QUEENSLAND.

From the Gulf of Carpentaria to the Darling Downs, north and south, the fossil remains of extinct mammalia have been found in indurated muds, the beds of old watercourses. The fossils are Diprotodon Australis, Macropus titan, Thylacoles, Phascolomys, Nototherium, crocodile teeth, etc. The Diprotodon inhabited the Queensland valleys freely, and the Crocodilus Australis had a great range inland. The Diprotodon remains are found chiefly in the most permanent water-holes. No human bones, flint flakes, or any kind of native weapons have yet been discovered with the extinct mammalia of Queensland.

Desert sandstone is the most recent widely-spread stratified deposit developed in Queensland. Since it became dry land the denudation of this formation has been excessive, but there is still a large tract *in situ*. Probably this desert sandstone covered the whole of Australia at one time. (It is possible that desert sandstone in Queensland has value for free gold.) On the vast plains west of the dividing range cretaceous strata are found; hot alkaline springs occur in these plains, and the discovery of these suggested the possibility of the existence of artesian water long before the bores were sunk, from which flow "Queensland's rivers of gold."

The whole of Queensland is a vast cemetery of fossilised species—on the surface, buried in drifts, or hidden in clays. The plains of the Flinders River disclose great deposits of marine fossil shells, belemnites and ammonites, and remains of extinct animals. In the Gulf of Carpentaria, 40 or 50 feet below the alluvial deposits forming the banks of rivers, firmly embedded in the hard cement—water-worn stones in an ironstone clay—are the bones of innumerable extinct gigantic animals that, far back in some prehistoric age, roamed over the Gulf country: diprotodon, nototherium, and zygomaturus—grass-eaters and flesh-eaters. The utter extinction of these creatures can only be explained by a great change of climate and great and lengthy droughts. The fossils are from animals of immense size; the teeth found are twice the size of an ordinary bullock's. Gigantic alligators, turtles and marsupials abounded in those days, suggesting a luxuriant and abundant herbage.

From an economic point of view one may say that three-fourths of the area of Queensland forms good pastoral land. Of this, 60,000 square miles contain valuable mines of gold, with outcrops of copper and lead ores, as well as rich deposits of tin; 24,000 square miles are capable of producing illimitable supplies of iron and coal. It may be safely asserted that in Queensland is a wealth of material resource comparing favourably with any other part of Australia.

FORESTRY AND TIMBER IN IRELAND.

The recent changes in the timber trade of Ireland have directed public attention afresh to the island's indigenous forest resources. It appears that afforestation has been receiving a measure of intelligent attention for the past decade or more. The Province of Munster possesses one-third of the wooded area of Ireland, and fells two-thirds of the annual cut of timber.

Of the total territory of Ireland, only 1·4 per cent. is under woods, as compared with 5·3 per cent. in England. Ireland has a lower proportion of its area in forests than any other country in Europe.

On the other hand, the exportations of wood and its manufactures in 1913 were valued at £474,000, and eight or ten of the country's substantial industries are based with some directness upon the native wood supply.

Although the stock of standing timber has been steadily depleted in recent years, the shrinkage in area is not striking. The highest recorded spread of forests is set down for the year 1880 at 339,858 acres, and during the ten years ended with 1913 the decline was only 5,495 acres. All authorities, however, both official and unofficial, insist in the strongest terms that the diminution of the timber supply cannot be gauged by area. Continuous selection and consumption of the best individual trees during a long series of years have left many so-called forest tracts practically devoid of processable wood, and it is doubtful if an average of more than 50 per cent. of a full crop can be found over the entire area returned as woodland.

On a forest area of 6,700 acres, chosen as typical, a thorough inspection in 1908 showed 47 per cent. virtually bare of valuable timber, 25 per cent. in tolerable condition, and only 28 per cent. properly stocked. As to age, 77 per cent. of the trees were over fifty years old and 45 per cent. were over seventy-five years old. Fresh corroborative data are supplied by the 1913 returns as to the age of standing forests. Out of 170,906 acres investigated, only 20,170 acres are below twenty-five years of age, while 98,469 are over fifty years of age, and 45,267 are from twenty-five to fifty years of age.

The number of trees felled in 1913 was 571,859, and the acres cleared were 1,462, while the number of trees planted was 2,488,162 on an area of 1,154 acres. The replanting thus fulfils the forestry principle that four times as many plantings as fellings should take place in any given year. The fellings, moreover, represent a decrease over former years, since the number of trees cut in 1911 was 903,341, and that in 1901 was 941,132. The weight of trees felled in 1913 was 245,210 tons, and this also indicates that cutting is not unduly rapid, since from one to two tons per acre is deemed a legitimate take in a well-managed forest, and the Irish acreage is 297,809.

As a less favourable consideration, it should be stated that in order to replace 300,000 acres every seventy-five years 4,000 acres should be replanted each year, as against 1,154 acres actually set out in 1913. A large share of the trees now standing are too old to be valuable for cutting and yet occupy forest ground. On the whole, the most hopeful feature is the wholesome increase in planting, the acreage now averaging about 1,100 per annum, as compared with 900 per annum during the years 1903 to 1907. In number of trees planted Leinster somewhat exceeds Munster, and the two provinces together plant two-thirds of the total for Ireland.

According to a report recently sent to his Government by the United States Consul at Cork, the decimation of standing timber in Ireland since 1900 has corresponded with similar developments in many other parts of the world, and has had similar causes, which are familiar to most persons. An additional cause in Ireland has been the breaking up of large landed estates, especially since 1904.

The findings of the Committee of the Department of Agriculture appointed in 1908 to report on the forestry situation dwelt on the need for conservation. Legislation was recommended to correct the disapproved tendencies of the Land Purchase Acts, and an elaborate scheme for national control of all forests with active management of a large part, not only of the afforestation, but of ordinary felling and marketing, was urged by the committee.

The amount of land available in Ireland for forest uses on sound economic lines was estimated at 1,000,000 acres, including existing woodlands, and this estimate was lower by half than previous assertions by forestry enthusiasts. The mountain land of Ireland is covered with wet peat, bare rock, or a gravelly porous soil, and only the latter is suited for trees. The peaty and rocky types of land predominate in the north and west. In general, the mountain land becomes less adapted for afforestation as the western coast is approached, and this is unfortunate, since the western parts of Ireland are least thickly populated, and therefore are most available, *primâ facie*, for forest planting.

The ideas of the committee were not put into effect, but their investigation increased the interest and intelligence shown in connection with the problems of replanting. Other influences in the same direction have been the Government Forestry School at Avondale and the Irish Forestry Society.

Varieties of Trees in Ireland.

Nondeciduous trees predominate in Irish forests. In 1913, of the total forest acreage (297,809), 93,640 were returned as conifers, 77,077 as broad-leaved, and 127,092 as mixed, with conifers probably predominating. The narrow-leaved class includes larch, fir, spruce, Scotch pine, etc., while the broad-leaved, or deciduous, covers oak, ash, beech, sycamore, birch, etc. The following table, compiled from various official sources, shows the acreage of each species in 1901 (the latest available year), and the number of each species felled and replanted in 1913:—

Varieties.	Area, 1901.	Felled, 1913.	Planted, 1913.
	Acres.	Number.	Number.
Larch	46,175	269,464	1,075,139
Fir	35,020	54,106	347,498
Spruce. . . .	15,291	26,073	268,425
Pine	3,377	23,379	185,020
Oak	25,158	47,375	54,900
Ash	7,398	15,830	44,360
Beech	9,826	26,837	69,340
Sycamore . . .	2,562	4,571	12,812
Elm	2,750	1,124	9,600
Other and mixed	162,184	106,100	421,068
Total . . .	309,741	574,859	2,488,162

It is evident that larch is easily the leading tree of Ireland, and also that nondeciduous trees are being planted more actively than broad-leaved varieties, although the latter are being freely cut down.

The most profitable ages at which the different varieties may be cut are as follows: Larch, 50-80 years; pine and spruce, 70-100 years; ash, 60-80 years; beech, elm, and sycamore, 80-100 years; and hedgerow trees of all kinds, 60-70 years. These figures presuppose healthy and sound trees, as a large share of trees in each variety develop defects, and must be cut earlier than indicated.

Of the 574,859 trees felled in 1913, 304,214 were used for mining purposes (mainly in England), 28,522 for railway ties, 17,357 for fencing, 6,269 for bobbins and spools, 24,538 for fuel, 74,404 for carpentry and furniture, 8,535 for vehicles and implements, 3,510 for clog soles, 1,300 for boat-building, and 17,266 for boxes. As to fuel, fencing, clog soles, and boxes, the proportions vary greatly in different years; but the heavy preponderance of the wood used for mining purposes (pit props) has been constantly maintained, and the proportion devoted to railway sleepers and to building and furniture appears to be fairly constant. There are 85 furniture factories in Ireland, 55 box-makers, 16 manufacturers of implement handles, 8 of bobbins and shuttles, and 8 of wheelbarrows; and basket-making, stave-making, and the making of boot-lasts, bog-oak souvenirs, walking-sticks, matches, and other articles are connected with the growth of timber and coppice in Ireland.

Except furniture, the principal kind of wood exported from Ireland is pit props. Practically all the rough timber is worked into various forms of struts and props for British collieries. The principal wood used is larch, with some fir and odd-size oak. The Lancashire and Scottish coal mines value larch more highly than do those of Wales. Before the war the Welsh collieries drew pit wood from Bordeaux and Bayonne in France, delivered at 20*s.* per ton at Cardiff, so that Irish sales to Wales were small. Scotch pine and spruce, which mature more slowly than larch, cannot profitably be grown for mining purposes, the Russian and Scandinavian wood of these varieties having gained the favour of the coal mines, which bid higher prices for it than for Irish wood. Larch remains, therefore, the logical Irish timber for mining use, as it can be harvested at thirty-five to forty years of age, the diameter being then 9 to 12 in. Scrub oak can also be thus used.

The exports of pit wood go almost wholly from Cork, Waterford, Wicklow, Wexford, and Tipperary, the five leading timber counties of Ireland. In 1913 the port of Cork alone exported 24,415 tons of rough timber.

For packing-cases, butter-boxes, egg-crates, etc., which are largely used in Ireland, Scotch pine and spruce of Irish growth are the leading woods, while poplar is sometimes used. Oak, ash, and beech are apt to be too heavy and too moist. Timber for boxes brings 8*s.* to 12*s.* 4*d.* per ton in the wood. The same varieties are used for railway sleepers. The price of these has risen by half within ten years, and now stands at 4*s.* each for 9-foot ties. Large imports used to be brought in from Baltic and Canadian sources, the 1913 aggregate being 9,836 loads, valued at £32,000. Spruce and Scotch pine are also used principally for building timber, such as joists, studding, sills, etc, and if sound are worth 15*s.* to 20*s.* per ton in the wood. Heavy timber for building and dock work is imported in large quantities, and considerable amounts are creosoted after arrival by the two Dublin and one Waterford creosoting plants.

The exportation from Ireland of blocks for clog soles has always been a substantial trade. Originally alder was used, but birch and beech are superseding it, and the value of wood for this purpose is 10*s.* to 13*s.* per ton in the log. Bobbins are made from beech, birch, or sycamore, obtainable at 6*s.* 2*d.* to 9*s.* 2*d.* per ton. Butter barrels (kiels) are of beech staves, and the wood costs 10*s.* to 13*s.* per ton. Aspen from Russia has been used in certain of the Dublin match factories, but Irish poplar has now taken its place.

For furniture-making, aside from osiers, oak, ash, sycamore, and beech, are used, at prices varying widely with their quality, but in general at rising costs. For telegraph poles, apart from imports, Irish larch and pine are available. The General Post Office is anxious to promote the use of these home-grown poles, and some official encouragement has been given with this end in view. The lengths required range from 22 to 40 ft., and the top diameters from 5 to 10 in. Except in sheltered positions, the larch in Ireland is apt to be curved at the base, owing to the strong and continual winds, and is thus unsuited for telegraph poles.

THE VEGETABLE WOOL OF ECUADOR.

Kapok, known in Ecuador as "lana de ceiba," or vegetable wool, is a product of the largest tree that grows in the forests of the littoral, a species of the genus Eriodendron (allied to the cotton plant). The ceiba bears most of its branches near the top, and the appearance of its bright yellow flowers marks the approaching end of the rainless season. After the flowers fade the pods that yield the kapok of commerce are formed: these are gathered and the fibre extracted by hand. Too early rains interfere with pollenation, resulting in many empty pods, when the natives refuse to devote much time to gathering the crop.

The tree may be grown in Ecuador up to an altitude of 5,000 ft. above sea level, the growth during the first year being about 25 ft. When two years old, on an average it will produce 100 to 200 pods, which contain 1 to 2 lb. of kapok; at five years, 200 to 300 pods, with 2 to 3 lb.; at six years, 300 to 400 pods, with 3 to 4 lb.; at ten years, 800 to 1,200 pods, with 10 to 20 lb. Two hundred pounds of kapok were obtained from one old tree. However, the tree is not cultivated in Ecuador.

From a recent report by the United States Consul-General at Guayaquil it appears that 100 lb. of crude material yield, after cleaning, 45 lb. of first grade kapok, 20 lb. of second grade, and 30 lb. of seed. The seeds must be carefully separated from the fibre, as the presence of oil in them (about 25 per cent.) will produce a stain which renders the fibre unfit for use. The

machine employed resembles a cotton-gin, and does no injury to the fibre or seed. To be marketable the fibre must be long and bright, free from seed and other *débris*, and not too tightly packed in bales of about 100 lb.

There were exported from Ecuador 162,341 lb. of kapok in 1914, 129,226 lb. in 1913, and 135,719 lb. in 1912. Of the seeds, Liverpool received 29,566 lb. in 1914, 84,531 lb. in 1913, and 183,744 lb. in 1912 for their oil. (After the oil has been extracted the residue is pressed into cakes for cattle feed.) First grade kapok sold in 1913 and 1914 for 6*d*. per lb., and second grade for 2¼*d*. f.o.b. Guayaquil, all of the latter being shipped to Peru and Chile. The seeds sold for 3*s*. 8*d*. per 100 lb. net.

In similar tracts of country there exists another but much smaller plant called "flor de seda," or silk flower, also a rapid grower. The product resembles kapok, but is much superior in all textile qualities, as it is finer and more brilliant. It is locally used in the manufacture of mattresses, not being separated in the local market from kapok. Silk flower has great future commercial and industrial possibilities, and, in the opinion of the Consul-General, would well repay scientific investigation and experiment.

EXPORT OF DESICCATED VEGETABLES FROM DENMARK.

Of late years an important trade in the export of desiccated vegetables, especially cabbages, was established in Denmark.

From its geographical position, between the North Sea and Baltic, as well as its proximity to the place of production, Copenhagen is particularly well situated for supplying the chief Scandinavian, Russian, Finnish, and even the British ports, with this article of food.

During the winter months huge piles of dried cabbages, carefully packed in sacks, used to be seen on the quays of the Danish capital awaiting shipment. The greater part of these stocks were sent to the Russian ports of Riga, Libau, Windau, or Reval, from whence they were forwarded by rail to Petrograd, Moscow, and the principal towns in the interior. The quality most in demand for the Russian market is the "Amac cabbage," a kind largely used throughout the empire for the preparation of "Bozschish" and other national dishes.

Amac, or Amager in Danish, is a small island, forming part of the city of Copenhagen, to which it is united by several bridges. It is inhabited by a colony of Dutch peasants, brought from Holland some five hundred years ago, by King Christian II., in order to introduce the Dutch methods of cultivation into Denmark. They still speak a Dutch dialect, and many of the women wear the picturesque national costumes of their mother country.

The Amager cabbage is small, close-leaved, and very compact. It is estimated that upwards of 10,000 tons of this vegetable were exported every year from Copenhagen, besides considerable quantities of potatoes, carrots, celery, and other vegetables.

The cabbages are desiccated in order to reduce their weight by $\frac{9}{10}$, and so save expense of transport, customs duty, etc. The dried vegetable also is not injured by frost, an important matter in northern climates.

ARTS AND CRAFTS.

The London Fair.—The London Fair and Market followed so closely on the British Industries Fair that it was not to be expected that it would contain a great deal that was new. It claimed, of course, to include foreign as well as English goods, but in the present state of affairs it was clearly improbable that many overseas firms would exhibit. Had the management been able to carry out their original intention, the exhibition would have been considerably strengthened by the inclusion of jewellery, silverware, and other metal work; but as Government did not allow this, the scope of the exhibits was practically the same as at South Kensington, save for the omission of the pottery and glass section, though a good many individual manufacturers exhibited at one or other of the fairs, but not at both. What struck the visitor to the Agricultural Hall, as soon as he emerged from the entrance hall, was how much better a building of this type was adapted to the needs of a show of this kind than the Victoria and Albert Museum. It was far easier to see the exhibits properly at Islington than it had been at South Kensington. The only thing one regretted was that fuller use had not been made of the space, and that there was no collection of posters and other large printed work. Amongst the toys the collapsible dolls' houses, etc., of the Armageddon Game and Toy Co. were attractive as well as ingenious, the swans of the Avon Toy Co. had a certain air of distinction, and the tin toys of Burnett, of Birmingham, were artistically a good deal better than such things are wont to be. The hand-painted dolls' furniture of the Olanda Toy Works, Amsterdam, was fresh, and had just that touch of interest which comes of its difference from English work of somewhat the same type. The metal jardinières, vases, and the like exhibited by several firms were very much on German lines. Had one seen them in Milan before the war, one would have deplored the influx of German goods into Italy; but the examples shown by Messrs. Soutter & Sons, of Birmingham, indicated some desire to strike out in a new and better direction. In the stationery section, the cards of Messrs. Ritchie & Sons, of Edinburgh, included some successful pieces of colour work; Messrs. Ibbotson's fancy papers for boxes and bookbinding were interesting, and the chalks and crayons shown by Binney and Smith, of Letch-

worth, had a quality and strength of colour which ought to have drawn attention to them even had they been less skilfully exhibited. As it was, the notices chalked up on brown paper helped the stand considerably.

Lettering and Design in Secondary Schools.—The exhibition of the Royal Drawing Society is always interesting as showing what kind of work is being done by the pupils of a number of secondary schools throughout the country. The fact that it has this year been housed in the Guildhall Art Gallery has naturally rather added to its importance. This makes it all the more to be regretted that, excellent as some of the drawing and painting is, the exhibits connected with arts and crafts do not come up to a higher level. No one who understands the conditions expects a very great deal in the way of design from school girls and boys; but many of the exhibits at the Guildhall are by students of from sixteen to nineteen years of age, and it ought to be possible to teach them a good simple alphabet which they can use and adapt when they want to set out notices or make a cover for the school magazine. Lettering is a simple branch of art craftsmanship which enters into almost every department of life, scientific as well as artistic, and a little training at school would not only be of real use to the girls later in life, but would help to direct them towards the appreciation of beauty in simple everyday things, to prefer a good printed page to a bad one, for example, and would save their friends from the unnecessarily ugly lettering which disfigures not only scientific and other note-books, but would-be artistic calendars and cards. Again, though no one nowadays wants to fetter the imagination of the youthful student, it is possible to teach him, or, at any rate, to lead him, to see that if he is designing a book cover, for instance, there are certain laws or principles which, if he follows them, will help his design, and if he ignores them will at the least mar its success. Proportion, balance, fitness are not mere conventions invented to embarrass the budding designer; they are in their way as natural as the laws of growth. The schools, of course, have hard work to teach all that is required of them, and even an art mistress or master does not necessarily understand much about design, but it looks as though if the subject is to be taught at all, it should have rather more thought bestowed upon it than is at present the case.

CORRESPONDENCE.

"OLD MASTER" POSTCARDS.

On page 378 of the Society's *Journal* of March 24th, you criticise certain postcards after the Old Masters shown by the Medici Society at the British Industries Fair. You further refer to certain other postcards issued by "a firm in Milan (whose name suggests a possible German origin) . . . It is true that [its] later productions are not (or were not before the war) quite as successful as the earlier ones." You further remark that the "ideal coloured postcard" will needs combine "the qualities of the English and Milanese cards."

I do not know how far the minor history of minor printing may interest you, but there hangs a tale by your story.

Hans Hoesch of Milan began, somewhere about the years 1900-2, to issue the postcards of which you speak. He also produced what, in 1906-8, became Nos. 1-7 of the Medici Prints, a series now numbering nearly 250 subjects.

Hans Hoesch was a German-Italian. His father had, sometime, worked for a big Viennese firm of collotypers. He was a genius, but genius and balance are not always synonymous. About 1902-5 I purchased various prints from him. Finding that the quality was maintained, and being entirely unable to comprehend—a failure shared by many practical painters here—how Hoesch got this quality at all, much less got it at the price, I, in 1906, went out to see him. In those days, my ignorance of collotype and "Old Masters" was equal. I gave Hoesch orders such as his soul had never dreamed of, and returned home.

Furnished with cash, the defects of his qualities overcame Hoesch. I need not relate the sorry tale. The courts intervened and Hans was long since forbidden even to enter the family "stabilimento." The more recently issued publications, postcards or otherwise, of the Hoesch works bear the name of his brother. Not every family breeds two geniuses in one generation. Hans was, in his way, a great master. His brother is not so.

You desiderate a combination of the Milanese and English card, and I will take it that by "Milanese" you mean the product of Hans.

But you speak of "Old Master" postcards. Such, it is to be presumed, should attempt to "reproduce" the original picture. Did Hans Hoesch so do? Not he! Hans was a supreme master in the art of suggestion. Neither in drawing nor in colour did his products necessarily resemble the paintings reproduced. He translated them into terms of "five-colour collotype." The product, a combination of Hans Hoesch and Leonardo, is a miracle of translation, but no more a reproduction of Leonardo than is a certain picture, in the Brera, by Cesare da Cesto an equivalent of the "Madonna of the Rocks."

Apart from the genius of Hans Hoesch, his cards were printed in collotype, and irresponsibly printed at that. Never did five out of a hundred agree in colour. And as for the 1914 versions, when Hans had been excluded from the firm these three or four years, by decree of the courts, between them and the worst impression of 1906 was a great gulf fixed.

The Medici cards are reproduced by mere four-

colour process. They show the miserable "screen." They pretend to be reproductions, and are to be judged as such.

The Medici postcard is, though I say it, a first-class commercial product, capable of daily repetition *ad infinitum.*

Before Hans Hoesch's postcards—not the inferior products of the firm since he left it—I have for ten years been humbled. He once offered to sell them to me wholesale at 60 lire per 1,000. Being offered a trial order for 10,000 he declined it. Even in a one-man works in the outskirts of Milan, before the Tripoli war, the price was incredible. I have never seen how to produce them at £4 per 1,000, works cost, and even so they could not be reproductions, nor could any standard be observed in the run. Hans Hoesch, more than once, all but made me a bankrupt. But, I repeat, Hans was of the race of "Great Masters."

PHILIP LEE-WARNER.

MEETINGS OF THE SOCIETY.

ORDINARY MEETINGS.

Wednesday afternoons, at 4.30 p.m.:—

MAY 3.—

MAY 10.—SIR FRANCIS TAYLOR PIGGOTT, M.A., LL.M., Chief Justice of Hong-Kong, 1905–1912, "Neutral Merchants and the Rights of War." DUGALD CLERK, D.Sc., F.R.S., Chairman of the Council of the Society, will preside.

MAY 17.—GEORGE PERCIVAL BAKER, "Hindu Hand-painted Calicoes of the Seventeenth and Eighteenth Centuries, and their Influence on the Tinctorial Arts of Europe." SIR WILLIAM MARTIN CONWAY, M.A., F.S.A., F.R.G.S., will preside.

MAY 24.—JOHN COLLETT MOULDEN, A.R.S.M., M.Inst.M.M., "Zinc, its Production and Industrial Applications." (Peter Le Neve Foster Prize Essay.)

INDIAN SECTION.

Thursday afternoons, at 4.30 p.m.:—

APRIL 27.—JAMES MACKENNA, M.A., I.C.S. (Deputy Commissioner, Myaungmya, Burma, and designated Agricultural Adviser to the Government of India), "Scientific Agriculture in India." The paper will be read by Sir Steyning W. Edgerley, K.C.S.I., K.C.V.O., C.I.E., Chairman of the Indian Section. SIR ROBERT W. CARLYLE, K.C.S.I., C.I.E., will preside.

MAY 18.—SARDAR DALJIT SINGH, C.S.I., "The Sikhs."

JUNE 1.—PROFESSOR WYNDHAM R. DUNSTAN, C.M.G., M.A., LL.D., F.R.S., "The Work of the Imperial Institute for India." THE RIGHT HON. LORD ISLINGTON, G.C.M.G., will preside.

COLONIAL SECTION.

Tuesday afternoon, at 4.30 p.m.:—

MAY 2. — THE RIGHT HON. SIR WILLIAM MACGREGOR, G.C.M.G, C.B., LL.D., D.Sc., "Some Native Potentates and Colleagues." THE RIGHT HON. VISCOUNT BRYCE, O.M., D.C.L., LL.D., F.R.S., will preside.

CANTOR LECTURES.

Monday afternoons, at 4.30 p.m.:—

J. ERSKINE-MURRAY, D.Sc., F.R.S.E., M.I.E.E., "Vibrations, Waves, and Resonance." Four Lectures.

Syllabus.

LECTURE I.—MAY 1.—*Periodic Motions.* Definitions and modes of production—Stable and unstable equilibrium — Inertia, gravity, and elasticity — Pendulums and spring oscillators of various kinds —Torsional vibrations, balance wheel—Corrugation of rails—Musical instruments—Complex vibrations and the quality of a tone—Vibrations on large scale, seismic tremors, vibrations of ships and buildings, lightning.

LECTURE II.—MAY 8.—*Waves in Ponderable Matter.* Transverse and longitudinal waves in solids and liquids — Methods of production and propagation — Polarisation — Wind waves — Ship waves—Tides and seiches—Cloud waves—Independence of wave trains—Superposition of harmonic motions—Sound waves—Submarine bells—Voice, phonograph, and gramophone.

LECTURE III.—MAY 15.—*Waves in the Ether.* Free and conducted—Light, heat, and electric waves — Alternating currents — Telephonic transmission—Wireless telegraphy—Submarine cables —Inductance, capacity, and resistance—Limits of known wave-lengths—Röntgen rays—Light—Heat —Reflection, refraction, and diffraction of wave motions—Stationary waves—Attenuation and distortion of travelling waves.

LECTURE IV.—MAY 22.—*Resonance.* Mechanical and electrical—Superposition of periodic impulses—Universal importance of the selective absorption of wave motions—Mechanical resonance or revibration — Screening of vibrations, absorption, and filtration — The acoustics of buildings — Sound resonators—Absorption of light waves—Coloured glass — Vision and photography — Absorption of electrical power by resonance—Tuning in telegraphy.

Journal of the Royal Society of Arts.

No. 3,310. VOL. LXIV.

FRIDAY, APRIL 28, 1916.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICES.

NEXT WEEK.

MONDAY, MAY 1st, 4.30 p.m. (Cantor Lecture.) J. ERSKINE-MURRAY, D.Sc., F.R.S.E., M.I.E.E., "Vibrations, Waves, and Resonance." (Lecture I.)

TUESDAY, MAY 2nd, 4.30 p.m. (Colonial Section.) THE RIGHT HON. SIR WILLIAM MACGREGOR, G.C.M.G., C.B., LL.D., D.Sc., "Some Native Potentates and Colleagues." THE RIGHT HON. VISCOUNT BRYCE, O.M., D.C.L., LL.D., F.R.S., will preside.

WEDNESDAY, MAY 3rd, 4.30 p.m. (Ordinary Meeting.) SIR HENRY HARDINGE CUNYNGHAME, K.C.B., Member of the Royal Commission on Food Supplies, 1905, "Supply of Food in Time of War."

Further particulars of the Society's meetings will be found at the end of this number.

INDIAN SECTION.

Thursday afternoon, April 27th, 4.30 p.m.; SIR ROBERT W. CARLYLE, K.C.S.I., C.I.E., Member of the Council of the Governor-General of India, 1910–1915, in the chair. A paper on "Scientific Agriculture in India," by JAMES MACKENNA, M.A., I.C.S., Agricultural Adviser to the Government of India, was read, in the absence of the author, by Sir Steyning William Edgerley, K.C.S.I., K.C.V.O., C.I.E., Chairman of the Indian Section.

The paper and discussion will be published in subsequent numbers of the *Journal*.

LIST OF FELLOWS.

The new edition of the List of Fellows of the Society is now ready, and can be obtained by Fellows on application to the Secretary.

PROCEEDINGS OF THE SOCIETY.

COLONIAL SECTION.

A meeting of the Colonial Section was held on April 11th, 1916; THE RIGHT HON. SIR WILLIAM MACGREGOR, G.C.M.G., C.B., LL.D., D.Sc., in the chair.

THE CHAIRMAN, in expressing his pleasure at occupying the chair, said he felt himself under very great obligation both to Newfoundland and to Sir Daniel Morris. During his term of office in Newfoundland there were several matters of very great interest, including the ancient question with respect to the French shore, and the establishment of the great pulp manufactory at Grand Falls, one of the finest establishments of the kind in existence, created by the energy and enterprise of Lord Northcliffe. He had also been greatly assisted by Sir Daniel Morris in 1879 in Fiji, where there was an outbreak of coffee-leaf disease, which at that time was practically new to the scientific world. The writings of Sir Daniel Morris, who had thoroughly investigated the subject, were a great help in dealing with the disease.

The paper read was—

THE FOREST RESOURCES OF NEWFOUNDLAND.

By SIR DANIEL MORRIS, K.C.M.G., M.A., D.C.L., D.Sc., F.L.S.

Two years ago the Prime Minister of Newfoundland, when on a visit to this country, said: "Even to-day Newfoundland is not in the public eye, and it is only occasionally that attention is drawn to its valuable resources and its great possibilities in the future." Very few people probably know that Newfoundland is 11,000 square miles larger than Ireland, only one-fifth smaller than Great Britain, three times the size of Holland, twice as large as Denmark, equal in size to three maritime provinces of Canada and about the size of the State of New York. "In addition to its great cod fisheries, the largest in the world, and its rich minerals, it has forests of spruce and other timber now

producing the pulp and paper upon which many of the London and some of the New York papers are being printed, and over three million acres of good agricultural land as yet practically untouched."

It is, I believe, twenty-three years since Newfoundland has formed the subject of a paper read before the Royal Society of Arts. After so long a period, I trust it will not be regarded as presumptuous on my part to propose to lay before you in this war time a brief summary of facts and figures that have been brought together relating to the forest resources of this oldest and the nearest portion of our Overseas Empire.

Perhaps one of the paradoxes of the war was that Newfoundland at the end of 1915 found itself more prosperous than ever in her history, despite the unfavourable circumstances that had operated just before the war and during the first few months of its progress. The fisheries were successful, and prices rose to almost double what they were in 1914. An estimate given in the *Times* mentioned that in the 1915 season's codding operations Newfoundland realised two million dollars more than in 1914. Further, operations connected with iron mining were greatly increased owing to the demand for iron and steel for munition-making in Canada. Similarly pulp and paper companies which had had to face adverse conditions at the outset of the war "have been operating in full blast." In addition, as will be shown later, a new industry has grown up in Newfoundland in 1915 for the production of pit-wood for colliery purposes, owing to the blockade of the Baltic and the inability to obtain supplies as formerly from Russia and Sweden. It is satisfactory to learn that this condition of affairs has been brought about although the Colony has 3,200 men engaged in the war—serving in the Naval Reserve and in the Newfoundland Regiment.

As regards accessibility Newfoundland is well placed. From this country a man leaves Liverpool on Saturday by the Allan or Furness Line and arrives at St. John's, the capital, on the following Saturday. From New York he can travel in a Pullman sleeping-car and in forty-eight hours he can be at a salmon pool in Codroy Valley and find splendid sport. Yachting and scenery are unequalled in any other part of the world.

Newfoundland offers special attractions to tourists and health seekers, and it is claimed to be a paradise for sportsmen. Of the large game the caribou stands foremost; but there are also bears, wolves and lynxes; fur-bearing animals such as foxes, otters, marten, minks, musk-rats and rabbits. Of birds there are willow grouse, partridge, Canadian goose, many varieties of duck, snipe, woodcock and plover. For the rod there is salmon and trout fishing. The writings of Selous, Hesketh Pritchard, J. G. Millais, Dugmore and Admiral Kennedy all bear ample testimony to the excellent sport and splendid scenery of Newfoundland.

Mr. Alexander Murray, C.M.G., for sixteen years Geologist to the Government, writes: "The climate of Newfoundland is, as compared with the neighbouring continent, a moderately temperate one. The heat is far less intense, on an average, during the summer than in any part of Canada, and the extreme cold of winter is much less severe. The thermometer rarely indicates higher than 70° F. in the former, or much below zero in the latter. The climate is undoubtedly a very healthy one, and the general physique of the natives, who are a powerfully-built, robust and hardy race, is a good example of its influence."

The island is occupied entirely by a white English-speaking element, of which 97·5 per cent. is native-born. There are no aborigines. The people, numbering 243,000, are law-abiding, industrious and temperate.

A useful summary of information respecting the forest resources of Newfoundland is contained in "Newfoundland in 1911," by Mr. P. T. T. McGarth, with a Foreword by the Premier, the Right Hon. Sir Edward Morris. Possibly a still more comprehensive store of facts and figures is contained in the Report of the Dominions Royal Commission, especially the Minutes of Evidence taken in Newfoundland in 1914 presented to Parliament in May, 1915 (Cd. 7898).

Physical Features.

As the map shows, the island is irregular in shape, with the general outline of a triangle. Its greatest length is over 300 miles and its total area 46,000 square miles. Its triangular extremities are Cape Norman on the north, marking the entrance to Belle Isle Strait, Cape Race on the south-east, one of the world's greatest seaboard outposts, and Cape Ray at its south-west, the chief landmark of the Gulf of Lawrence route. All along the coast are innumerable bays and harbours.

Perhaps the most striking physical features of the coast are the several peninsulas which jut out from the main structure. There is the Avalon peninsula on the eastern coast, which is almost

another island—the isthmus between Trinity and Placentia Bays being only three miles wide; and there is Burin peninsula between Placentia and Fortune Bays. On the west coast there is Port-au-port peninsula with the great northern peninsula, formerly called by the French the Petit Nord, and more recently known as the St. Barbe peninsula. The general surface of Newfoundland is hilly, but no marked elevations are reached. The mountain ranges extend north and south; the principal is the Long Range Mountain, which begins at Cape Ray and continues north-east for 200 miles. Its highest peak is 2,000 ft. There are several lesser ranges with peaks from 1,000 ft. to 1,730 ft.

The geology of the island presents numerous points of interest. The rocks range from the Laurentian to the Carboniferous, and are those in which most of the world's metallic wealth occurs.

Inlets, Rivers, and Lakes.

Newfoundland has an immense number of inlets along the coast. As a result, no portion of the island is more than sixty miles from the sea. There are also numerous rivers. The longest is the Exploits River—200 miles long—which drains an area of 4,000 square miles and is navigable for thirty miles; the Gander, 100 miles long, and its tributaries drain a similar area. Both flow in a northerly direction. The Gambo and Terra Nova flow in an easterly direction into Bonavista Bay. On the west the principal river is the Humber, 80 miles long. This passes through a picturesque and well-wooded country. Along the south coast the rivers are smaller owing to the configuration of the country, but they are numerous and easily accessible. In addition, there are large inland bodies of water, such as the Grand Lake, covering 200 square miles; the Red Indian Lake, 67 square miles; the Deer Lake, Gander, Gambo, Terra Nova, and George IV. lakes. Further, there are dispersed all over the country lesser bodies of water locally termed "ponds."

Water Power.

As may be gathered from the above, Newfoundland is singularly well supplied with facilities for coasting and river traffic, and is a remarkably well-watered country. Water power is available in numerous localities, and the Government offers leases on favourable terms.

"Leases are granted by Government for terms of years of the right to use the waters of any river for driving machinery subject to such rent and conditions as the Crown may prescribe and to the preservation of the vested rights of all persons holding lands whose interests may be affected by the use of such water with a fine of $100 per each offence for introducing sawdust or other deleterious matter into such water." The Royal Commission sums up the situation by stating that "Newfoundland shares with Canada the advantage of great potential water power."

Trade.

As regards trade it is sometimes said that Newfoundland exports all that it produces and imports all that it consumes, but according to the report of the Royal Commission this statement, like many other generalisations, does not stand the test of statistical examination. The total external trade per head of population is £25 5*s.* as compared with £29 7*s.* for Canada, and £9 9*s.* for the United States, so that the external trade of Newfoundland per head is nearly as great as that of Canada and three times that of the United States.

It is probable that the main lines of development in Newfoundland will continue to be associated with the three principal industries that have already occupied chief attention—viz., the fisheries, the mines, and the forests.

In regard to the fisheries, these have generally contributed nearly 80 per cent. of the total exports. The cod fisheries of Newfoundland are the largest in the world. A million and a half hundredweight of dried codfish is exported in addition to large quantities of herrings and lobsters, cod oil, seal oil, seal skins, and whale oil.

The mineral wealth is regarded as very considerable. The deposits of hematite iron at Bell Island are reported by the Royal Commission to be "remarkable." It is said there is nothing at all comparable to them in any of the other Dominions "except, perhaps, those at Iron Knob and Iron Monarch in South Australia." Further, it is possible they may become of "immense potential importance to the iron and steel industries of the Mother Country as well as those of Canada."

For transport purposes, in addition to the facilities afforded by the numerous inlets, rivers, and lakes, there are railways with a total mileage of 800 miles. Associated with these is a flotilla of eight steamers. By means of the agency of the railroad and the coasting steamers, it is claimed that the trading conditions of the island are being steadily extended and improved.

Forest Areas.

The timbered areas are generally found in the valleys of the larger rivers and their tributaries, and on the banks of the lakes and ponds,

confined, in many cases, to strips from one to two miles wide. It is estimated that there are altogether about 10,000 square miles (6,500,000 acres) of wooded lands in the Colony. The best timbered areas on the rivers and water-courses draining the east coast are on the Gander River, Dog Bay Waters, Indian Arm, Exploits River and its lakes and tributaries, the Halls Bay Waters and the rivers flowing into the south side of White Bay and into Baie Verte. Those on the west coast are associated with the Grand Lake Waters, Deer Lake, Humber River, and others flowing into Bay of St. George and into Bay St. John, Bonne Bay, and Hawke's Bay. On the south coast there are many areas of timbered country at the bottom of the bays and along the lower reaches of the rivers. In some sections very considerable areas of large timber and large quantities of trees suitable for pulp wood still remain.

All the known timbered areas in Newfoundland, except those lying within the three-mile limit of the shore reserved by the Government, are held under licence by private parties or by companies. The conditions under which these licences are issued give the holder the right to cut timbers on lands described therein for a term of ninety-nine years on the payment of an annual rental at the rate of $2 per square mile.

In the case of lumber there is a royalty of 50 cents per M. feet B.M., payable on all timber cut on the area except such timber as is manufactured into pulp and paper, which is not subject to a royalty.

In the production of sawn or manufactured lumber there are a dozen large mills in operation under licence, and 120 small mills which produce cooperage stock, barrels, shingles, and laths. The annual value of the output of these is estimated at £120,000. In 1906–7 the value of the exports of sawn lumber reached a total of £65,000; but in later years the value has fallen to less than £1,200. One explanation of this is the increased quantity of lumber absorbed by local requirements. In spite of this, a considerable quantity of hard pine and other woods, not obtainable in the Colony for inside parts of buildings, furniture and carriage building, is imported. The value of these in 1912–13 amounted to £21,000.

Of the spruce lumber, which is of exceptional quality, Mr. Turner, Deputy Minister of Agriculture, reports that it is used locally for general building purposes, and for ship and boat building, or, in the case of the smaller fir and spruce, is manufactured into pulp. A very small proportion of the birch timber is utilised; the principal uses at present are for the construction of the under-water parts of the hulls of schooners and for wharf piles, as the wood is found to last better than most for these purposes; it is also used for sheaves for rollers, for carrying haulage cables at the Bell Island Iron Mines, spools for paper, and laths for binding pulp for export at Grand and Bishop's Falls, and some for car building and furniture. One mill at Bay d'Espoir uses a large proportion of its cut of birch as well as spruce and fir for the manufacture of furniture, while the factories in St. John's use a considerable quantity for this purpose. Tamarack and juniper are used for schooner construction and for flooring in buildings. In addition to the timber manufactured, as before mentioned, a very large quantity is cut annually and used for firewood, fencing, poles for erecting fish flakes, spars for boats and vessels, telegraph poles, railway ties, pit props, wharf piles, etc. As no return of the timber used for these purposes is made it is not possible to give the quantity, but, according to Mr. Turner, it is probably as great or greater than the quantity used in the mills.

Labrador.—The peninsula of Labrador, with its 600 miles of coast and 120,000 square miles of territory, is a dependency of Newfoundland. The boundary between Labrador and Canada is a line running due north and south from Blanc Sablon in the Strait of Belle Isle to latitude 52° N. Newfoundland, therefore, owns the outlets to the Atlantic of all the large areas drained by Sandwich Bay and Hamilton Inlet, and the lesser fiords that indent the coast.

Recent explorations by competent observers, and the writings of Dr. W. T. Grenfell and others, show that much of Labrador is not a country of "awful desolation," but in many parts well wooded and containing latent resources of value in forests, fisheries and minerals. The timber trees, very similar to those of Newfoundland, consist of white and black spruce, balsam fir and larch, the Jack or Banksian pine, cedar, white birch, poplar and aspen. The forest areas are reported to be almost continuous over the southern portions to 53° N. As our Chairman, when Governor of Newfoundland, explored some parts of Labrador in the summers of 1906 and 1908, he is well qualified to speak as to the resources and prospects of the country.

It is generally recognised in Newfoundland that Labrador may eventually become the

centre of a large wood-pulp industry. In the meantime it might supply pulp wood to some of the mills operating in Newfoundland.

Timber Trees.

The pine or white pine of Newfoundland (*Pinus strobus*) is known in England as the Weymouth pine, as it was introduced in 1705 by Lord Weymouth. It is a fairly common ornamental tree in parks and gardens in this country. On account of the value of its timber, for a century or more it has played a conspicuous part in the material development of the United States and Canada. It is the more generally useful of all the pines. As the supply is falling off, prices for white and yellow pine of good quality have considerably risen in recent years. In Newfoundland it is stated that "in some sections, notably on the Gambo, Gander, and Exploits Rivers, and at Dog Bay, good pine is still to be found." In other districts the trees are more scattered. The sawn lumber produced from the white pine, with some spruce, is estimated to reach an annual value of £200,000. Most of it is devoted to local purposes. It has been very little exported in recent years. *Pinus strobus* is not used for pulp purposes. The red pine (*Pinus resinosa*), which somewhat resembles the Corsican pine in this country, grows fairly plentifully in Newfoundland, and is largely used in the construction of vehicles and for household furniture. On account of the resinous character of the timber, it furnishes an excellent material for railway ties.

The black spruce (*Picea nigra*) is widely distributed in Eastern America and Canada, and forms an appreciable proportion of the timber trees of Newfoundland and Labrador. The superintendent of the Grand Falls Mills, in a memorandum prepared for the Dominions Royal Commission, speaks of the black spruce as affording "the best material for pulp-making there is." This is supported by Mr. Reuben F. Horwood, managing director of the Horwood Lumber Company and of the pulp mills at Campbellton, who says: "Newfoundland spruce makes wood pulp equal to the best, and superior to most on the market, and it bears a high reputation."

After six years' experience at the Grand Falls Mills the superintendent supplies the following further information: "Black spruce gives a long and strong fibre. The smoothness of the fibre gives the paper a good finished surface. As the tree grows comparatively slowly, the wood is very solid and heavy—about 30 lb. per cubic foot bone-dry weight—giving a large yield of pulp. This reaches about 2,200 lb. of ground wood pulp and about 1,200 lb. of bone-dry sulphite pulp each per cord of wood." The wood of the black spruce contains more resin than the wood of the balsam fir, and is slightly darker in colour.

The balsam fir (*Abies balsamea*) derives its name from the transparent balsamic resin yielded by it. This is known as Balm of Gilead and Canadian balsam. The tree is very abundant in the central and northern districts of Newfoundland. At the Grand Falls Mills it is stated that possibly more than one-half of the pulpwood used there is balsam fir. There is no record what proportion is used at the Bishop's Falls and the Campbellton Mills. The superintendent at Grand Falls furnished the Royal Commission with the following summary of the results with balsam fir: "Balsam fir gives a fibre a good deal shorter and weaker than the black spruce. The fibres are not so smooth as the fibres of the black spruce, and it is difficult to obtain a good finished surface on paper made entirely from balsam fir pulp; but these trees grow very rapidly—often twice as fast as the black spruce—which tends to make the wood soft and spongy, especially when the trees grow large. The wood is light (weighs about 24 lb. per cubic foot bone-dry weight), and consequently gives a smaller yield of pulp, viz., about 1,850 lb. of ground wood-pulp, and about 1,000 lb. of bone-dry sulphite pulp each per cord of wood." An important point in using balsam fir is that the utmost care must be taken when removing the bark to see that none is left, for most of the resinous matters in this species are concentrated in the bark. If used all by itself in the manufacture of sulphite pulp it gives a comparatively good yield, and only requires a weak acid. The pulp is whiter but not so strong. The balsam fir was for a long time considered by American and Canadian mill-managers to be of little value for pulp-making. It is only within the last ten years it has been so largely used.

The white spruce (*Picea alba*), although fairly abundant in Newfoundland, is not specifically mentioned as being utilised for pulp purposes. It is easily distinguished from other spruces by its bluish disagreeably smelling leaves. It is said that in northern Quebec only the tops of the white spruce are converted into pulp, the trunk being used for sawn lumber and for railway ties, piles and telegraph posts. The American larch, commonly known as the tamarack (*Larix*

americana), thrives in certain areas in Newfoundland. Tamarack and juniper are reported to be used for schooner construction and for flooring buildings. The tree vegetation of Newfoundland, in addition to the above, includes a large number of broad-leaved trees, some of which may also be utilised for making wood pulp. Among birches the canoe or white or paper birch (*Betula papyrifera*) grows to a good height. The wood is light, strong, tough and close-grained. The heart wood is tinged with red. The yellow birch (*B. lutea*) is another strong-growing tree, with close-grained, satiny timber largely used in the manufacture of furniture. The cherry birch (*B. lenta*), also known as the black, sweet, and mahogany birch, produces a heavy, very strong and hard wood extensively used in the manufacture of furniture. With regard to a wider utilisation of birch timber in Newfoundland, the Deputy Minister of Agriculture suggests the establishment of "factories for making such articles as flooring, bobbin stock, bobbins, spools, shoe shanks, staves, veneer, dowels, chairs and furniture stock, piano backs and other articles, into all of which this wood is manufactured in other countries." "Such factories," he says, "would not require very large powers to operate, and there are many localities in which water power might be developed, which, while not sufficient for the operation of large plants, such as those required in paper and pulp factories, would be sufficient for the running of the machines used for making these articles."

The sugar maple (*Acer saccharum*) is found in Southern Newfoundland. In addition to the sugar produced from the sap, it is of great economic importance on account of its splendid timber, which is strong, close-grained, and polishes well. Timber with curled and contorted grain is known as "Bird's-eye" maple, and is used for cabinet work.

The black ash (*Fraxinus sambucifolia*) grows to a large size in swamps and along the banks of rivers in Southern Newfoundland; the rather coarse-grained wood is durable, and is used for a variety of purposes.

The American elm (*Ulmus americana*) is also present as a large tree in Newfoundland. It yields a heavy tough timber, which is used for wheel sticks, in cooperage and boat- and ship-building. The balsam poplar, or tacmahac, and the aspen or quaking poplar yield light timber, which may be used to some extent for wood-pulp purposes, as in Canada.

According to Mr. S. Charles Phillips, in the manufacture of paper pulp, Canada, in 1914, used 1,224,376 cords of wood. Of this 68 per cent. was spruce, 25 per cent. balsam fir, 3 per cent. hemlock, and nearly 2 per cent. Jack pine (*P. Banksiana*)—the balance being poplar.

Wood Pulp.

In botanical literature we continually come across the term cellulose. This applies to one of the main constituents in the structure of all plants, namely, that which forms the casing or wall of the different cells. In fact, it forms what may be called the woody portion of the plant, and constitutes the skeleton of all vegetable fibres. One of the most familiar forms of cellulose is cotton fibre. As pointed out by Mr. C. F. Cross, the applications of cellulose to the necessities of human life are as infinitely varied as they are colossal in magnitude. The utilisation of vegetable fibres in textile industries and in paper are based on the fibrous forms of the naturally-occurring cellulose, which must possess such structural qualities as strength, elasticity and specific gravity. In addition, they must possess the power of resistance to chemical changes to enable them to withstand wear and tear. Staple textiles of this group are cotton, flax, hemp, and jute. Other fibres of a coarser character are used in rope-making and brush-making industries. During the latter part of the nineteenth century the progress made in the use of various forms of cellulose has been almost phenomenal. Taking one industry, that of paper, which formerly was almost entirely made from rags either linen or cotton, owing to the insufficient supply of rags and the consequent rise in price, other fibres began to be adopted as substitutes. Mainly through the persevering efforts of Mr. Thomas Routledge in the seventies, esparto grass from North Africa was utilised for paper-making, and the success of this is shown by an annual consumption of something like 250,000 tons. Most kinds of straw are also capable of being used for paper-making. It closely resembles esparto, and is reduced to pulp by a somewhat similar process. During the period from 1870 to 1880 a still greater advance was made, as it was demonstrated that cellulose well adapted for paper-making could be obtained from the timber of coniferous trees. These trees, as is well known, are widely distributed all over the world. The development in this direction has been so great that wood pulp now furnishes the main source of supply for paper-making. The total value in 1912 of raw materials imported into this country for paper-making

was £5,800,000; of this wood pulps represented 70 or 80 per cent.

Mr. Cross, in a recent article in *Nature*, states that wood pulps are so largely adopted for paper-making, not only on account of their quality or merits as cellulose, but being obtained from a massive material they are capable of being produced in a state of exceptional cleanliness and by economical processes. Moreover, as the paper-maker found himself provided with a "half stuff" clean, cheap, and presumably unlimited in quantities, its production displaced the chemical pulping of such raw material as esparto and straw. There is one drawback, but that is inevitable at present—viz., the dependence of the English paper-mills upon foreign supplies. To some extent this can be obviated by tapping the enormous resources of Canada and Newfoundland. Canada is credited with forest areas of 800 million acres, and, under a system of organised forestry, it should eventually be capable of largely meeting the requirements of this country. At present Canada is the second largest producer of wood pulp, the first being the United States of America. As is here shown, Newfoundland, and Labrador also, are likely to provide an appreciable supply, provided their resources are carefully guarded and fully utilised.

Paper and Pulp Mills.

The most important and far-reaching event that has occurred in Newfoundland in recent years has been the establishment of a pulp and paper industry by the Anglo-Newfoundland Development Company, followed soon afterwards by the Albert Reed Company, of London. The Anglo-Newfoundland Development Company, which is known locally as the "A.N.D. Company," determined in 1905 to locate its mills in Newfoundland, after spending three years in seeking an adequate supply of pulp-wood and a suitable site elsewhere. Exhaustive tests of woods in Canada, Sweden, Norway, and other countries where forest growths suitable for the manufacture of pulp and paper are found, were made. The conclusion was reached that Newfoundland was most worthy of consideration, and a self-contained forest area of 3,400 square miles in the centre of the island was secured. This is nearly twice as large as the whole of Prince Edward Island. From the Grand Falls on the Exploits River the company secured the necessary power, with communication from the mills to tide-water at Botwood.

The company gave the following as the reasons that weighed with them in making their decision: That timber is cheap and of excellent fibre; that labour is plentiful, and, compared with the United States and Canada, moderate in price; that the cost of logging is low because of the dense growth of the wood and the general topography of the country, water being abundant and the whole terrain such that the logs can be got to the rivers for driving with a minimum of cost and labour.

The logging operations carried on by the A.N.D. Company are necessarily on a large scale. The felling takes place in winter, when the fishermen find congenial and useful employment on land. The size of the trees used for pulp-wood must not be less than four inches across at the small end. The total yield from each winter cut is about 60 millions superficial feet of timber, equivalent to 120,000 cords of pulp-wood. A cord is a cubical measure (4 ft. × 4 ft. × 8 ft.) containing 128 cubic feet; according to the time it is cut the weight may vary from two to two and a half tons. Usually a ton weight of dry pulp is obtained from each cord. As already stated in the case of the black spruce, a cord of wood gives about 2,200 lb. of dry ground wood pulp, or 1,200 lb. of bone-dry sulphite pulp.

Grand Falls Mills.—These fine mills, owned by the Anglo-Newfoundland Development Company, were completed in the autumn of 1909, when the first paper was made in the Christmas week of that year. During the next two and a half years the mills were run with three paper-making machines, eighteen wood-pulp grinders, and two sulphite-pulp cooking digesters. The output was a daily average of 120 tons of paper. In 1912 additions to the plant were made of two other paper-making machines, six additional grinders, and one extra digester, which provided for a total daily production of news paper averaging 190 to 200 tons per day, and a surplus production of ground wood pulp for export averaging thirty tons per day. The mills at the time of their completion were the largest in the world, and represented the most perfect assemblage of paper-making plant and equipment that engineering skill and experience, backed by ample capital, could provide. They now supply the requirements of four British newspapers. The capital involved is £1,668,653, which includes £490,000 debentures.

The raw material, that is the pulp-wood, is obtained from forest areas held by the company aggregating 3,400 square miles. These areas are on the banks of the Exploits River and its tributaries, reaching in a south-westerly direction as far as King George IV. Lake. They extend to

the north-east to the coast in the Red Indian Lake country. In the logging operations a force of 1,500 men is employed. These are located in eighty camps. In spite of the enormous yearly consumption of pulp-wood the company is satisfied that it possesses "more than an ample supply" for the needs of the present mills.

The whole of the power operating these mills is derived from the Grand Falls. The total height of these from the top of the dam, at the head of the rapids, to the bottom of the power-house is about 120 ft. There is a direct head of water of 113 ft. The power generated is 7,500 h.p. This is sufficient to run all the machinery in the mills, outside of the grinders, which take 16,000 h.p. direct from the water-wheels.

Two Grades of Pulp.

The pulp produced is of two qualities—mechanical pulp and sulphite pulp. The former is produced by forcing the wood logs, after they are cut into short lengths and barked, by hydraulic pressure against the face of a rapidly revolving grindstone, continually flooded with water. The fibres of the wood are torn away by the friction of the stone, and the constant stream of water carries the pulp into a pit below. When fully sieved and screened the pulp is distributed either to the paper-machines for making into news paper, or to the hydraulic presses which squeeze out the water, leaving sheets of pulp with 40 per cent. moisture, in which state it is packed in bales for export.

In the case of sulphite pulp, the prepared logs are chipped by a powerful machine into small pieces or flakes about an inch square and one quarter of an inch thick. These chips are next thoroughly "digested" with a chemical solution (bisulphite of lime) at a high temperature.* By this means the chips are gradually reduced to a soft pulpy mass. The latter is thoroughly washed with clean water and finally sent to the paper-mill. The combination of the two stocks—mechanical and chemical pulp—are put together by the paper-mill and result in the finished product of news paper. The five paper-machines make sheets of various widths from 112 in. to 152 in.

The completed paper having been rolled on reels which are running at the rate of 575 ft. per minute, and properly wrapped and protected for shipment, is conveyed by the company's own railroad to its shipping port at Botwood, and there shipped on chartered steamers to England. The average amount paid in wages and salaries by the company in Newfoundland varies from £175,000 to £180,000 per annum. It speaks well for the adaptability of the Newfoundland people, for the most part fisher-folk, that at the Grand Falls Mills only 1 per cent. of the work-people are from outside the Colony.

In the neighbourhood of the Grand Falls Mills, following the example of the best traditions of British commercial enterprise, the A.N.D. Company has established a town of 2,500 inhabitants. This contains well-built houses and bungalows, a hospital, a good club, bath-rooms, a large school, a town hall which is the centre of all public amusements, and spacious athletic grounds. Outside capital has established itself in stores which supply all requirements. At a distance of three miles a farm supplies the town with milk and vegetables. The head-quarters of the logging operations are at Miller Town, a settlement of about one hundred houses with a church, school, hospital and stores complete.

Bishop Falls Mills.—These are owned by A. E. Reed & Co. (Newfoundland, Ltd.), who are associated with Albert E. Reed & Co., of London. The latter operate eight paper-mills in the south of England. The mills were completed and commenced operations in April, 1911. The area of timber licences held by the company is 820 square miles, situated mostly in the Exploits watershed east of Grand Falls. The water-power derived from the Bishop's Falls has a capacity of 14,000 h.p. The mills equipped for the manufacture of mechanical paper pulp have eighteen grinders capable of yielding 140 dry short tons per twenty-four hours. Most of the production is shipped to England. The number of mill hands is 200, with 450 employed in the woods in winter. The resources of the company in Newfoundland are stated to be ample for all its requirements.

At Campbellton (Indian Arm), in Notre Dame Bay, the Horwood Lumber Company has a pulp-mill, and others are in contemplation.

It was pointed out by Mr. S. Charles Phillips, in his recent paper before this Society, that in 1913, a normal pre-war period, Newfoundland supplied this country with news paper (on reels) to the extent of 17·4 per cent. of the total imports. On the other hand, in 1915, a full year of war, paper on reels showed a total decrease of nearly 30,000 tons—the total imported being 106,720 tons. Of this quantity Newfoundland contributed 44·7 per cent. Thus,

* The lime for the manufacture of sulphite pulp is obtained locally, and is said to be quite pure and suitable for the purpose.

for the first time in the history of the paper trade, Newfoundland took a premier position as an exporter to this country of paper on reels—the total amount being 47,789 tons, or 15,410 tons in excess of those of Norway.

The following figures show the export of paper and of pulp since the industry first began:—

Year.	Paper.		Pulp.	
	Tons.	Value.	Tons.	Value.
		£		£
1910. .	7,900	73,000	6,900	14,000
1911. .	21,100	197,000	27,200	52,000
1912. .	26,800	250,000	42,100	75,000
1913. .	44,400	415,000	57,500	91,000
1914. .	40,077	374,000	51,605	77,645

Pit Timber.

In addition to the production of paper and pulp and certain descriptions of lumber, Newfoundland affords an excellent field of operations for pit timber.

The total annual consumption of pit wood, or pit props, for the coal mines of the United Kingdom is estimated at 4½ million tons, of the value of £5,000,000. The chief supply in the year 1913 was obtained from Russia, France, Sweden, Portugal and Norway. On the outbreak of the European war it became evident that the supplies of pit wood would be largely curtailed, and the Board of Trade took steps to ascertain how far other existing sources of supply would meet requirements. Among the new sources from which pit wood could be obtained was Newfoundland, and a Commission of Inquiry was dispatched there and a report was presented in December, 1914 (Cd. 7728). It was stated that very large areas of suitable timber exist in the island, a considerable proportion being close to the seashore or to many bays and rivers, and therefore easily transported to the various points where it could be loaded on to steamers. The suitable timber consists of fir and spruce, the former being a more quickly-grown timber than the latter. Within three miles of the shore over the whole island the timber rights are reserved by the Government. Ordinarily anyone may cut timber on this three-mile limit for firewood, house-building, boat-making and other purposes, but not for export, except in the form of pulp. By a special Act since the outbreak of the war the Government have sanctioned the export of pit wood, and this concession is still in force, and probably may be continued until the end of the war. The conclusion arrived at by the Commission of Inquiry was that Newfoundland could apparently be equal to an annual output of 300,000 cords of pit wood, and that it could meet nearly half the shortage from the Baltic occasioned by the war. After some trial shipments had been made, and the pit wood was found to meet fully the requirements of the collieries, a considerable trade has been established between Newfoundland and the United Kingdom. Last year thirty-three cargoes were shipped, and others are likely to follow during the coming summer. If pit wood is supplied at an average price of about $5 per cord and, say, one-half of the annual quantity mentioned above is shipped, this would mean that an additional £100,000 would be circulated in wages amongst the working people of Newfoundland.

Re-afforestation.

This is a subject that intimately concerns the success of the wood-pulp industry in Newfoundland. It has already received some attention. Mr. Reuben F. Horwood stated that the rapid growth of the trees is an item of great value in the reproduction of the Newfoundland forests. Along some of the watercourses and on the low-lands near the river outlets the forests would produce a new growth in fifteen years. On an average over the island he thought that the new growth might take thirty to fifty years. Where the larger trees were cut out the smaller trees that were left grew more rapidly, and under such conditions a rotation of twenty to thirty years might be possible. Mr. Vincent Jones was of opinion that, "with judicious and scientific safeguards," the forests might be rendered capable of indefinite reproduction. The uniformly moist climate of Newfoundland is very favourable to the rapid growth of trees.

The Royal Commission recommended that, in order that the forests of Newfoundland should be a permanent asset, it was necessary to lay down scientific regulations as to the conditions on which cutting should be permitted. It added, "whilst the larger operators may no doubt lay down certain rules to suit their own convenience, experience elsewhere shows that Government control on such a question was essential. We venture to suggest that the Newfoundland Government should devote its early attention to this question."

Forest Fires.

As in Canada and elsewhere, it was becoming a matter of serious concern to guard against forest fires. The evidence given before the Royal Commission in Newfoundland indicated the gravity of the situation. Mr. Horwood stated, "during the past twenty years the average loss to the country from forest fires would be from £1,000,000 to £2,000,000 annually." In his opinion, "before any reforms in cutting or re-afforestation methods are considered, this criminal waste of public wealth should be dealt with, for it constitutes the most serious problem in conservation that Newfoundland had to consider." The forest fires in Newfoundland are said to be caused in large proportion by railway trains; also by sportsmen, and to some extent by careless woodmen. The Deputy Minister of Agriculture reported that, "unfortunately in the past large sections of the best timbered country have been burnt over by forest fires, but of late years the organisation of a forest fire patrol by the Government, with the assistance of the operating lumber companies, has considerably lessened the danger of loss from this cause."

Mr. Vincent S. Jones stated that the Anglo-Newfoundland Development Company had organised its own system of fire wardens for the protection of their property from fires caused by the railway. During the past four years the system "had been successful, and between five and six hundred fires have been put out annually, which might have developed with bad results."

The Royal Commission drew special attention to the danger from forest fires as follows: "It was stated in evidence before us, that during the last twenty years the average loss caused by fire has been very heavy, and much of the damage is said to have originated from the sparks from railway engines. Complaint was made that, though the law requires precautions to be taken, and the most approved spark-arrestors to be used, it is not properly enforced. The fitting of a suitable spark-arrestor is easy and inexpensive, so that there is little excuse for negligence in this matter."

"Recently the Government has made an appropriation of £1,042 annually for the appointment of a chief ranger and fire wardens, and a further appropriation of £833 for the establishment of a fire patrol. This latter sum is supplemented by small payments by licensees (which, however, are entirely optional), amounting in 1913 to less than £1,000. It appears to us that these sums are unduly small considering the magnitude of the interests involved."

Steamship Communication and Cables.

The Royal Commission reported that the coastal services and direct services with Canada and the United States leave little to be desired. There is a daily service across the Cabot Strait with Nova Scotia, and a regular weekly service with Halifax and New York. The means of direct communication with the Mother Country is not so satisfactory. Although there is a subsidised steamer service costing the Colonial and Imperial Governments £4,000 per annum, the Royal Commission reports that the most modern and fastest boat running between the United Kingdom and Newfoundland is the property of an unsubsidised company. It adds: "We entirely agree with the views expressed by the Prime Minister of Newfoundland at the Imperial Conference in 1911 as to the need for a faster and better service, and we cannot recommend the continuance of the present state of affairs."

Newfoundland is exceptionally favoured as regard cable services, and therefore in a position to assist in promoting Imperial trade. Nine Atlantic cables are landed near St. John's, and are laid thence to New York and Canada. One cable, which is entirely under the control of the Newfoundland Government, connects St. John's and Nova Scotia and other parts of Canada.

In addition to the cable services, a through wireless service from the United Kingdom to Newfoundland is now in operation.

Appendix.

The following information, communicated as the result of comparatively recent observation in Newfoundland, by Mr. Richard W. Wilson, M.I.Mech.E., will be read with interest:—

"I travelled inland from the coast on the east, west, and south side of the island, and although the higher elevations as well as the coast line were barren, the inland valleys were well wooded.

"At the sides of the rivers and lakes I saw large tracts of spruce and fir, and also some pine and birch. Most of this timber was straight and sound, and admirably adapted for the manufacture of pulp; but there was a fair proportion of trees also large enough for the manufacture of good lumber. The tallest trees reached a height of quite 70 ft., many of them being over 20 in. in diameter, and they were so situated as to be easily transported to the tidal waters. Excellent sites for the erection of mills and for

the loading of ocean-going ships existed, too, in very many places. Waterfalls for providing power were plentiful also.

"I was told by the inhabitants that re-afforestation of these timber lands where the wood has been cut down takes about forty years; but, even if one adds ten years to that, a very large perpetual supply of wood is obtainable both for lumber and pulp, sufficient to keep at least half-a-dozen pulp-mills going, and lumber-mills besides, working full time.

"Labour is plentiful, for when this is most required in the logging camps the fishing is over; and the Newfoundlander is as handy with his axe as he is with his oar and his tiller. Newfoundland is certain to become a valuable source of pulp and lumber to this country, for there the trees are, and none of the forests are at a great distance from the sea.

"Moreover, Newfoundland is not so much bound up with ice as most other countries are which produce this class of timber. Heavy ice packs, certainly, are driven in on the east and west coasts in the late spring; but the south coast is entirely free from drift ice. The temperature of Newfoundland never reaches the low degrees it does in Canada, and the thaw sets in earlier. Jutting out into the Atlantic to a much greater distance than most people realise, Newfoundland is much nearer the Mother Country for shipment of its produce than most of the countries from which are derived the increasing tonnage of lumber and pulp."

DISCUSSION.

Lord Northcliffe said the fact that he was coming to the meeting became known to someone, who remarked that he (the speaker) might be more usefully employed in doing something for the war. As a matter of fact, the development of the forest lands of Newfoundland was doing something for the war. Quite lately one of England's neutral friends had placed an embargo on the export of material which we are obtaining in great abundance from our oldest colony. It was due to Mr. Mayson Beeton and others, who were the real pioneers of the wood pulp industry in Newfoundland, that the newspapers with which he was associated were not entirely dependent for their supplies upon neutral countries. The prime reason for fixing upon Newfoundland was the certainty they felt with regard to the coming of the war. The forests of Newfoundland were so tightly packed that much of the work of cutting down the trees consisted in merely clearing the forest and letting in light, and as a matter of fact the forests throve much better after the clearing process had been adopted than they did in their primeval state. The interior of Newfoundland was extremely little known. Although on the map it appeared to be divided into locations all over the island, very few people indeed had ever crossed the island in more than one direction; but those who had crossed it had been able to bring back news of very valuable plantations of timber that could be made into paper. Newfoundland possessed many advantages for the manufacture of paper, and many other sources of wealth, and he had no doubt that if the island had been in the hands of the Germans it would have been long ago exploited. It was a colony more valuable than any single German colony, but, perhaps owing to the fact that Great Britain possessed such vast dominions, the island had not been exploited any more than Australia had been exploited. Sir Daniel Morris had indicated the kinds of wealth that had been produced by the very haphazard methods by which the British Empire had been developed. One of the advantages of the great war—and even the war had some advantages, although they were hard to see at the moment—was the fact that it caused this country to concentrate attention on the things within its grasp. Two years ago it would have seemed impossible to bring pit-props from Newfoundland for the coal mines in Great Britain; but that had been done, and he had seen trenches in Flanders also supported by pit-props from Newfoundland. So that the little colony, neglected for hundreds of years, had come into prominence by the declaration of war in August, 1914. The islanders were tremendously patriotic. They were almost entirely of English, Scotch, and Irish ancestry, the great proportion of them being descendants of Devonshire men. They had sent to Gallipoli and Flanders a very considerable portion of their 243,000 population. Only that day he had had the pleasure of reading a message sent to the Governor of Newfoundland from Headquarters, thanking the island for the fine men it had sent to the war. When it was remembered how very remote the island was from the war and the rest of the world, it would be realised that that was a great achievement. The reading of the island was naturally very largely composed of American publications, New York being within two and a half days by post. He considered the patriotism of the islanders who had thrown up their vocations and come to the help of the Mother Country one of the most touching things in the whole history of the war. Their bravery in Gallipoli, which possessed a climate entirely unsuited to them, was splendid. No one but the War Office could have conceived the idea of sending men from a land of ice to one of the hottest parts of the world, but the conduct of the men was such as to call forth the commendation of General Cayley on the spot. Not satisfied with the contingent it had already sent, Newfoundland was busily engaged in raising another contingent. When the words of Sir Daniel Morris and Sir William MacGregor, one of the best Governors Newfoundland ever had, were read by the people of that colony, they would see how

grateful this country is to them for their help in material and in men.

Mr. A. Ralph Reed said it was a pleasant thing to find in the centre of London so much interest shown in the forests of Newfoundland, because in the ordinary way Newfoundland was apt to be rather overlooked, lying as it did under the shadow of its greater neighbour, Canada. There was no doubt that the Newfoundlander was extraordinarily deficient in his appreciation of timber; he would think nothing of cutting down a large tree for the sake of a small part, when he could get what he required by going a little further on. It had been said that a Newfoundlander who was fly-fishing, and whose fly caught in the branches of a tree, would cut the tree down to get his fly! As time went on, that defect in his character would, no doubt, be remedied. It was very difficult to get the Newfoundlander to settle down to any kind of industrial labour. He had been told by the superintendent of a large mill that, with the exception of a few of the foremen and leading hands, practically every man in the mill had left and returned at least three times; but as almost the whole countryside knew how to work in a pulp-mill, there was no difficulty in obtaining fresh hands. The Newfoundlander was also the most self-confident person in the British Empire, and never appeared to be taken by surprise. When the magnificent new paper machines were started at Grand Falls, the Newfoundlander made a special point of regarding them as if he had a similar machine in his own parlour.

Mr. S. Charles Phillips said he had travelled a good deal in Newfoundland, and had taken great interest in all matters that appertained to the manufacture of wood pulp and its further manufacture into paper. The paper question was one of extreme seriousness to Great Britain, which was so much dependent upon foreign countries, more particularly Scandinavia, for the raw and manufactured product. It was to be hoped, for the sake of the country, that the mill at Grand Falls would be the forerunner of many other mills, not only in Newfoundland but in Canada, to which this country could look to provide wood pulp and, if necessary, paper. Sweden had placed an embargo on chemical wood pulp, which must of necessity be incorporated in all grades of paper, in order to give it strength and backing, and it was owing to Sweden's action that Great Britain was confronted with what might be a paper famine. A great deal of the wood pulp was now being sent by Sweden to Germany, where it was turned into a base for high explosives. He was pleased to know that there were schemes in course of development which it was hoped in time would greatly assist this country in being independent of the whims of other countries, friendly or otherwise, and Sweden would only have herself to thank for the diversion of trade from her shores to Canada and to Newfoundland.

Mr. R. D. Wilson, M.I.Mech.E., in proposing a vote of thanks to the author for his interesting paper, said it would be useful not only to Newfoundland but to many who had sought information about the forests of the island and had been bewildered by the conflicting statements given by the Newfoundlander concerning his forests. He hoped that when the people of Newfoundland awoke to the importance of the forests they would be wise enough, in taking up the question of re-afforestation, not to start by re-planting saplings, as was done in many countries, notably Germany. The forests of Newfoundland were chiefly spruce. As the pulp question was so important, it was also important that the spruce should be re-afforested; and as people believed that when the trees in a forest were cut down other trees very often grew in their place, he wanted to mention that it was more a matter of climate than soil by which Newfoundland re-afforested itself in spruce. Spruce required a large amount of water, and the tree had no doubt selected Newfoundland because of the immense supply of water in the subsoil there. Temperature did not interfere with the growth of the trees, because the highlands of Siberia were the coldest portions of the earth, and yet the trees grew there. Re-afforestation took place naturally in Newfoundland by the birch first of all occupying the soil, and being elbowed out a few years later by fir and spruce; then came a struggle between the fir and the spruce, and eventually the spruce predominated, especially on the south coast in the neighbourhood of the Gulf Stream. When the Government decided on re-afforestation he hoped they would call to their aid such men as Sir Daniel Morris, who would warn them not to begin by planting saplings, but to trust to the forces of Nature. The French had followed that method in their oak forests.

Mr. Byron Brenan, C.M.G., seconded the motion, which was carried.

Sir Daniel Morris, in responding to the vote of thanks, desired to express his great indebtedness to the Director of the Royal Gardens at Kew for a set of fresh specimens of the principal Newfoundland trees used for paper and pulp purposes, and pit wood; to the Director of the Imperial Institute for the loan of logs of spruce and balsam fir, and for three samples of pit wood; to the Anglo-Newfoundland Development Company for a sample reel of news paper; and to the A. E. Reed Company for a sample of mechanical wood pulp which forms the chief constituent of ordinary news paper, and for a large picture of their pulp mills in Newfoundland; also to Miss Willmott for a branch of the balsam fir from her garden at Great Warley, Essex.

Sir W. MacGregor has since forwarded the following note upon Labrador timber:—I found that on the Hamilton River the trees were chiefly black spruce, but with a mixture of white spruce and "var," with some "balsam," fir, poplar, and aspen. The trees were generally

40 to 50 ft. high, but many white spruce went up to 70 or 80 ft. It seems that experts have stated that the black spruce of Newfoundland gives the best paper-pulp in the world. In Newfoundland forest fires have done immense damage to the forests. Fires were more rare in Labrador, and the result was that very little forest was occupied by the rather useless birch. In the north of Labrador, beginning at Hudson's Straits, there is no timber. I made as complete a collection of the botany about Cape Chidley as was possible during the week I spent there, and, so far as I remember, the tallest tree I found was a willow about two inches high. Not very long ago I saw in a certain national gallery a picture of Cape Chidley which not unnaturally interested me very much, more especially as it represented some picturesque rather storm-beaten spruce trees growing in the crevices of the rocks, with large numbers of very ordinary-looking penguins standing at attention on the cliffs. The artist had probably read something sometime about the garefowl of Newfoundland seas, a bird to which apparently the name "penguin" was first applied. About the entrance of Hudson's Straits very little drift timber is procured, but near to some of the Moravian stations further south there are patches of forest whence a certain amount of firewood can be procured. In my time in Newfoundland there were some negotiations on foot for concessions of those patches of forest to Europeans. It would be absolutely wrong for any governor or government to sign away any such concessions in the Esquimaux country, as this would not only deprive them of the bit of firewood that it is possible for them to secure, but would also most injuriously affect the few fur animals that remain. It has to be remembered that trees grow very slowly in northern Labrador. Firewood could, when I was there in 1908, be obtained in the Bay of Nepartok, some twenty miles from Hebron, say 150 miles from Killineek, on the west side of the Chidley peninsula. But the Esquimaux complained bitterly that when they prepared firewood there and stacked it for drying, it was stolen in a wholesale manner by the white fishermen. Dr. Grenfell was also a sufferer from the same cause. On the hills near Chateau Bay I saw numbers of very extraordinary larches, several of them not more than a foot or two in height, spread out like a great gridiron with a diameter of three or four yards. From the acting manager and the foreman of the Grand River Pulp and Lumber Company on Mud Lake, near the mouth of the Hamilton River, it was learned that the timber sawn there was almost entirely black and white spruce, and "var." The last is the fastest grower, and yields the worst timber; the white spruce is the largest tree, and gives the best timber. The oldest tree they had seen had 171 rings of growth, and a diameter of 3 ft. It had been noticed that a tree of 6 in. in diameter at the base would have about 40 rings. I carefully examined two logs of white spruce that had been procured for the mounting of a saw-mill on the Kennimon River, and found that one with a base circumference of 6 ft. 5½ in. had 212 or 214 rings, as counted by two different men; the other had a base circumference of 7 ft. 1 in., and 235 or 240 rings, as counted by the same two men. A very fine Coddington lens was used in this count, and the line on which the counts were made was shaved clean by a sharp knife. Naturally the rings near the circumference were exceedingly thin. The trees were perfectly sound at the heart. These were the oldest spruce trees I had known. I came to the conclusion that under favourable circumstances spruce trees grow in height in Newfoundland about a foot a year. The smallest logs being sawn at Mud Lake, at the time of my visit, had a diameter of about 15 in., and counted about 60 rings. It may be worth while to advert in a few words to a kind of forest that may become of considerable importance within the jurisdiction of that colony. I refer to the submarine forest. In no other place have I seen such fine seaweed, laminaria, as on the Labrador coast. It is hardly necessary to say that agriculture, already in a condition of active evolution, will be still more so when this awful war is over. The cultivation of the fields must steadily become more and more intensive. That means better preparation of the soil, and a greater use of artificial manures. Everyone concerned in agriculture knows that this means the liberal use of nitrates, of phosphates, of potash, and of lime. It is in regard to the supply of potash that I wish to speak. It may be mentioned in passing that Newfoundland, in the Hamilton River alone, could have water power sufficient to manufacture an unlimited quantity of nitrolin from the nitrogen of the air, as is now being done in Norway on a large scale. Potash is simply indispensable in vegetable growth; indeed, no cell can grow without it. It is absolutely necessary in the production of carbohydrates. It is required in large quantities in growing cabbages, turnips, potatoes, barley, etc. You may know that Germany has immense deposits of potash in the vast deposits of salts at Strassfurt in Saxony, and in other places, and that in this supply she has practically a monopoly of the supply in the so-called kainite, which contains the chloride and the sulphate of potash. The potash question has been a matter of bargaining between Germany and the United States, and the latter have offered large rewards for the discovery of potash deposits at home, so as to be independent of Germany. The natural supply of potash to the soil is chiefly from the decomposition of granite, which may contain as much as 5 per cent. of potash, but as an acre of potatoes, for example, will require, say, from 1 to 2 cwt. of potash, the soil soon becomes exhausted. In spite, however, of the tremendous supply required by America, it was reported in our *Board of Trade Journal* of January 14th, 1915, that the United States can obtain more potash than they require from the seaweed

of 400 square miles of their Pacific coast. This means the establishment there of the old industry of the western islands of Scotland, the preparation of "kelp." It takes about twenty tons of the laminaria to give one ton of kelp ash. And the ashes will contain about 10 per cent. of the sulphate of potash, and some 13 per cent. of the chloride, the same salts as exist in the German deposits. The laminarias contain other ingredients that are of some value. Now, as the seaweed only requires to be collected and dried, and as it will burn without other fuel, the preparation of kelp ash, or of potash salts, could be made an important industry for the Esquimaux and the other settlers on the Labrador coast; and at the same time supply the United Kingdom with all the potash required here. The leader of the National-Liberals in the German Reichstag lately stated in parliament that to meet the interest on the cost of this war Germany will require additional taxation to the extent of £200,000,000 a year. The chances are that under such circumstances a heavy export duty will be put on kainite if Germany continues to have a monopoly of the supply. It would be well worth the trouble to examine the Labrador coast to see whether, with the labour to be had there, and the fine laminarias obtainable, the kelp industry could not be worked so as to meet our wants in potash for agricultural purposes, and render us, too, independent of the German supply.

MEETINGS OF THE SOCIETY.

Ordinary Meeting.

Wednesday afternoon, at 4.30 p.m.:—

May 3.—Sir Henry Hardinge Cunynghame, K.C.B., Member of the Royal Commission on Food Supplies, 1905, "Supply of Food in Time of War."

Colonial Section.

Tuesday afternoon, at 4.30 p.m.:—

May 2. — The Right Hon. Sir William MacGregor, G.C.M.G, C.B., LL.D., D.Sc., "Some Native Potentates and Colleagues." The Right Hon. Viscount Bryce, O.M., D.C.L., LL.D., F.R.S., will preside.

Cantor Lectures.

Monday afternoons, at 4.30 p.m.:—

J. Erskine-Murray, D.Sc., F.R.S.E., M.I.E.E., "Vibrations, Waves, and Resonance." Four Lectures (May 1, 8, 15, 22).

Syllabus.

Lecture I.—May 1.—*Periodic Motions.* Definitions and modes of production—Stable and unstable equilibrium — Inertia, gravity, and elasticity — Pendulums and spring oscillators of various kinds —Torsional vibrations, balance wheel—Corrugation of rails—Musical instruments—Complex vibrations and the quality of a tone—Vibrations on large scale, seismic tremors, vibrations of ships and buildings, lightning.

MEETINGS FOR THE ENSUING WEEK.

Monday, May 1...Royal Society of Arts, John-street, Adelphi, W.C., 4.30 p.m. (Cantor Lecture.) Dr. J. Erskine-Murray, "Vibrations, Waves, and Resonance." (Lecture I.)

Victoria Institute, Central Hall, Westminster, S.W., 4.30 p.m. Rev. H. J. White, "The Connection between the Vulgate Version of the Bible, and the Theology of the Western Church."

Royal Institution, Albemarle-street, W., 5 p.m. General Monthly Meeting.

Chemical Industry, Society of (London Section), at the Chemical Society, Burlington House, W., 8 p.m. 1. Mr. J. S. G. Thomas, "The Evaporation of Naphthalene in Dry and in Moist Coal Gas." 2. Professor F. Clowes, "An Historical Summary of our Knowledge of Sulphur in Coal Gas."

Farmers' Club, at the Surveyors' Institution, 12, Great George-street, S.W., 4 p.m. Mr. A. Amos, "Clover Sickness."

Engineers, Society of, Caxton Hall, Westminster, S.W., 5 p.m. Conference on "Engineering and Scientific Research," to be opened by Dr. J. A. Fleming.

Tuesday, May 2...Royal Society of Arts, John-street, Adelphi, W.C., 4.30 p.m. (Colonial Section.) Sir W. MacGregor, "Some Native Potentates and Colleagues."

Royal Institution, Albemarle-street, W., 3 p.m. Mr. L. Binyon, "Indian and Persian Painting."

Alpine Club, 23 Savile-row, W., 8.30 p.m. Captain L. S. Amery, "Mountain Walks in the Balkans."

Wednesday, May 3...Royal Society of Arts, John-street, Adelphi, W.C., 4.30 p.m. Sir H. H. Cunynghame, "Supply of Food in Time of War."

Civil Engineers of Ireland, Institution of, 35, Dawson-street, Dublin, 8 p.m.

Sanitary Institute, 90, Buckingham Palace-road, S.W., 5.30 p.m. Dr. A. Waller, "The Economics of Food Supply in War Time."

Public Analysts, Society of, at the Chemical Society, Burlington House, W., 8 p.m. 1. Messrs. W. H. Willcox and J. Webster, "Salvarsan and Neo-Salvarsan, Excretion and Secretion of." 2. Mr. H. G. Greenish, "Microscopical Methods."

Royal Archæological Institute, at the Society of Antiquaries, Burlington House, W., 4.30 p.m.

Thursday, May 4...Linnean Society, Burlington House, W., 5 p.m. 1. Mr. E. A. Bunyard, "The Origin of the Garden Red Currant." 2. Dr. J. C. Willis, "The Dispersal of Organisms, as illustrated by the Floras of Ceylon and New Zealand." 3. Mr. R. J. Tillyard, "A Study of the Rectal Breathing Apparatus in the Larvæ of the Anisopterid Dragonflies." 4. Mr. W. E. Collinge, "Description of a new species of *Idotea* (Isopoda) from the Sea of Marmora."

Chemical Society, Burlington House, W., 8.30 p.m.

Royal Institution, Albemarle-street, W., 3 p.m. Sir E. Ray Lankester, "Flints and Flint Implements." (Lecture I.)

Iron and Steel Institute, at the Institution of Civil Engineers, Great George-street, S.W., 10.30 a.m. (Annual Meeting.)

Friday, May 5...Royal Institution, Albemarle-street, W., 5.30 p.m. Sir J. M. Davidson, "Electrical Methods in Surgical Advance."

Iron and Steel Institute, at the Institution of Civil Engineers, Great George-street, S.W., 10 a.m. (Annual Meeting continued.)

Geologists' Association, University College, W.C., 7.30 p.m.

Textile Institute, Manchester, 2.30 p.m. (Annual Meeting.)

Saturday, May 6...Royal Institution, Albemarle-street, W., 3 p.m. Professor W. H. Bragg, "X-rays and Crystals." (Lecture I.)

London: Printed by William Clowes & Sons, Ltd., Duke Street, Stamford Street, S.E., and published for the Royal Society of Arts by G. Bell & Sons, Ltd., York House, Portugal Street, W.C., in the Parish of St. Clement

Journal of the Royal Society of Arts.

No. 3,311. VOL. LXIV.

FRIDAY, MAY 5, 1916.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICES.

NEXT WEEK.

MONDAY, MAY 8th, 4.30 p.m. (Cantor Lecture.) J. ERSKINE-MURRAY, D.Sc., F.R.S.E., M.I.E.E., "Vibrations, Waves, and Resonance." (Lecture II.)

WEDNESDAY, MAY 10th, 4.30 p.m. (Ordinary Meeting.) SIR FRANCIS TAYLOR PIGGOTT, M.A., LL.M., Chief Justice of Hong Kong, 1905-1912, "Neutral Merchants and the Rights of War." DUGALD CLERK, D.Sc., F.R.S., Chairman of the Council of the Society, will preside.

Further particulars of the Society's meetings will be found at the end of this number.

COLONIAL SECTION.

Tuesday afternoon, May 2nd, 4.30 p.m.; THE RIGHT HON. VISCOUNT BRYCE, O.M., D.C.L., LL.D., F.R.S., in the chair. A paper on "Some Native Potentates and Colleagues" was read by THE RIGHT HON. SIR WILLIAM MACGREGOR, G.C.M.G., C.B., LL.D., D.Sc.

The paper and discussion will be published in subsequent numbers of the *Journal.*

LIST OF FELLOWS.

The new edition of the List of Fellows of the Society is now ready, and can be obtained by Fellows on application to the Secretary.

PROCEEDINGS OF THE SOCIETY.

EIGHTEENTH ORDINARY MEETING.

Wednesday, May 3rd, 1916; CAPTAIN CHARLES BATHURST, M.P., Chairman of the Central Chamber of Agriculture, in the chair.

The following candidates were proposed for election as Fellows of the Society:—

Alcoff, William, c/o J. K. Robinson, Iquique, Chile, South America.

Apcar, John Gregory, 44, Chowringhee-road, Calcutta, India.

Barnes, Professor James Hector, B.Sc., F.I.C., Punjab Agricultural College, Lyallpur, India.

Black, Professor A. Bruce, State Normal School, Bloomsburg, Pennsylvania, U.S.A.

Goculdas, Narottam Morarjee, Shanti Bhavan, Pedder-road, Bombay, India.

Horne, William Edgar, M.P., 5, Tilney-street, Park-lane, W.

Isachsen, Halfdan B., Stavanger, Norway.

Janji, Suryabhan, Camp Keliweli, Akola District, Berar, India.

Mukhopadhyaya, Kumar Sree Panchanan, Uttarpara Raj, Uttapara, Bengal, India.

Newlands, Alexander, M.Inst.C.E., Highland Railway, Inverness, Scotland.

Northcliffe, Lord, 22, St. James's-place, S.W.

Oakden, William Edward, F.C.S., M.S.C.I., 11, Lonsdale-road, Barnes, S.W.

Saklatvala, Nowrojee B., Messrs. Tata, Sons & Co., Navsari Buildings, Fort, Bombay, India.

The following candidates were balloted for and duly elected Fellows of the Society:—

Adenwala, Moteeram Heerabhoy, Heera Bag, Shahibag Post, Ahmedabad, India.

Kale, Professor Vaman Govind, M.A., Fergusson College, Poona, India.

Khan, M. A. Lateef, Furhut Munzil, Saifabad, Hyderabad, Deccan, India.

The paper read was—

SUPPLY OF FOOD IN TIME OF WAR.

By SIR HENRY HARDINGE CUNYNGHAME, K.C.B.

The present war with Germany has brought forcibly before the country the question of securing adequate supplies of food in time of war, and for that purpose I desire to call

attention to the findings of the Royal Commission appointed to consider that subject in the year 1903.

I do this not merely with a view of resuscitating forgotten controversies, but of calling attention to a plan proposed by me which obtained the support of the dissentient minority, as well as the somewhat guarded approval of the majority of the Commissioners.

The Commission was presided over by Lord Balfour of Burleigh. His present Majesty, then Prince of Wales, was a member of it, and it comprised, among others, Lord Burghclere, Lord Chaplin, the late Duke of Sutherland, Sir Henry Seton-Karr, Mr. Edmund Robertson, the Comptroller of the Board of Trade, two admirals, the Oxford Professor of International Law, Lord Emmott, the president of the Liverpool Corn Trade Association, and Mr. John Wilson, M.P.

I had also the honour of being a member, in my capacity as one of the officials of the Home Department.

It is interesting, after the lapse of thirteen years, to look back at the problem as it was then presented and to examine the findings of the Commission in the light of subsequent events.

The importance on the outbreak of war of a sufficient supply of food is too obvious to need proof. The remarks which follow apply to almost all kinds of food, about five-sixths of which come to Great Britain from abroad. But corn is chiefly under consideration, because it forms the principal article of diet among civilised peoples, and is being consumed in increasing quantities by savage nations. In Great Britain nearly one-fourth of the money expended on food is spent upon flour and bread.

The wheat lands of the world though not nearly exhausted are not illimitable, and it does not seem probable that the price of wheat will ever again fall so low as it was in the first years of the present century.

Roughly speaking, the annual consumption of corn is 350 lb. for each head of population, or rather more than 30,000,000 quarters (of 480 lb. each). Of this amount in 1903 about 6,000,000 was produced in Great Britain, 10,000,000 came from the British colonies, 6,000,000 from Europe, 4,000,000 from the United States, and 5,000,000 from South America and elsewhere. The principal routes by which it came were the Atlantic, which carries 60 per cent., and the Mediterranean, by which there comes about 13 per cent. In winter there were usually about 4,000,000 quarters of wheat at one time on the ocean coming to us, and about half that amount in the summer. During the spring wheat begins to come from the Pacific coast of America, in April it begins to arrive from Australia, in May from India, in August the American winter wheat begins to arrive, in October we get wheat from Rumania, and in November the arrival of the Canadian wheat commences.

Our stores of wheat in this country vary from seventeen weeks' consumption in November down to about five or six weeks' consumption in August.

These figures include wheat in stores, wheat in the hands of millers and bakers, and wheat in the hands of farmers. In fact they represent our total available supply. I have preferred to give the figures proved before the Royal Commission. They are somewhat different from the figures of to-day. For instance, we now produce about 7,000,000 qrs. of wheat instead of 6,000,000, but the figures are not so different now from what they were at the date of the Royal Commission as to make any material difference to the argument or the conclusions.

It follows, then, that if at a critical period an enemy could intercept our imports of wheat, even for a short time, our position would certainly become very serious.

Now it must be remembered that the production of wheat differs from that of manufactured articles and of much other raw produce, chiefly in this, that it is seasonal. It is not eaten as produced. On the contrary, though some of it is eaten at once, the remainder is eaten at varying periods up to a year at least after it is reaped, and in some cases longer still. Hence it must be stored. In order to secure its preservation it must be kept dry, and well aërated. It must occasionally be cooled, because like all stored seed it tends to heat when kept in large masses.

In the case of American wheat this storage is done in America. Minneapolis and Chicago alone are computed to have storage capacity for over 11,000,000 qrs. And in America there is probably storage for 100,000,000 qrs., or three times the whole annual consumption of Great Britain. America need not fear starvation by any war that is not waged upon her own territory. The cost of such storage for a year on each quarter of corn is estimated at 1*s.* 6*d.* for interest on capital, 1*s.* 6*d.* for rent of store, and 9*d.* for inspection, carting, aërating, etc., making a total of from 3*s.* 9*d.* to 4*s.* This cost

of storage is inevitable; it must be incurred and forms part of the cost of production of wheat.

We may naturally ask, What are the securities which ensure us against a deprivation of our wheat supply? The first, of course, is our Navy. But it must be borne in mind that our Navy can only be effectual as a weapon of offence. We cannot scatter it so as to protect trade-routes. All we can do to protect those routes is so to threaten the enemy's navy that it dare not detach any considerable forces to attack our trade.

The second security we have is, that at the time we are at war with some foreign Power a wheat-producing friendly neutral can still supply us. This supply could only be prevented in two ways. First by the extension of an effective blockade to all our ports. In this case, if wheat were declared by our enemy to be contraband of war, on the ground that it might feed our troops, the enemy might take the wheat and the neutral vessels carrying it. Secondly, our enemy might decide to be bound by no rules of war, and to sink at sight and without warning all ships, both ours and those of neutrals, which were found carrying wheat to our ports. And what is to prevent him? Simply our own force or the force of the neutral whose ship was taken. For although such action by our enemy would be illegal from the point of view of international law, yet there is nothing binding other neutral nations to enforce international law. It is at present only a code which he may keep who chooses and he may break who can. The enforcing of it on third parties is no part of the duty even of those by whom it was agreed and formulated.

Again, although according to the laws of war a cruiser has only a right to destroy such ships and cargoes as she cannot take into port, there is nothing to prevent her from sinking them at sight if she is ordered to do so by a government that has decided to obey no moral or international code.

The majority of the Royal Commission formed the opinion that, though there might be some uncertainty as to whether the rules of international law would be observed by an enemy with whom we were at war, yet that public opinion would have a restraining influence on its breach, and that the interests of neutral nations in supplying us with food would count for something. Moreover, the Admiralty had given its opinion that, in case of war with any two great maritime Powers, our supplies from oversea would not be very materially diminished.

On this assumption, and on the assumption that the rules of international law remained unchanged, the majority of the Commission came to the conclusion (par. 250, p. 59) that: "Not only is there no risk of a total cession of our supplies, but no reasonable probability of serious interference with them, and that even during a maritime war there will be no material diminution in their volume, unless we sustained such a naval disaster as to lose command of the sea" (par. 116, p. 27).

In view, however, of the rise in prices which a war would bring about, the Commission, in a very hesitating way, advised that a scheme for encouraging wheat storage, by "offering storage room rent free, would be open to the fewest objections" (par. 261, p. 61). (*See* Report, Parliamentary Blue Book, 3 vols. [Cd. 2643, 2644, 2645, 1905].)

This report, however, was not unanimous. It met with opposition on the part of the late Duke of Sutherland, Lord Chaplin, the late Sir Henry Seton-Kerr, Professor Holland, and the author.

We did not dispute the view that, until the British Navy had been put out of action it would be impossible to cut off our corn supplies; but we considered that, even assuming that we were to risk all on our Fleet, yet that in view of the great rise in price which even a partial defeat might cause, some steps should be taken to increase the supplies normally present in the country.

A number of schemes had been proposed. One was Government aid to farmers at home, to induce them to store their crops for a time before selling them. The disadvantage of this plan is that farmers have not got proper arrangements for storing wheat, which is subject to attacks by vermin, to heating and deterioration; and besides, British wheat does not keep so well as Canadian or Australian.

Another proposed plan was for the Government to buy and store wheat and to sell it from time to time according to some pre-arranged scheme or some sliding scale. This plan, however, was condemned by all the members of the Commission, both on account of the disturbance to trade and the difficulty of fixing the prices (Report, par. 259, p. 60, and Dissentient Report, par. 78, p. 80).

The plan of subsidising merchants to induce them to keep stocks of wheat was likewise on all sides disapproved.

The next proposal, known as the schemes of Mr. Govan and Mr. Marshall Stevens, for

providing free storage, met with a hesitating approval from the main bulk of the Commissioners, and was recommended by the dissentient minority.

The plan was to subsidise companies who would erect stores, by paying them 6*d.* a year for twenty years for every quarter of corn for which they provided accommodation. In consideration of this the companies were to offer storage free of rent up to the capacity of their stores, to all who demanded it. This would apparently leave to be paid by the persons storing the wheat the cost of inspecting, carting, aërating and loss of interest, say, altogether about 2*s.* 6*d.* per quarter per annum (Report, p. 48). Observations upon this plan were offered by the principal dealers in wheat in the United Kingdom (Report, p. 190 *et seq.*).

The gist of these observations was that the importers of wheat would not take advantage of the plan, and the reasons given are very interesting and instructive. For instance, that "when grain is once stored there is a more limited market for it." No merchants "would care to have their goods locked up for sale in any particular area." "Favourable market conditions could not subsist concurrently with full granaries. Such stocks would annihilate all prospects of profits on the corn merchant's ordinary trading." "No doubt it would be a good thing for the millers of the neighbourhood, but it would largely obviate the necessity of the millers keeping stocks in their mills, and the probable effect would be that there would be actually less grain in the particular district than if the warehouse were not in existence." One writer suggested that we ought to have a navy "strong enough to convey our supplies across sea in spite of all opposition." Another "that the farmers ought to be subsidised to enable them to grow wheat." One very frankly said, "If I sell wheat in America for May delivery in Chicago or New York, it is obviously useless to me if stored in Great Britain. I not only miss my local speculation and milling demand, but I am absolutely tied to one market for export, instead of having the choice of the whole of Europe, and a mere concession of 2*d.* per bushel (*i.e.*, 16*d.* a quarter) in rent would in no way compensate me for loss of market." Another wrote, "Very little grain now comes to this country on account of foreign owners who are wise enough to know that if held in their own country they have all the markets of the world open to them during the whole time they are holding their grain, and can sell it any day they like, instead of being obliged to wait until the buyers of that market choose to purchase, which would be the case if they shipped unsold to this country."

And verbal evidence was given to the effect that corners and combines are more easy to "engineer" if the stocks are kept in the country of production than if they are stored in the country of consumption (*Q.* 1106). These replies make it clear that the reason why wheat is stored in the country of production is because it gives the wheat speculators and dealers an advantage in that they can to a large extent regulate prices in the country of consumption by retaining the power up to the last moment of sending it to one market rather than to another. Thus, for instance, if the wheat is stored in America, and a sudden demand for it arises in some part of the world, either from war or other cause, the enhanced price caused by a sudden increased demand is felt in all those countries that have not got a considerable quantity of stored wheat, and they will be subject to every fluctuation produced by any cause. On the contrary, a country that has a large wheat supply stored up is much less subject to variation of price. A large supply of wheat acts like the fly-wheel of an engine. It steadies prices and causes fluctuations to become less abrupt.

I have quoted these replies and evidence, not because so obvious a truth needs proof, but because it is not often that those engaged in a trade so freely admit the means adopted by them to "engineer" their profits. They are, of course, no worse than other men, nor do they probably make more money than other people; but the reasons they give for objecting to storage in Great Britain are the very reasons that ought to make the public insist upon it. For it is precisely at crises that all this price-engineering procedure comes into play, and it is certain that the raising of prices would be prevented, not only in time of peace but still more in time of anticipated war, if larger stocks were held in Great Britain.

I now pass to the consideration of the plan which I suggested. After the lapse of thirteen years I can only say that the more I reflect upon the matter the less objection I can see to it.

I had better, I think, reproduce it in the form in which it was placed before the Royal Commission (Vol. III. Appendices to the Report, XLIV. p. 327), together with the criticisms to which it was subjected.

APPENDIX No. XLIV.

Scheme Proposed by Mr. H. H. S. Cunynghame, C.B., a Member of the Commission, for Obtaining a Stored Supply of Foreign Wheat in the United Kingdom.

It must have struck everyone how inconvenient and dangerous it is to us that in the necessary interval between the harvest and consumption of wheat the grain should be kept in America and other foreign countries rather than in the United Kingdom.

We have evidence that it costs no more to store and handle wheat in the United Kingdom than in America (*Q.* 811, 1288, 1325, 1378, 1490, 1721, 1926, 2061). The reason why corn is kept at present in America, rather than in the United Kingdom, seems principally to be the increased control it gives to the corn speculator, who, so long as he keeps the supply of wheat in hand, can fix the prices that shall rule the market.

Hence it seems probable that only a very small inducement would be necessary in order to cause buyers to secure delivery of the corn to the United Kingdom some months before it was consumed, rather than, as at present, to live from hand to mouth (*Q.* 816).

The question is, how this inducement is to be supplied. There seem to be four possible ways of doing this :—

(1) To encourage storage by some system of bounty, or gratuitous storage by Government.

(2) For the Government to store and deal in wheat.

(3) To make it obligatory by law for imported wheat to be stored a certain time before being consumed.

(4) To levy a tax on imported wheat which is not stored for a certain period.

It is the last of these modes I would suggest for consideration. In order to carry it out I suggest that an import tax of, say, 4*s.*, might be levied on imported corn and flour; but if the importer would bond his corn he should not be obliged to pay the tax till he took the corn out of bond, and then only to pay a tax reduced, say, by 1*s.* for each month it had been kept, so that if he kept it four months he would pay no duty at all.

It is obvious that these figures have been adopted as a conjecture. Other figures and periods might be more suitable. But it seems probable that the fact that a vendor who had stored his wheat would have a 4*s.* advantage over one who had not stored his wheat would be a sufficient inducement.

The suggested advantages of this scheme are :—

(1) That it would check the danger of foreign wheat corners (*Q.* 1108, 2071).

(2) It seems probable that grain would be stored in preference to flour. In this case the milling industry would profit, and we should have the advantage of the offals.

(3) It involves no new administrative departure, for the methods of levying taxes on corn and bonding are perfectly understood. There is no danger of smuggling, and as corn is large in bulk in proportion to its value, there would be no danger of surreptitious removal. The stores would all be large, because size would promote economy in handling, so that supervision would be easy.

(4) It does not involve the Government in the purchase of grain or the building of stores or the sale of grain, together with all the attacks and misunderstandings to which Government dealings in articles of common consumption give rise (*Q.* 1390).

(5) It does not involve the keeping of wheat for any periods longer than those for which it is kept already (*Q.* 857-861).

(6) If wheat is to be kept, it is preferable that it should be some good keeping kind of foreign wheat, such as hard Canadian or Australian wheat, rather than British wheat, which does not keep so well.

(7) Almost any method of bounties on storage of imported wheat involves the expenditure of a considerable yearly sum of money; but there is good reason for thinking that a very small inducement ought to turn the scale in favour of British storage.

Therefore, everything given over this would not only be thrown away, but worse; it would act as an encouragement to the foreign wheat importers and a further discouragement to the British farmer, already hard-hit.

Whereas, on the contrary, a tax, in so far as it operated at all, would on the one hand be a gain to the Exchequer, and on the other hand an encouragement to farming industry.

But I greatly doubt whether under this proposal any tax would be paid. It seems probable that importers would prefer to store the wheat rather than pay the tax.

A tax is a better plan, I think, than absolute compulsion to keep the wheat, because under a tax, if prices are high, the storage automatically relieves itself and tends to steady prices.

I can easily understand, of course, that those interested in the grain trade would naturally incline to some scheme of bounty on storage, but the general consumer may be expected not to view the scheme so favourably, and to ask why we should pay people for keeping wheat in the United Kingdom when the evidence shows that it costs no more to do so than to keep it in America.

This proposal is, of course, not contrary to Free Trade principles, nor protective in its character. Any advantage it gives to the British wheat-grower is incidental. It might be asked: "Will this scheme diminish the amount of wheat imported, or will it raise the price ?"

With regard to the first question, the statistical appendix to the evidence of this Commission, p. 95, shows that a rise in price has very little influence on the amount consumed.

With regard to the second, it could not raise it by more than the extra cost of storage in the United Kingdom, of, say, 10,000,000 quarters over what the storage of that quantity of wheat would have cost in America.

We have evidence that this extra cost of storage ought to be very small, for it is as cheap to store wheat in the United Kingdom as in America. Even if the extra cost of storage came to 1*s*. per quarter on the amount stored the advantage would be that, instead of having to levy taxes to pay it, by the suggested scheme it would pay itself, partly out of the pockets of the British consumer, partly (as all import duties do) out of the pocket of the foreign producer, while any rise of price it caused in wheat would accrue to the benefit of the farmer, as well as of the revenue.

It therefore appears to be the cheapest mode of attaining the object.

There seems to be little doubt that money would be forthcoming to build proper stores. Some existing stores are falling into disuse, owing to the decreasing amount of corn stored in the United Kingdom. Any scheme of home storage involves the coming into existence of stores, whether under the compulsion of a tax or the inducement of a bounty. H. H. C.

Upon this proposal the majority of the Royal Commission reported as follows:—

MR. CUNYNGHAME'S PROPOSAL.

In addition to the proposals examined above, a scheme has been laid before us by one of our number, Mr. Cunynghame, the aim of which is, by certain fiscal arrangements, to cause wheat to be stored in the United Kingdom rather than in the country of production. With regard to this scheme, we find that, so far as concerns expense, it is certainly more economical than any in the preceding classes, for it entails practically no charge on the revenue except that of collecting the tax, and if any considerable proportion of imported wheat paid the tax rather than go into bond, the plan would soon be self-supporting. It also has the merit of simplicity. Moreover, it should certainly act as a means of steadying prices; for if prices rose by more than 1*s*. per quarter, the rise would bring into the market all the reserve which had been in bond three months, and on which the merchant could now afford to pay the remaining 1*s*. tax and still make a profit. If prices rose more than 2*s*. per quarter, it would automatically set free the reserve which had been in bond only two months, and so on, a process which would, of course, tend to reduce prices to their original level. If the reserve were inexhaustible, the more prices increased the more wheat would be thrown on the market, and the result would be all that could be desired; but Mr. Cunynghame has mentioned four months as the period during which imports would have to be bonded in order to become free of duty, and it would scarcely be possible to extend the time much beyond that point, so that the maximum amount in store at any given time could not be more, and would probably be a great deal less, than 10,000,000 qrs. As a rise of 4*s*. per quarter is not an abnormal amount in the fluctuations of wheat prices, and as in the period preceding an outbreak of war prices would almost certainly rise beyond that point, it is at least a possible contingency that importers would be tempted to sell out their reserve at once, with the result that when war actually broke out it might conceivably all have vanished. In fact, it is one of the chief disadvantages of Mr. Cunynghame's scheme that the maintenance of the reserve at any given quantity could not be made certain and the scheme might easily be rendered abortive from the point of view of food supply in time of war, unless some restrictions as to sale were placed upon holders of the stock, in which case, of course, it would

be necessary to offer them some compensation. We should add that Mr. Cunynghame has explained that it is not of the essence of his scheme that the tax should be 4*s.* per quarter. Any sum, even 1*s.* per quarter, would be enough that would act as an inducement to the storage of wheat in the United Kingdom.

We are also afraid that the scheme would cause a certain amount of disturbance to the corn trade. For example, it would presumably do away with all dealing ex quay or ex ship, if the storage in this country became obligatory, and it seems probable that the system of sending wheat on consignment would also have to be discontinued if it became universal to bond wheat for the four months; for it is not likely that a foreign owner would agree to hold his wheat in store in the United Kingdom, seeing that by so doing he would restrict his choice of market and make himself dependent on the price ruling in the United Kingdom at the end of the four months.

A practical difficulty in working the scheme also occurs to us. Wheat arrives in this country in varying degrees of condition. In some cases it may be expedient to pass it into consumption without delay, but it is obvious that if this scheme were in operation, that could not be done without the payment of 4*s.* per quarter, an amount which would clearly be prohibitive.

There is the general argument in favour of all schemes and proposals for permanently increasing the stocks of wheat held in this country, namely, that they will probably operate to the detriment of speculators who may be endeavouring to raise prices, whether by cornering or by trade rings and arrangements. One of the reasons why wheat is kept in America rather than shipped to England undoubtedly is the advantage it gives to the grain exporter in controlling prices. The very fact that the wheat is in the country of consumption prevents the fear of its being diverted from its destination, and thus aids in steadying prices. There can be no greater preventive of possible corners and violent fluctuations in the United Kingdom in time of war than an increased permanent stock at home.

I do not know whether the authors of this criticism considered it as condemnatory of the proposal. To me it seems that their remarks only strengthen and emphasise the points for which I was contending.

I need not, I think, further explain this proposal, which is, of course, intended for adoption, not during time of war, but during a time of peace in preparation for war. It might be accompanied by the erection of public granaries as at Chicago, or their erection might be left to private enterprise. The securing of the work of aërating the grain, of milling it, and of using what is called the "offal" or husks for feeding cattle, would alone employ a considerable number of men, and would be of great benefit to farmers.

Granted that some inferior grain came over which would not keep, it could be released by special order and on special terms, and would still be very valuable feeding-stuff for stock and poultry. This offal amounts to about 30 per cent. of the corn, and of it only about 2 or 3 per cent. is sheer waste.

I can only ask why we should permit, and even encourage, a system which secures a food supply in time of war to America instead of to Great Britain, which secures the industry of handling the corn to Americans instead of to Englishmen, which provides the American farmer with the offal of the flour paid for by the people of Great Britain, and which is used by speculators as a means of livelihood at the expense of the consumers of this country.

We cannot produce and consume wheat simultaneously, as, for example, we produce and consume coal. Corn only comes in at the harvest, at one time of the year. Storage is, therefore, a necessity in the case of wheat, whereas it is not a necessity in the case of coal.

It costs no more to store the wheat here than abroad. Why, then, are we to allow speculators to keep it in America merely in order that they may be enabled to engineer the markets to their own advantage?

I use the word "engineer" not wholly in a bad sense. Legitimate engineering of the market may in some cases result in producing uniformity of prices by anticipating falls of price as well as rises. "Buying forward" is quite a legitimate operation. But where those engineering processes involve grave danger to the very existence of our country it is the duty of Government to guard against them, especially when they tend not to lower the prices of the staple commodity of life but to raise them.

Even, however, if it were admitted that the conclusions of the majority of the Royal Commission were right in 1905, and that the minority was wrong in dissenting from them, yet that report needs reconsideration to-day.

It was made upon three assumptions:—

1. That the British Navy would be kept up

on the two-nation power standard. This condition is expressly laid down (see par. 130, p. 30).

But the two-power standard no longer exists.

2. Again, the report assumed that the principles of international law would most probably be observed by our enemies (par. 113, p. 26), and enforced by neutrals (par. 111, p. 26). They have been openly violated by Germany, and neutrals, even including those whose rights have been violated, have merely protested but declined to intervene.

3. The report was made on the assumption that captures at sea would be made in the then recognised methods (par. 146, p. 34). Those who signed it did not contemplate the use of submarines without warning against merchant vessels. Unless this war shall result in the formation of a *defensive and offensive* league of humanity in war and a restitution of our Navy to the position of relative superiority that it possessed in 1904, the conclusions of the report cannot be supported. I do not believe that the majority who then voted for them would consider those conclusions applicable to the present state of affairs.

The only two proposals that met with favour at the hands of the majority or minority were some scheme of free storage, and that which I submitted. Both would be useful, but on the whole, after comparing them, I still prefer my proposal.

The free storage scheme only offers free rent, the advantages of which to the corn merchant vary from 6*d*. to 1*s*. 6*d*. per quarter of corn per annum, according to various estimates or schemes.

I doubt whether this would be sufficient to induce the speculator to give up the advantage he obtains by storing the wheat in America. The advantage he obtains from engineering is too great to be foregone for so small a benefit, especially as under the free storage scheme he would himself have to pay the remaining costs of storage in Great Britain, such as aërating, carting and inspecting, which might be greater than what they now charge him for the same services in America.

But according to my plan, if he does not store in Great Britain at all, he loses 4*s*. a quarter right off, whereas if he stores for half the year, or such period as shall be considered reasonable, he loses nothing at all.

Of course, my plan might be combined with the provision of a public granary conducted under Government supervision and at cost prices. Such work as this could perfectly be done by Government-paid servants, being a matter involving no speculation, no risks of the market, no duty of estimating future prices, but merely efficiency of a purely routine character, and might well be done by our soldiers in time of peace.

Lastly, the plan does not involve the abandonment of "Free Trade principles." It might be combined with Free Trade, or with a protective tariff.

Even if it were a form of Protection, why should we, in levying our import taxes, select coffee, sugar, tobacco and things that we do not ourselves produce, apparently expressly in order that any incidental advantage which might be obtained from the protective action of the taxes may not be obtained for English producers by ourselves?

It may be good morals for the governors of a charity to refuse to receive funds derived from a bazaar lottery, on the ground that they cannot countenance gambling, or receive money from a tainted source, but surely protection of native industry, whether wise or unwise, is not on a moral level with State gambling. Nor can we say that protection of trade is so poisonous that we ought rather to risk national starvation by an enemy than resort to it.

What if the agricultural labourer and farmer profit a little by a scheme designed to promote national safety? Are agricultural wages and profits so high that there is no need to consider the interests of the agricultural classes?

Are the industrial classes so selfish that every Act of Parliament must be in favour of industry and against the interests of agriculture? Even at the worst, suppose the scheme failed, and that no foreign corn was stored in Great Britain, a tax of 10*s*. a quarter on imported corn would cause at least 15,000,000, qrs. of corn to be grown in Great Britain, instead of 7,000,000, and would bring in a revenue of about £7,000,000 sterling of money, besides benefiting agriculture and giving us a secure food supply in case of war. It is difficult to compute what the loss would be, because against the rise in home price there would have to be put the advantage of increased agricultural wages and the wages obtained from handling and storing the corn. In any case, it would be a cheap investment if it secured a constant minimum supply of wheat for six months' consumption.

But, for the reasons stated above, I do not believe the scheme would fail. There are no

intrinsic difficulties against storage of corn in this country, where means of communication are good both by land and water, where mechanical appliances are to be obtained, and where labour is certainly not dearer than in America.

There are two further objections which I mention, because they were made to me at the Commission by two of the members who signed the majority report.

One of them said that it would be a bad plan to have a security from starvation, because the people would then never vote the money necessary for a strong fleet, and that this feeling of security would lure them to destruction. He even went on to deprecate the spending of money on an army. "We are a maritime nation," he said; "if our Navy is beaten we are done." The other said that a provision of food for the eventuality of war was useless, because the working-men of Europe would take care that there never was another European war.

Comment on these opinions is needless. By the mercy of Providence, and in spite of the most determined refusal to look facts in the face, we have probably escaped from a serious calamity. It is to be hoped that when the opportunity comes we shall not again risk our national existence by refusing to take the most obvious precautions for our safety.

DISCUSSION.

The Chairman (Captain Bathurst, M.P.), in opening the discussion, thought that while the author's scheme would afford the country much greater security than it enjoyed under existing conditions, it would be well to supplement it in some very material respects. He thought Sir Henry had over-estimated the amount of food which came to Great Britain from overseas. Something like five-sixths of our bread-stuffs before the war came from abroad, but very nearly half of the meat consumed was produced in the country. He entirely agreed with the author's statement that it did not seem probable that the price of wheat would ever again fall so low as it was in the first years of the present century, but he ventured to add that it was not well it should, because it threw land out of cultivation and rendered our position extremely precarious in time of war. He had never been greatly convinced by the report of the Royal Commission; in fact, he thought the author's scheme was the most convincing part of a report which was inconclusive and somewhat lacking in courage and definiteness. The proposals in the report were in effect whittled down to two: first of all that there should be a national indemnity, contrasted with national insurance against loss or capture by the enemy; and, secondly, the offer of storage room rent free for wheat in this country, whether produced here or overseas. It was interesting to note that the reason a national indemnity was advocated, as compared with national insurance, was owing to the desirability of keeping the rates of freight as far as possible at a normal level. What an interesting commentary the rates now being paid were upon the forecast of the Royal Commission! He did not think it was an exaggeration to say, looking at the actual facts which the war had brought to their notice, that if the German Fleet had not been penned in German waters by the British Fleet at the outbreak of hostilities, and if German submarines had been twenty times as numerous, not to mention the activities of an increased number of Zeppelins, the dread of starvation would long before this have finished the war to England's discomfiture and shame. Those conditions, he suggested, were bound to prevail in any future war, and if so they were conditions against which it was but common prudence to provide. An indemnity granted by Government to food-carrying ships would not ensure those ships reaching our shores, although it would encourage the shippers to run greater risks. The only really safe course was the greater production of food at home. Under the author's scheme the bulk of the food would have to come from overseas, and any enemy this country had to face in the future would make every effort to prevent its reaching our shores. Increased production at home must depend upon definite Government encouragement and protection. Thirty years ago Bismarck, who had proved to be a true prophet and a true constructive statesman in many respects, said: "There is no greater national calamity than for wheat to fall below a price at which farmers can produce it at a profit." For a long series of years following the commencement of the great agricultural depression wheat was grown at a loss, with the result that wheat production was greatly reduced, and this country had to depend to a greater and greater extent upon foreign supplies. In 1892 wheat fell to 22*s.* 6*d.* a quarter, and at one period in his own part of the country the price of straw was more than the current local price of grain. He believed Bismarck was right, and that it was in the highest national interest to take care that wheat could be grown in this country at a profit, if it was only a bare profit, so as to put some sort of premium upon its production by British farmers, which would be a great factor in increased security. He had for many years advocated a bonus or bounty on the part of the Government as an inducement to both large and small farmers to grow more wheat. He suggested in a pamphlet, which he wrote four years ago, that that bounty might be the difference between 35*s.* a quarter and the current market price of good sound wheat. He further estimated that on the basis of the seven previous years the amount the Government would have had to provide at the most in any one year

would not have exceeded the cost of a Dreadnought, and the national security resulting would be infinitely greater than that provided by a battleship. Even the storage of overseas wheat in silos in Great Britain would not afford adequate security during a prolonged war. The author's scheme would no doubt serve all necessary purposes if the war lasted no longer than six months; but in a war of any greater length the greatest security was to be found in a largely increased home production. It was often said that it was quite impossible to double the present output of home-grown wheat. In that connection it was well to remember that wheat was grown much more intensively nowadays than it used to be, and much better varieties were grown. Thanks very largely to the experiments which had been translated into most valuable results through the Mendelian Research at Cambridge, wheats were now being largely grown by the best farmers in this country which, instead of producing 32 bushels to the acre, produced 40 bushels of 70 lb. as against the old English average of 60 lb. A good sample of Little Joss, which was a very popular Cambridge wheat, would probably run to 67 lb. a bushel. The Royal Commission evidently did not foresee that it would be possible in this country, as the result of the research, to grow wheats similar to those which had been raised in Manitoba and India, which possessed the baking qualities of the best of the wheats of other countries. Wheats of that character were in fact being grown in England, and although there was a lingering prejudice amongst millers against British wheats they had enormously improved during recent years. Farmers were always being criticised for not growing what the public was deemed to require, but it must be remembered that there was no industry more insecure than the agricultural industry, particularly in regard to arable husbandry, and yet there was none more vital to the nation, as war experiences were proving. One additional advantage accruing from the growth of a largely extended area of wheat was that it would be possible to avoid sending very large sums of precious money overseas in times of war to pay for wheat which came from abroad. He believed this country was paying for food from overseas something like £300,000,000 a year at the present time. They ought to be able to keep at least £150,000,000 of that in this country if greater encouragement were given to the home production of food. When the war was over the country would be almost bound to develop the production of sugar on British soil, and if that was the case the valuable residues which resulted through the growth of a crop of sugar beet would be a great encouragement to the extended cultivation of all cereal crops, particularly wheat. Whereas after the war wheat would still continue to be the chief British crop, he was not at all sure that sugar beet would not become the farm crop of second importance only in this country. The other members of the Royal Commission, in criticising Sir Henry's scheme, suggested that it would produce considerable disturbance to the corn trade. Personally he could not conceive of its producing a greater disturbance than that which had been caused since the war began by the Government purchase of wheat, very often in large quantities, without any warning to farmers and millers, creating enormous disturbances in the markets throughout the country, and causing sometimes a fall in the price of wheat of no less than 10*s.* a quarter in something like the same number of days. That could not be a healthy condition of affairs. He was glad to notice that towards the end of his paper the author asked why it should be considered a crime to afford some measure of prosperity to the agricultural classes. He thought that by now it must be fairly demonstrated, as the result of the war, that a greater measure of prosperity must be provided for the agricultural classes. It was quite certain that the agricultural labourer was going to obtain substantially larger wages after the war than he had done before, and that would only be possible if the products of the farm fetched a higher price. Although no doubt the cry of the demagogue in favour of cheap food was very attractive to the populace, he could not conceive any more delusive cry, or any cry that was more likely to land the country in difficulties in times of national crises. It was not to the nation's interest that food should be sold at a less cost than that at which it could be produced in the country. He was afraid it was always suggested that any schemes that would benefit the agricultural industry would give an unfair benefit to the landowner. Personally he thought it was quite possible to devise a scheme which would limit the advantage to be derived by the landowner. It would be a very good thing if the landowner did derive some benefit out of any such scheme, because it would be a far greater inducement to him to be more genuinely personally interested in the development of his own land, and the promotion of the greatest British industry upon that land, than he was at the present time. The tendency of the policy of all Governments for many years past had been to convert the landowner into a mere rent-receiver instead of being, as he ought to be, the managing director of a great industrial business.

The Right Hon. J. Round thought the war had proved that it was extremely important for the nation to produce more food in the future than it had done in the past. The Chairman's statement that £150,000,000 per annum might be kept in the country by the production of more food at home was an exceedingly important one, which he hoped would be widely considered.

Mr. A. E. Humphries (Past-President of the Millers' Association) said the author had stated

that about five-sixths of the food consumed in this country came from abroad, but Mr. Rew, of the Board of Agriculture, in a paper read before the British Association in the previous year, had stated that it was only one-half. Most people, when they referred to the proportion of food produced at home, dealt almost entirely with wheat production. It was a fact that this country did not produce at home more than 20 to 25 per cent. of the wheat it required, but taking the whole of the food of the country he agreed with Mr. Rew that it produced approximately one-half. The author had suggested that when wheat was brought into the country it should be stored for four months, but that in certain cases it should be used for consumption forthwith. That was an absolutely necessary provision, because even in Manitoba snow had occurred during harvest-time, and great difficulty had been experienced in keeping the wheat. North Russian wheat contained 17, 18, and 19 per cent. of water, and in such cases the wheat would not keep. The author said that English farmers did not possess facilities for storing. If Sir Henry referred to granaries he agreed, but if he meant that English farmers could not store wheat satisfactorily he profoundly disagreed with him, because it was impossible to store wheat in a better manner than in ricks. The amount of damage done by rats the farmers could, to a large extent, prevent. English wheat, which was in a physical state unfit for use soon after it was harvested in a bad season could, by the succeeding May, June, or July, after it had been properly stored, come out perfectly fit for food, and English millers were only too willing to pay good prices for it. The author had referred to the great advantage that would accrue from the millers grinding the wheat in the United Kingdom so that the offals could be used in the country. He agreed, but he wished to point out that only about 10 per cent. of the flour consumed in the United Kingdom was imported. Since the Government had stopped the export of offals, the whole of the offals made at home were kept in this country, and they represented within 10 per cent. of the possible maximum. He did not feel at all hurt at the "chipping" merchants and millers continually received. It was often thought that in pre-war times millers and merchants made a great deal of money, but that was not the case. The amount of profit upon the transaction was incredibly small. A huge volume of business was done on an extremely small margin, and that was the reason the trade was driven into big concerns. The trade was an extremely hazardous one, in which sometimes huge profits and sometimes huge losses were made, and when the two were balanced only a small and reasonable profit remained. He agreed with the author that what had happened in the past had to be revised in the light of what was now happening, but although there was a case for investigation, the members must not run away with the idea that the British public was being "bested" or "done" by the corn trade.

Mr. W. T. Chadwin said that wheat had always been referred to as if it were the one food product upon which this country was dependent. He contended that commodities should be sold at such prices as would prevent waste, and if the working-classes could buy bread at 6*d*. a loaf they had no right to complain. That would enable the price of wheat to be kept in this country at about 45*s*. a quarter, and under those conditions there would be no hardship to the consumer of bread, and an inducement would be offered to the farmer to enable him to increase his arable cultivation at a profit. One means that tended in that direction was the cultivation of sugar beet. Had a sugar-beet industry been started in this country in years past, the system of agriculture would have been immensely improved thereby. In his opinion it should be the basis of an improved agriculture. The sugar beet should be followed by corn crops, and there was ample evidence to show that thereby the produce of the land would be increased by 25 per cent. A much larger number of cattle could be reared on the land and the whole welfare of rural England would be improved; it would be possible to pay higher wages, to house the agricultural labourers better, and the spending power of the community would be increased.

Mr. W. J. Paul (Ipswich) thought the paper was too narrow in its scope, as the author had not realised the great importance of the importation of cereals into this country. The production of cattle and the production of wheat were so intermixed in this country that the one could not be touched without interfering with the other. The Government was guilty of a most lamentable error of judgment at the present time in prohibiting English vessels loading more than 25 per cent. of anything else but wheat. As a consequence, cereals required for feeding cattle in this country had risen to such a point that ordinary maize was selling at the present time at the same price as English wheat. If that state of affairs continued only a very little longer, English wheat would go into the mouths of pigs instead of human beings.

Mr. C. P. Ogilvie said he did not think the paper went far enough, as wheat could not be separated from the other cereals. Linseed was of the greatest importance in that connection, and if prices rose much higher cattle would be eating the food that the Government had bought to protect the people of this country from starvation. Linseed and maize were just as important to the country as wheat, otherwise there would be a shortage of food in the shape of beef. There had been a large decrease in the amount of wheat and frozen meat imported into this country from Argentina since 1908, but he believed that the decrease, so far as the wheat was concerned, would be greatly made up by the intelligence possessed by the farming industry of this country. England could not boast of what she had done in

the past in regard to agriculture, and a great deal remained for her to do in that direction.

Mr. W. F. Giles mentioned that in the north of England and in Scotland very little permanent pasture was to be seen, the land being almost entirely arable, and a tremendous number of bullocks and sheep were reared. It would be of interest to know whether in the author's opinion a similar system could be adopted by the farmers in the south. An extraordinary amount of manure was put on the land; the crops grown were chiefly root crops for the feeding of the bullocks, and the labour was well paid. He believed that in the grass rotation the land was put down to grass for one year, or at the most two years, a very strong-growing kind of clover being sown, and some giant Italian rye grass. It was rare in Northumberland to see any great areas of land down to permanent pasture, and yet at the same time large areas of corn were grown. If a similar system could be adopted in the south he thought it would help to keep up the food supply of the country.

Mr. Walter F. Reid said that the author had referred only to wheat. One important food, namely, the potato, had been omitted altogether. A much larger quantity of food in the shape of potatoes could be grown on a given surface of land than wheat. He differed in the conclusions drawn by the author as to the advantages derived from storing wheat in this country compared with America. The miller preferred to have the corn stored for a long time in a dry climate like America, rather than to have it sent over to this country in its moist state. Potatoes had been the standby of the Germans during the present war. Their bread tickets would have been useless to them if they had not possessed an enormous supply of potatoes. He thought the object aimed at by the author would be attained not by the storage of imported wheat but by producing either wheat or other food material ourselves in the country. He deprecated continual adherence to wheat as a food. He lived for many months without eating any wheat food and was much the better for it. Education in the use of different kinds of food was of the utmost importance. The growth of sugar was undoubtedly an advantage to agriculture, but whether it was an advantage to the food supply of the country was another question. The chief advantage from the national point of view of growing sugar beet was that practically every element that was taken out of the land—the potash, the manure, and everything else—went back again, except what was given to the cattle. An excellent substitute for sugar existed in this country in the shape of honey. Since sugar has become scarcer the demand for honey had enormously increased, and the output of honey could be multiplied indefinitely without a single extra acre of land being used. The bee-keeper obtained his honey from his neighbours' crops, and did not use a yard of his own land for producing it.

The Chairman, in proposing a hearty vote of thanks to the author for his most interesting paper, hoped Sir Henry would not be discouraged by the few words of criticism that had fallen from some of the speakers; the question must be regarded simply from the point of view of national security. If any injury was done to any trade it was not justifiable except in the highest national interests, and he could not conceive that the millers of the country were destined to suffer in any way under a reasonable application of the scheme which the author had put forward. He suggested to Mr. Reid, as a chemist, that unless the potato was eaten in its jacket it would be hardly so nutritious as bread that contained the germ and the skin of the berry. If education on food values on the lines Mr. Reid suggested was given, much of the very white bread that was eaten would be discarded, and perhaps also some of the rather carelessly skinned potatoes that formed a very small portion of the British diet.

The resolution of thanks was then put and carried unanimously.

Sir Henry Cunynghame, in reply, said he entirely agreed with the remark that had been made that much the best way to deal with the subject was to grow, if possible, enough food of all kinds at home to make the country quite secure in case of war. But it must be remembered that for many years to come this country would be dependent on foreign countries for food supplies to a considerable extent, and the main suggestion contained in the paper was that, if the country depended on foreign supplies of wheat, those supplies should be kept in this country instead of in America. That would make the country secure for eighteen months or two years instead of only five weeks, as at present, and even that was something to the good.

Sir Graham Bower writes:—I greatly regret that my health—I am slowly recovering from a bronchial attack—will prevent me from hearing the paper by Sir Henry Hardinge Cunynghame on "Supply of Food in Time of War," for it is a subject in which I have for some years taken an interest. Various solutions have been proposed, but all are open to objection. A Government store of corn is open to two objections—(1) that it involves a lock-up of capital during peace in the shape of the storage of goods that deteriorate, and (2) the knowledge that large Government stores might be thrown on the market would discourage private importations. With reference to a Government subsidy to private merchants, the tendency of modern commerce is in the direction of small stocks and a quick turnover, for large stocks mean idle capital. The proposal of a subsidy to merchants to keep two months' stock in hand is

at first sight tempting, and is actually in force in the case of the Frozen Meat Company of the Island of Mauritius. But on closer examination practical difficulties present themselves, and such a subsidy must necessarily carry with it a stipulation as to price—a very difficult question. The cultivation of waste places is a newspaper folly. As president of a farmers' club, which includes four hundred farmers, I can say that every waste place that we know of is put to the best use to which it can be adapted, and that anyone who was fool enough to sink money in the cultivation of waste places would soon ruin himself. Even the county councils, who are not famous for wisdom in the purchase of land for small holdings, have sense enough to keep clear of waste places. A minimum price of corn has been suggested by Lord Milner's committee. But this is another folly, as any agricultural economist can certify. A high price of corn is fatal to the existence of the small-holder, who can only live as a fruit farmer, market gardener, or dairy farmer. To all these cheap feeding-stuffs are a necessary condition of existence, and a minimum price of corn would exterminate the small-holder just as the rise in the price of corn killed the yeoman farmer in the latter part of the eighteenth century. I do not even discuss what the town artisan would say to such a proposal. There remains therefore the traditional British policy, which may be described as Free Trade and the Blue Water school. This has been our policy, and appears to have been justified by results. For (*a*) Food is cheaper in England than in any of the belligerent countries; and not only cheaper, but more plentiful. (*b*) Since the outbreak of war, four of the belligerent nations —France, Italy, Austria, and Germany—have been forced to adopt the policy of free importation of food. (*c*) The protective duty on food has not made food more plentiful in the protected countries. On the contrary, it has been scarcer than in England. I would have been glad to have heard Sir Henry Hardinge Cunynghame's views, and to have compared them with those I have formed, but that is not possible.

GENERAL NOTES.

Export of Phosphates from Tunis.—According to the statistics published by the *Direction générale de Finance*, Paris, the total quantity of phosphates of lime exported from the Protectorate of Tunis in 1914 amounted to 1,427,162 metrical tons, of the value of 32,824,719 francs (£1,312,789 sterling). This is 28 per cent. loss, as compared with the quantity exported in 1913. The chief ports for the shipment of this substance were Sfax, which alone exported 61 per cent. of the above quantity, Tunis and Soussa. 28 per cent. of the exports was shipped to France, 29 per cent. to Italy, 14 per cent. to Great Britain, 7 per cent. to Germany, 5 per cent. to Holland, 4 per cent. to Spain, and the remaining 13 per cent. to ports of eight other countries. As regards nationality of vessels engaged in this trade, 26 per cent. were Italian, 18 per cent. French, 11 per cent. British, 10 per cent. Greek, 11 per cent. Danish, and the remaining 26 per cent. under other flags. It is anticipated that the results for 1915 will be greater than those of the preceding year, notwithstanding the war and the scarcity of labour which has been felt throughout the country. The shipments from the two principal deposits of phosphates, viz., those of Kalaa-Djerda and Gafsa, are reported to be very considerable at the present time, the former being not less than 25,000 tons, and the latter 91,000 tons per month.

Oil on the Grand Trunk Railway.—The Grand Trunk Pacific Railway (according to the *Canadian Gazette*) now uses oil on 700 miles of its track in Western Canada. To make this possible the company had to complete and set up oil plants at Jasper, McBride, Prince George, Endako, Smithers, and Prince Rupert, B.C. Economy and the elimination of smoke and the greater safety of the forest ranges near the line are the advantages of oil fuel.

MEETINGS OF THE SOCIETY.

Ordinary Meetings.

Wednesday afternoons, at 4.30 p.m.:—

May 10.—Sir Francis Taylor Piggott, M.A., LL.M., Chief Justice of Hong-Kong, 1905–1912, "Neutral Merchants and the Rights of War." Dugald Clerk, D.Sc., F.R.S., Chairman of the Council of the Society, will preside.

May 17.—George Percival Baker, "Hindu Hand-painted Calicoes of the Seventeenth and Eighteenth Centuries, and their Influence on the Tinctorial Arts of Europe." Sir William Martin Conway, M.A., F.S.A., F.R.G.S., will preside.

May 24.—John Collett Moulden, A.R.S.M., M.Inst.M.M., "Zinc, its Production and Industrial Applications." (Peter Le Neve Foster Prize Essay.) Dugald Clerk, D.Sc., F.R.S., Chairman of the Council of the Society, will preside.

Indian Section.

Thursday afternoon, at 4.30 p.m.:—

June 1.—Professor Wyndham R. Dunstan, C.M.G., M.A., LL.D., F.R.S., "The Work of

the Imperial Institute for India." THE RIGHT HON. LORD ISLINGTON, G.C.M.G., will preside.

JUNE 23 (Friday).—SARDAR DALJIT SINGH, C.S.I., "The Sikhs."

CANTOR LECTURES.

Monday afternoons, at 4.30 p.m. :—

J. ERSKINE-MURRAY, D.Sc., F.R.S.E., M.I.E.E., "Vibrations, Waves, and Resonance." Four Lectures.

Syllabus.

LECTURE II.—MAY 8.—*Waves in Ponderable Matter.* Transverse and longitudinal waves in solids and liquids—Methods of production and propagation—Polarisation—Wind waves—Ship waves—Tides and seiches—Cloud waves—Independence of wave trains—Superposition of harmonic motions—Sound waves—Submarine bells—Voice, phonograph, and gramophone.

LECTURE III.—MAY 15.—*Waves in the Ether.* Free and conducted—Light, heat, and electric waves—Alternating currents—Telephonic transmission—Wireless telegraphy—Submarine cables—Inductance, capacity, and resistance—Limits of known wave-lengths—Röntgen rays—Light—Heat—Reflection, refraction, and diffraction of wave motions—Stationary waves—Attenuation and distortion of travelling waves.

LECTURE IV.—MAY 22.—*Resonance.* Mechanical and electrical—Superposition of periodic impulses—Universal importance of the selective absorption of wave motions—Mechanical resonance or revibration—Screening of vibrations, absorption, and filtration—The acoustics of buildings—Sound resonators—Absorption of light waves—Coloured glass—Vision and photography—Absorption of electrical power by resonance—Tuning in telegraphy.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, MAY 8...ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 4.30 p.m. (Cantor Lecture.) Dr. J. Erskine-Murray, "Vibrations, Waves, and Resonance." (Lecture II.)

Royal Institution, Albemarle-street, W., 5 p.m. General Monthly Meeting.

Surveyors' Institution, 12, Great George-street, S.W., 5 p.m. Mr. F. N. Keen, "A Scheme for the Development of Agricultural Land."

Geographical Society, Burlington-gardens, W., 8.30 p.m. Mr. J. E. Stabler, "Travels in Ecuador."

TUESDAY, MAY 9...Faraday Society, at the Institution of Electrical Engineers, Victoria-embankment, W.C., 8 p.m. 1. Mr. E. Hatschek, "An Analysis of the Theory of Gels as Systems of Two Liquid Phases." 2. Mr. F. C. Thompson, "The Properties of Solid Solutions of Metals and of Intermetallic Compounds." 3. Mr. F. C. Thompson, "The Annealing of Metals." 4. Dr. F. J. Brislee, "The Changes in the Physical Properties of Aluminium with Mechanical Work. II.—Specific Heats of Hard and Soft Aluminium." 5. Messrs. R. Seligman and P. Williams, "A Note on the Annealing of Aluminium." 6. Mr. Z. Jeffries, "Grain Size Measurements and Importance of such Information." 7. Mr. E. J. Hartung, "A Contribution to the Theory of Solution."

Illuminating Engineering Society, at the ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 5 p.m. 1. Annual Meeting. 2. Discussion on the Report of the Research Committee.

Royal Institution, Albemarle-street, W., 3 p.m. Mr. L. Binyon, "Chinese Painting.' (Lecture II.)

Brewing, Institute of, Trocadero Restaurant, Piccadilly-circus, W., 8 p.m. Dr. H. T. Brown, "Some Reminiscences of Fifty Years' Experience of the Application of Science to Brewing Practice."

Zoological Society, Regent's Park, N.W., 5.30 p.m. 1. Miss D. M. A. Bate, "On a Small Collection of Vertebrate Remains from the Har Dalam Cavern, Malta, with Note on a New Species of the Genus *Cygnus*." 2. Dr. J. C. Mottram, "An Experimental Determination of the Factors which cause Patterns to appear Conspicuous in Nature."

Economics and Political Science, London School of, Clare-market, W.C., 5 p.m. Mr. A. Toynbee. "World Relations and World Organisation—the Racial Aspect."

WEDNESDAY, MAY 10...ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 4.30 p.m. Sir F. T. Piggott, "Neutral Merchants and the Rights of War."

Biblical Archæology, Society of, 37, Great Russell-street, W.C., 4.30 p.m. Mr. W. L. Nash, "The Totemic Origin of the Egyptian Gods."

Geological Society, Burlington House, W., 5.30 p.m. 1. Dr. F. R. C. Reed, "Carboniferous Fossils from Siam." 2. Mr. H. G. Smith, "The Lurgecombe Mill Lamprophyre and its Intrusions."

Optical Society, at the Chemical Society, Burlington House, W., 8 p.m. Dr. G. F. C. Searle, "Apparatus Used for the Teaching of Optics at the Cavendish Laboratory, Cambridge."

THURSDAY, MAY 11...London Society, at the ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 7.30 p.m. Mr. T. F. Ordish, "Shakespeare's London."

Royal Institution, Albemarle-street, W., 3 p.m. Sir E. Ray Lankester, "Flint and Flint Implements." (Lecture II.)

African Society, Hotel Cecil, Strand, W.C., 7.30 p.m. Lieut.-Col. S. M. Pritchard, "Experiences in German South-West Africa."

FRIDAY, MAY 12...Royal Institution, Albemarle-street, W., 5.30 p.m. Dr. A. C. Benson, "Vulgarity."

Malacological Society, Burlington House, W., 7 p.m. 1. Mr. G. B. Sowerby, "Descriptions of New Mollusca." 2. Mr. T. Iredale, "Solander as a Conchologist." 3. Messrs. T. Iredale and W. L. May, "Misnamed Tasmanian Chitons."

Physical Society, Imperial College of Science, South Kensington, S.W., 5 p.m. 1. Dr. H. S. Allen, "The Latent Heats of Fusion of Metals and the Quantum Theory." 2. Mr. T. Smith, (*a*) "Lenses for Light Distribution"; (*b*) "The Choice of Glass for Cemented Objectives."

SATURDAY, MAY 13...Royal Institution, Albemarle-street, W., 3 p.m. Professor W. H. Bragg, "X-rays and Crystals." (Lecture II.)

Municipal and County Engineers, Institution of (N.E. District), Hull, 10 a.m. Mr. F. W. Bricknell, "Recent Municipal Works and Practice in Hull."

London: Printed by WILLIAM CLOWES & SONS, LTD., Duke Street, Stamford Street, S.E., and published for the Royal Society of Arts by G. BELL & SONS, LTD., York House, Portugal Street, W.C., in the Parish of St. Clement Danes, in the City of Westminster.—May 5, 1916.

Journal of the Royal Society of Arts.

No. 3,312. VOL. LXIV.

FRIDAY, MAY 12, 1916.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICE.

NEXT WEEK.

MONDAY, MAY 15th, 4.30 p.m. (Cantor Lecture.) J. ERSKINE-MURRAY, D.Sc., F.R.S.E., M.I.E.E., "Vibrations, Waves, and Resonance." (Lecture III.)

WEDNESDAY, MAY 17th, 4.30 p.m. (Ordinary Meeting.) GEORGE PERCIVAL BAKER, "Hindu Hand-painted Calicoes of the Seventeenth and Eighteenth Centuries, and their Influence on the Tinctorial Arts of Europe." SIR WILLIAM MARTIN CONWAY, M.A., F.S.A., F.R.G.S., will preside.

Further particulars of the Society's meetings will be found at the end of this number.

PROCEEDINGS OF THE SOCIETY.

NINETEENTH ORDINARY MEETING.

Wednesday, May 10th, 1916; DUGALD CLERK, D.Sc., F.R.S., Chairman of the Council of the Society, in the chair.

The following candidates were proposed for election as Fellows of the Society :—

Baddeley, Miss Mary, 113, The Crescent, Denmark-hill, S.E.

Banerjee, J. C., 21, Canning-street, Calcutta, India.

Driver, Robert Manning, Cowley, Horsell, Surrey.

Madden, S. Wilbur, 76, Sparks-street, Rangoon, Burma.

See Teong Wah, J.P., 10, Balmoral-road, Singapore, Straits Settlements.

Thomas, Miss Harriet E., 48, Clark-street, Newport, Rhode Island, U.S.A.

The following candidates were balloted for and duly elected Fellows of the Society :—

Donelan, Dermot O'C., J.P., Regent Palace Hotel, Piccadilly-circus, W.; and Sylanmore, Tuam, Co. Galway, Ireland.

Phillips, S. Charles, M.S.C.I., 47, Cannon-street, E.C.

THE CHAIRMAN, in introducing the reader of the paper, said that Sir Francis was a very distinguished lawyer, who had a large experience of international law. His work for many years in the Crown Colonies, and also as legal adviser in preparing the Constitution of Japan, gave him a special right to speak on all international legal questions.

The paper read was—

NEUTRAL MERCHANTS AND THE RIGHTS OF WAR.

By SIR FRANCIS TAYLOR PIGGOTT, M.A., LL.M.,
Chief Justice of Hong Kong, 1905–1912.

The subject of "blockade" has many facets; the different points of view from which it may be studied are as variant as the twelve-times-told tale of Guido and Pompilia which, set together, make "The Ring and the Book." And so, in spite of having of late written much, I venture on this further study of it, and will endeavour to put before you what I conceive to be its evolutionary principle.

There is invariably accompanying war of arms and men a secondary warfare of wordy dispute between the belligerents and the neutral Powers. Like the bourdon which persists through the skirl of the pipes, diplomatic grumbling is heard through the din of battle; protests in respect of cargoes alleged to be wrongfully seized, of ships denied access to ports to which they allege they are lawfully bound, appear side by side with accounts of battles lost and won. Commerce thrusts itself into the teeth of war; neutral "rights," as the merchants insist on calling them, are for ever cramping the hands of the fighting men, and neutral Governments are perpetually endeavouring, with long-drawn argument, to shackle the full exercise of belligerent power. I hope I shall not shock this distinguished audience, many of whom, I am sure, are deeply versed in the writings of the jurists, when I say that, in the majority of cases, these "neutral rights" of commerce are but the very shadow of a dream.

Does it not occur to you as strangely singular that when two nations are fighting for their existence—I put no higher stake in issue—some other nation to whom the question in dispute is of no concern should be busily insisting that the commerce of its merchants is being disturbed? When the whole street is in an uproar the huckster cries his wares in vain. If the belligerents, or one of them, were setting the ideas of civilisation at defiance: if those notions of fair fighting which the world has accepted as the laws of war, were being flagrantly disregarded, then a protest from the neutral nations would be intelligible, for if those ideas are put in jeopardy they, too, must suffer. Or, if treaties to which the neutral nations are parties, whether for guaranteeing the integrity of a State, or for safeguarding those ideas on which the continued sanity of the world depends, then again a protest from the neutral nations would be intelligible. Or again, if such protest were based on material loss, as that the wanton destruction of some small State had greatly damaged the neutral traders' flourishing commerce, yet, though the standard were a lower one, the protest would at least be intelligible. But when such a protest is not made, when there is another protest of an altogether different nature, which must, were it regarded, fetter the action of one of the belligerents to the advantage of the other, which must limit the exercise of that vast engine of war, the Fleet—by means of which the command of the sea has been fairly won—then one pauses to wonder what the world is coming to. Yet again, if two neutral nations, such as Spain and Norway, whose merchants had built up a great and honourable commerce, were to find that commerce seriously impeded by a war waged across the trade-routes, that their vessels were damaged or sunk by reckless strewing of mines, or even delayed in the pursuit of their lawful avocations by continuous fighting, their protest that "neutral trade is free" and not to be interfered with by other nations' wars would, though perhaps not practical, at least be intelligible. But a protest under cover of this worthy old formula, that trade which is in no sense "neutral trade" within the true and simple meaning of the words must not be interfered with, that trade which deliberately runs counter to the means adopted by a belligerent for crushing his enemy must still be allowed to pass to him and maintain him in the fight, is a departure from that old tradition of war which, as I hope to show you, has always enabled the neutral merchant to be successfully countered in every step he has taken to supply the enemy with commodities which the belligerent has declared he shall not have. Such a protest would make the waging of war subservient to commerce. I maintain that war being what it is, and the issues of war being what they are, all commerce between neutral merchants and the enemy, whether it be direct or indirect, must be subject to the control of the belligerent—such control, that is, as he has the power to exercise at sea. If he has lost that power the battle is half lost too, and it cannot be re-won by whining appeals to a neutral Government to violate its neutrality.

Let me admit at once that what we call International Law has not as yet formulated this as its ultimate proposition; but as to its soundness as a proposition of belligerent ethics I have no doubt whatever. Like all other ultimate propositions it is *in græmio*, awaiting the occasion for coming to the birth. The occasion is with us now; for not till this War did we know the full extent of the mischief of which the neutral merchant is capable, nor with what insistence he would press for the enjoyment of what he asserts to be his "rights," on which that power for mischief depends.

This is, and is alone, the issue between the Allies and the Neutral Nations. The Order in Council of March 11th, 1915, declared that all commodities going to Germany, either direct or indirectly through neutral countries, would be seized and dealt with as by the Order provided. "All commodities" include not merely absolute contraband, but conditional contraband, and non-contraband. The United States, in its Protest of April 2nd, 1915, championing the cause of the Neutrals, claimed that "innocent shipments may be freely transported to and from the United States through neutral countries to belligerent territory, without being subject to the penalties of contraband traffic or breach of blockade, much less to detention, requisition, or confiscation." Seeing that "innocent shipments" are intended to include everything except contraband of war, to which alone it is contended that the doctrine of "continuous voyage" applies, I think I have not overstated the case.

The position of a belligerent towards the neutral nations, as it is commonly understood, is a curious tangle of circumstances which has produced many strange theories; for each nation is in turn neutral and belligerent. When it is neutral its merchants strive to serve two customers; but when it is belligerent the

Government seeks to be on the best terms with those very merchants whom it makes it its business to thwart in their dealings with the enemy. It was, therefore, not to be expected that any very lucid statement of principles could emerge from the clash of such mutable interests. It certainly put the neutral merchant in a very dominant position, of which he has not been slow to avail himself; that position has determined the tone of the American protests to the Allies. Moreover, the attempt to reduce something in the nature of principle to writing has generally been undertaken in times of peace, when the theorist comes into his own. He has always sought to govern the action of a belligerent towards neutral merchants by juristic principles, and encumbers the subject with a series of cut-and-dried propositions. As the years of peace succeeded the writings grew and grew, till the great War came and realities stared us in the face.

The thesis of this address is that the action of a belligerent towards neutral merchants is governed by belligerent principles, tempered by discretion, and that the "rights" of the matter are only to be ascertained by reference to the play of elemental forces which war sets in motion. I have stated the nature of the claim about which the projectiles of diplomatic warfare are flying, but I want to put it once again in quite bald non-juristic language. The American merchant claims to supply to the enemy, with the assistance of other neutral merchants, commodities which the belligerent has declared he shall not get; "with the assistance of other neutral merchants," because he knows that if he attempted to supply them to the enemy direct he would meet short shrift, and would at once confess himself beaten in the unequal contest of merchantmen against blockading cruisers; and, to use his own language, the belligerent would be within his rights.

War lets loose upon a suffering world two opposing elemental forces: to use the jargon of the day, the "will to profit" and the "will to win." The conflict of these forces pervades the whole subject; and you will see how always the "will to win" has won. As belligerent power has triumphed over commercial activities in the past, so it will triumph in this last struggle which is impending—for, believe me, commerce is in its last ditch. And it will triumph because —I hesitate to use the word, but there is no other—because the belligerent is in the right. Let me explain why I use it in this connection. We believe, as I shall show you presently, that there is a standard by which international disputes can be settled, and that it is the same as that by which ordinary disputes between man and man are settled. Civilised nations have created Prize Courts for the decision of disputes between neutral merchants and the belligerents. They are courts set up by the interested belligerent himself, and so they violate in principle that fundamental canon of administering justice, that no man should be judge in his own cause. And yet the nations who are on the side of civilisation have taken a pride in appointing the best men to do this justice. It remains to their everlasting credit that the reputation for being a good Prize Court judge is the greatest a judge can seek; and there have been many very great in the continents on both sides of the Atlantic. The Prize Courts are the guardians both of neutral rights and of belligerent power, and in the past have held, and in the present they now hold, an even judgment, and many are the cases which have ended in an order for restitution of the vessel. It may surprise some to hear that the "Springbok" and the "Peterhoff" were thus released.

The weapon by which a belligerent is able to control the commercial activities of the enemy with neutral merchants is sea-power; but this in its turn is controlled by practical considerations of geography. In order that you may appreciate exactly the claim of the neutral merchant as put forward by the United States, I have asked a Cubist friend to prepare this map of part of the world by help of which I hope to make things plain (see page 470).

The direct route from neutral **A** to belligerent **G** may be barred by a close blockade: to use the term to which we are accustomed, "rightfully." Now, if goods, any goods, contraband or not, are sent from neutral **A** to neutral **B** and thence to belligerent **G**, it is clear that, equally rightfully, they and the vessel carrying them will in due course be seized for breach of blockade. Therefore the contention that "innocent shipments" may be "freely transported" to and from the United States through neutral countries to belligerent territory" is not accurate. If there is anything at all in the contention it must be limited to those neutral countries, such as **H**, which are contiguous to **G**, the belligerent. At once, therefore, the proposition is "sicklied o'er with the pale cast" of suspicion.

Now, under a close blockade, it is a fact that access from neutral **A** to neutral **H** was not barred. But it is also a fact that **E**, the

belligerent, had a remedy when contraband was found going from **A** to **G** by way of the neutral **H**. The Prize Courts discovered, or evolved, the doctrine of "continuous voyage."

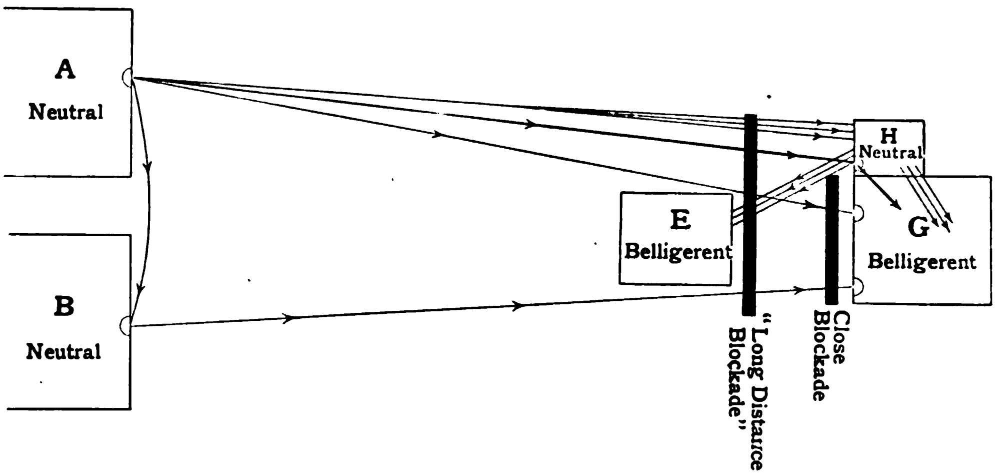

Diagram illustrating the Application of the Doctrine of "Continuous Voyage" to Blockade.

So much depends on an accurate appreciation of the meaning and of the genesis of this doctrine, the whole present dispute between the Allies and the neutrals turns upon it, so many misconceptions have gathered round it, that I shall deal with it at once.

Among the early cases in which the doctrine was established, one of the most instructive is the "William," decided by Sir William Grant in 1806. During the Napoleonic wars the British Admiralty had declared, by "Instructions to the Fleet,"* that neutral vessels should not trade between the enemy countries and their colonies. It is quite immaterial to my argument to inquire whether these "Instructions" were justifiable; they were an exercise of belligerent power, and neutral merchants recognised that if their ships engaged in this trade they ran the risk of being captured. But the ingenious owners of the "William" desired to get a cargo of cocoa from La Guira, a Spanish colony, to Bilbao; and this is how they thought to accomplish it. She first put in at the neutral port of Marblehead in Massachusetts, where the cocoa was unloaded, the ship's bottom cleaned, sugar from the Havannas taken on board, and then the cocoa reshipped, after which she set sail gaily for Bilbao and, falling in with a British frigate, got herself captured. In due course, coming before Sir William Grant, she protested that she was on a voyage from Marblehead to Bilbao, and ought not to have been captured within the meaning of the "Instructions." But that very astute judge pointed out the fallacy of the contention. "The truth," he said, "may not always be discernible; but when it is discovered it is according to the truth, and not according to the fiction, that we are to give the transaction its character and denomination." The voyage from Marblehead to Bilbao was the fiction; the voyage from La Guira to Bilbao was the truth. It was certainly a circuitous voyage, but it was a continuous voyage, and the ship was condemned.

Many such conflicts between the neutral merchant and the belligerent arose during the American Civil War. The same spirit of evasion prompted British merchants to send contraband of war to Charleston stopping at Bermuda and Nassau in the Bahamas. In one well-known case such cargo was sent on board the "Bermuda," and all sorts of ingenious documents were prepared to darken and disguise her true destination. Chief Justice Chase, of the United States, declared that the voyage of the contraband from Liverpool to Charleston did not lose its continuity because of a transhipment, or of a dozen transhipments, at neutral ports. The fact that Charleston was blockaded was immaterial. There was an enemy destination of the cargo which made the contraband seizable at any point of her voyage. And so the doctrine of "continuous voyage" came, from force of circumstances, to be applied to the cargo. The exercise of belligerent power was the declaration that contraband shall not get to the enemy,

* More precisely, "Instructions for the Commanders of our Ships of War and Privateers that have or may have Letters of Marque against France, Spain, or the United Provinces," dated March 28th, 1798.

the "will to profit" prompted the evasion—logic did the rest.

The lesson of this important decision has been wrongly learnt. It has been remorselessly criticised. More than one writer has inveighed against the infringement of precious neutral rights. All unite in declaring that the American Prize Courts created a new doctrine which stretched International Law beyond due limits; though some, I am bound to say, praise their courage and wish our courts, or at least our Government, would do likewise. I think the view I have put before you is the sounder—that there was neither stretching of old nor creation of new doctrine, nor any special courage, involved in the decision. It was simply a question of evolution: the neutral merchant wriggling to cut the meshes of the net which had caught him, the deft fisherman casting the net with logical precision still wider.

So greatly do I believe in this unerring law of evolution that I think I should here state the faith that is in me, even though it startle you. Certain technicalities alone made the Order in Council of March 11th, 1915, necessary. The main principle it laid down, together with the exceptions which I shall presently indicate—the cordon of cruisers being placed in their present stations, and due notification given to the neutrals—would infallibly have been reached by the Prize Court without the Order.

It is often said, and the Declaration of London perpetuated the sayings—first, that this doctrine of "continuous voyage" only applies to absolute contraband; secondly, that it does not apply to blockade. These are the vain imaginings of the theorists in peace time. The Order in Council has applied it even to non-contraband, and Article 19 of the Declaration of London happily received decent though tardy burial on March 30th last.

The "Bermuda" was condemned, and rightly, for carrying contraband to the enemy. But she was also condemned for an attempt to break blockade, for this reason. The American Prize Law, like the English, condemned vessels for the intent and not merely for the fact of breaking blockade. A vessel sailing from Liverpool with intent was seizable one day out. Obviously, in these circumstances, the principle of the "William" applied, and the fact that she put into neutral ports did not cure the intention. So the doctrine of "continuous voyage" in its simplicity was held, and rightly, applicable to blockade, as the American and English Prize Courts understood it.

So, if you will look at my map once more, you will see that according to American and British views as to the rightful exercise of belligerent power, a vessel starting from **A** with intent to break the blockade of **G** could have been seized between **A** and **B**, and her sham neutral destination would not have availed her. The importance of this is not lessened by the fact that we have adhered to the principle of the Declaration of London, that a vessel is now seizable only when she is caught within the area in which the blockading forces are operating.

This inquiry lets a little light on the claim of the United States as to "innocent cargoes," and justifies suspicion of the proposition. It is not to supply them to the enemy merely with the assistance of other neutrals, but with the assistance of those neutrals only who are contiguous to the enemy, and therefore are in a better position to assist in the evasion of the exercise of belligerent power. There is a little rift in the lute; the note of protest is not quite so pure and undefiled as we were led to suppose. There is a quaver in the rendering of that good old song about the freedom of neutral trade. Can we not see the "will to profit" busily at work? Have not the wits of the neutral merchant been sharpened by the geographical fact that there is only a land frontier between **H** and **G**, which prevents the Tyrant of the Seas exercising her sea-power?

Now, looking at the question merely as the play of elemental forces, this is the most natural development in the world. Putting all questions of "right" on one side, it is a very natural attempt at evasion, which the belligerent will naturally and legitimately endeavour to counter. But I protest against the evasion being padded out with old formulas which have nothing whatever to do with the question. The consequences of the geographical fact are plain on both sides; and I maintain that the consequence for the belligerent is that as his sea-power cannot be exercised to stop supplies going from **H** into **G** in the same way as it can stop them going from **B** into **G**, it *must* be exercised before they get to **H**; cargoes going to **H** with an enemy destination *must* be intercepted.

At this point a little analysis will be profitable; and I put this question, What foundation is there for the assertion that trade between the neutral merchant and the enemy in any form is a "right"? Trade is bilateral; it is made up of a vast series of contracts; and what is true of one is true of the mass.

I must, however, here interpose the remark

that if all contracts which related to supplies of any kind to the enemy were made f.o.b., much of the trouble would be removed. The property in the cargoes having passed out of the vendor we should have nothing to deal with but enemy property. I have quite enough on my hands without raising the ghost of the Declaration of Paris; but I may say that, by the light of what we know now as to the inner meaning of non-contraband, the notion that the neutral flag covers enemy goods except contraband is contrary to the spirit of neutrality. The legitimate counter-stroke is the exercise of the right involved in blockade; for that right annihilates the doctrine of the Declaration that "free ships make free goods."

But with regard to trade which is carried on by the neutral merchant who does not avail himself of the contract f.o.b., if it is true to say that he has a "right" to have his contract left intact by the belligerent, so also must the other party to the contract, the enemy, have that right. But this is negatived by contraband and blockade. The "right" of the neutral merchant must, therefore, be a very one-legged business, and the only way in which the body of it can be kept standing would be by substituting the belligerent in the contract for the enemy—pre-emption in fact. But President Wilson likes pre-emption no more than he does condemnation. Let us, however, be serious. Is a person to be heard to say to a State, "You cannot put that man in prison or condemn him to death, because he is under contract with me to perform certain duties"? If he cannot say this to a State in peace, how can he say it to a State at war? Yet that is what the neutral contractor in effect says to the belligerent.

Oh, but, it is said, seizures in the case of contraband and blockade are the result of a "compromise." The materials for a compromise in such a matter between neutral merchant and belligerent are not very promising. Even a compromise between the belligerent and neutral Governments will not hold water, for a neutral Government does not protect its merchants when they carry contraband or break blockade. It simply abandons them to their fate: withdraws, as it is called, the protection of its flag. And their fate is decided for them by the belligerent.

But I put this further question: Why is interference with the belligerent right of war to be tolerated? War hath her rights not less inviolable than peace. Do not such epithets as "lawful" and "innocent," when applied to trade which does in fact interfere with the conduct of war, beg some question which has as yet never been fully stated? "Lawful" undoubtedly does; and as for "innocent" it means not harmful. Is not this term disposed of by the consideration that the right of judging whether harm will result from neutral trade must rest with the belligerent—cannot be with the neutral merchant? And this consideration is admitted on all sides to be sound, because the list of contraband and the declaration and extent of blockade are within the discretionary right of every belligerent.

Have I not said enough to show that what the United States really claims is this: that, although the belligerent can stop all cargoes going direct from the neutral merchant to the enemy, yet he may not stop them when they are going indirectly? Such a claim is based on evasion of belligerent power, and evasion cannot be raised to the dignity of a "right."

The only accurate appreciation of the facts is, that seizure of all cargoes going direct or indirectly to the enemy is the exercise of the primeval right to treat any one who assists my enemy as being himself my enemy.

But I will not plead guilty to the charge of heterodoxy; I have protested against the misuse of the term "right," not so much against its use. "Law" has been in such constant use since the subject came first to be discussed that it is not lightly to be abandoned. What is law? It is the determination where right lies in the ever-varying circumstances of human life. The primary right not to be interfered with in the doing of anything which is not unlawful often entirely disappears under the influence of the general maxim *sic utere tuo ut alienum non lædas*. It is only in this restricted sense that you have a right to use the King's highway; but, if you do not violate the statute of the land, you may even use it unlawfully, or rather negligently, as by tying up a donkey in the middle of the road, or by riding furiously along it, so long as there is no one in the way. But the secondary or positive rights spring from the circumstances of daily life, and vary with them; and if the circumstances some fine morning should evolve this curious coincidence, the negligent tying of the donkey in the road and the furious rider along it, resulting in a collision in which both donkey and horse are killed, it is conceivable that the owner of each should bring an action against the other; the judges would then have to disentangle the threads of circumstance in order to determine the resultant rights.

Now in the matter of negligence and contributory negligence the Courts have hit out these rules for dealing with them:—first, the defendant being negligent, he is liable for the damage suffered by the plaintiff; but, secondly, the plaintiff's duty is to avoid the defendant's negligence if he can, or he will be held to have been contributorily negligent; but, thirdly, the defendant's duty in his turn is to avoid the plaintiff's contributory negligence if he can, or he will not save himself from the consequences of his original negligence.

I see in these common law pedestrian cases (*Davies* v. *Mann* and *Butterfield* v. *Forrester*) a clue to the problem of the rights and duties of nations in this conflict between commerce and war. We have always maintained that the springs of right which should govern the conduct of nations are the same as those which govern the conduct of the individuals which compose them. One branch of the British argument in the Behring Sea dispute, where the question was what rights of property a nation could claim over the seals when they left their breeding-grounds on the Pribyloff Islands for the Pacific Ocean, was entirely based on the analogy of the law as to the coneys, and of the rights of an owner of decoy ponds as declared in the suit of *Keeble* against *Hickeringill*. The principles governing the duties of man in the infinite variation of human action must also govern the duties of nations in the infinite variation of national action. This is what I take International Law to be; and I presume that these are the principles on which the Hague Tribunal will act, the circumstances arising. There is no international law of contract or of tort, nor any international criminal law, which differs in its principles from municipal law. The invasion of Belgium by Germany, reduced to its essence, was trespass on a national scale, far removed in degree, but the same in quality as the trespass, long years ago, of the villagers who followed Oldacre, huntsman of the Berkeley, over the property of Mr. Hume.

The reason, then, why I seek in the subject in hand an analogy from the common law of contributory negligence, is that the law, with its acute perception of the springs of human action, finds in them an alternate, almost rhythmic beat of cause and effect—effect transmuted into cause, and so on in endless series; and in the rules of evidence, the machinery for ascertaining the right, the burden of proof is perpetually shifting from one side to the other. This alternating beat is palpable in the law of contraband. Reduced to its essence, it is the result of the perpetual conflict between commerce and war, the alternating rhythm in the play of those larger natural forces which engender wars and the desire to profit from them. You will find clearly traced the interference of the trader in the conduct of war countered by the belligerent; the counter evaded by the trader; the belligerent countering him once more, and so on; evasion, prompted by the "will to profit," and counter-stroke, prompted by the "will to win," in regular recurring series, as I will endeavour now to show you.

I assume fighting and trading to be elemental forces, and I premise only these two primary rights to evolve from them: that of a belligerent nation not to be interfered with in its war; that of a neutral merchant not to be interfered with in his legitimate trade.

I assume, further, that if a belligerent were to interfere deliberately with the normal trade of one neutral merchant with another it would give rise to a just ground of complaint.

The belligerent power to which I refer may, of course, be exercised by both belligerents; and the trade of the neutral merchant may also be with both belligerents. But, for convenience, I deal only with the case of one belligerent to whom the balance of sea-power has left the command of the sea; and him I refer to as "the belligerent"; his adversary who has lost command of the sea I refer to as "the enemy." The "neutral" is the neutral merchant of any State, but not the State itself.

It is not difficult to see how these two elemental forces came early into conflict. Alberic Gentilis tells us* that in the time of the Armada the traders helped the Spaniards both with provisions and munitions of war, and that the English "requested" them to desist. The traders replied that the request was against the law of nations and a violation of the freedom of trade. Whereon Gentilis remarks—"An all-important question this. Equity was with the English; strict law was with the traders. The latter wished to avoid the loss of the profits of their commerce; the former objected to the doing that which imperilled their safety. The rights of traders are to be respected, but still more the safety of the State." I do not know where Gentilis got his "strict law" from; but he certainly appreciated the natural principle which all the world from all time has recognised—the right of self-defence; and he puts the

* I have availed myself here of Dr. Walker's valuable "History of the Law of Nations."

justification for the attitude of the English expressly on this ground, calling it "equity."

From this point development must have been along two inevitable channels. The merchant would appeal to his Government to help him recover his goods; the belligerent would also appeal to that Government to keep its traders within its own neutrality. The Government would point out to its merchants that action on its part would imply justification of their trading, and be inconsistent with its neutrality towards the belligerent; and to the belligerent it would answer, "If we stopped our merchants trading we should be helping you, and that would be inconsistent with our neutrality towards your enemy." So the trader, neither forbidden nor protected, followed the lure of the dollar and ran the risk; and, seeing that the belligerent could not deal with him in the neutral country, the risk he ran was at sea, when the belligerent's cruisers were about. His cargoes were seized.

But what of the "freedom of the sea" and the jurisdiction of the national flag? The jurisdiction of the flag depends for its specific exercise on express municipal enactment, and in this case there is none; the protection on which the freedom of the sea depends is withdrawn.

These principles are condensed into the formula: a neutral merchant sends contraband to the enemy at his own risk at sea; or, if it has been sold f.o.b., at the risk of the consignee.

At this point a positive right has developed out of the circumstances of war, known as "the right of search"; and a correlative duty to submit to search under penalty of being fired into and compelled to heave to. The recognition of the power to seize has engendered this logical train of reasoning. In order to capture contraband on its way to the enemy you must first ascertain by examination whether there is anything to capture. This right is an outcome of, this duty is a recognition of and submission to, the right of war; and from its nature all neutral vessels submit to it anywhere on the high sea; though discretion and practical considerations have limited its exercise to vessels with enemy destination.

All this sounds very arbitrary when it is stated in so many words. But when words are translated into practice we know that there is an Intelligence Department with infinite ramifications whose researches turn suspicion in a multitude of cases into certainty. With a curious inversion of logic one of the by-arguments of the American Protest seems to insist that you ought not to suspect until you are certain.

Note here that this submission to the right of search has led to the evolution of the duty to search, the omission of which lies at the root of the German "frightfulness" at sea. Note, too, one natural development of power. Search would, in ordinary circumstances, be conducted at sea. But the growth in the size of ocean steamers and the complexity of their cargoes have made it necessary to bring ships into port for examination; and it has been skilfully pointed out in the recent British reply to the United States that this is in reality yet another example of the manner in which belligerent power must and will counter the evasions of the neutral merchant. Search for contraband at sea has become increasingly more difficult, evasion increasingly more easy. Copper can be concealed in bales of cotton, rubber in trusses of hay. *Therefore* the search must be more thorough; *therefore* it must be conducted in port.

Another development is to be noted in regard to the list of contraband itself. The power of declaring what goods shall not go to the enemy rests with the belligerent. Why? For the simple reason that, being at war, he *will* do so. To say that the artificial ideas which have engendered conditional contraband and the "free list" are to bind the belligerent for evermore is to say that war is to stand still while the world goes round. War is no longer conducted by standing armies. Nations are now in arms. But, say the purists, "munitions of war" is a fixed definition, and must never be enlarged. According to them "foodstuffs" are only conditional contraband; and raw cotton, oil seeds and nuts, and rubber, and metallic ores are on the "free list." Perhaps it is better to drop the curtain at this point over the vain endeavours of the Declaration of London to achieve the impossible.

But the important developments, wherein the alternating shock and counter-shock of the elemental forces are so clearly visible, are to be found in the emergence and gradual amplification of the doctrine of "continuous voyage."

The belligerent declares that he will seize contraband going to the enemy. "Very well," says the neutral merchant, "I will send them to a neutral country first. 'Neutral trade is free,' and a neutral country wants all sorts of things, including munitions of war for its own protection. Therefore, if my vessel is bound for a neutral port, the idea of enemy destination must be negatived." Most ingenious; and still

more ingenious if a neutral port is selected at a nicely convenient distance from the enemy ports, so that the risk of seizure is reduced to the short run in; because contraband destined for the enemy is seizable anywhere on the high sea, and the risk would then be eliminated all the way from Liverpool to, say, Nassau.

Not thus are Prize Court judges easily deceived. *Prudens simplicitas!* To imagine that because a ship bound for Charleston puts in at Nassau she is not bound for Charleston! A devious voyage truly, but nevertheless a continuous one. Thus the simple evasion was countered, and the Prize Court wins the stroke.

Whereupon the neutral merchant says to his agent in the neutral port, "let us tranship the cargo into another vessel, and then send it on to our friend the enemy." The evasion was too palpable, and the long arm of the Prize Court condemned these "innocent cargoes." True it was that the enemy destination of the cargo had previously been inferred from the enemy destination of the vessel which carried it; but though you tranship it into another vessel, the enemy destination of the cargo is not changed. Nor is it changed if you were to tranship it a dozen times at a dozen neutral ports, of which one might be St. George in Bermuda and another Nassau in the Bahamas. Thus was this new evasion countered, and the Prize Court wins the second stroke.

Undefeated, the merchant was prompt with a fresh evasion. There shall be something more than a mere transhipment; the goods shall pass into the Customs, pay duties, do everything needful to hoodwink the watchful frigates. But the logic of the Prize Court was inexorable. "Not so, my friend; lightly come may lightly go. The payment of the extra shipping charges does not deceive us; the enemy wants these goods, and what do a few thousands of pounds more or less matter in war? If, as you say, these cargoes are really for the neutral, when they would be 'neutral trade' and free, they must be going into the 'common stock' of the neutral port; thus alone can we be sure that they are not going to the enemy." So was the third evasion countered, and the enunciation of the "common stock" principle gave the Prize Court yet another point in the game.

Let us note, by the way, that all this time the neutral merchant's Government has been sitting with hands folded, merely watching the game, and seeing fair play.

But now comes the turn of the neutral merchant to score. If "not unmoved, yet undismayed," he sets his wits to work once more, and finds the way of evasion open before him. You follow the conditions: the vendor in the neutral country, the enemy purchaser, the confederate in the intermediate neutral port. Between them they arrange that the cargoes shall pass into the common stock of the neutral port, and that presently, when vigilance is relaxed and suspicions are allayed, they shall come out of it again. Nothing could be much simpler for three sharp-witted men. The necessary secret arrangements between neutral vendor and enemy purchaser with the neutral merchant at the intermediate neutral port are not very difficult to imagine or to carry out. The purchaser is the enemy; it is a gratuitous assumption that the vendor is neutral; it is equally gratuitous to assume that the intermediary agent is neutral, or even innocent; he also may be an enemy ensconced in the neutral port to carry on the business of the Fatherland.

But before giving my reasons for believing that the Prize Court must win the last stroke in the game, I must pause to deal with the question of blockade. From its nature there has been no scope for the play of the elemental forces. It was just a simple struggle between belligerent and neutral merchant: pull devil, pull baker. The belligerent declared his intention of seizing all vessels and all cargoes going to the blockaded coast; the merchant declared his intention of getting his cargoes through the blockade if he could. All clumsy disguises were thrown to the winds, no subterfuges were necessary; the merchant (I beg you to note that he still persists in calling himself a "neutral" merchant) is going to run the blockade, and take the risk of seizure.

Developments have, however, arisen owing to the increase of weapons of defence employed by the enemy to destroy the effect of the blockade on himself, and so enable the merchant to reach his ports unmolested. The "imminent danger" to vessels trying to get in—the characteristic feature of blockade—may be entirely eliminated by the creation of an offensive force of submarines, aircraft, mines, and swift cruisers, operating against the blockading squadron. The inevitable result has been to push the squadron farther and farther out to sea.

Now, the United States Government admit the imperious force of circumstances; they agree that the blockading squadron need no longer stay in the offing; but they put it no higher than this, that the ships may be moved out of

harm's way, for they see that if it were to be justified on broader grounds the consequences to their contention would be so formidable that it would crumble away. For when the squadron moves seaward from the offing access to neutral ports will be barred, and so apparently the whole gospel of blockade will be scattered to the four winds of heaven.

But the United States Government propose the simplest of methods for picking up the pieces—free entrance and exit through the blockading squadron must be allowed to neutral traffic. Hence the famous postulate about "lawful traffic" and "innocent cargoes."

But let me remind you that we already know a good deal about this formula, and find it no true postulate at all, but only a thin screen of words devised to hide the truth that the neutral merchant intends to use the land frontier between neutral **H** and belligerent **G** for all it is worth. And we are agreed that evasion of belligerent power cannot involve the elimination of that power from its legitimate field of action. The inevitable conclusion I suggested as the result of the neutral merchant's action was that all cargoes going from **A** to **H** with an enemy destination *must* be stopped. And here, following the law of development along another channel, the method of stopping them has been found.

We are dealing with elemental forces, and I confess that I do not value at two pence considerations such as this: can this be called a "blockade" in the strict sense of the term? or this, that those old hampering conditions attached to blockade preclude us from using this new manifestation of power to its utmost; or this, that the geographical configuration of the group of neutrals which cluster round the enemy makes it impossible to enforce the blockade with equal rigour against all neutrals, for the old rule only forbad deliberate partiality between them. The base right is this, that from time immemorial cutting off *all* supplies from the enemy has been recognised as a belligerent right. The neutral merchant and the enemy between them, with the assistance of a well-paid third party, have devised means for evading the exercise of this power; they persist in getting goods across the land frontiers, or through the territorial waters, of contiguous neutral countries; therefore they must be stopped, and the "long-distance blockade" is the obvious method of stopping them. Any attempt to control this exercise of power by reference to old formulas, or to antique definitions which cling like barnacles to the word "blockade," is merely a confusion of means with the end. And specially in regard to that old definition that "blockade may not bar access to neutral ports," the simple answer is that the close blockade never intended to.

And this brings our old friend the neutral merchant once more upon the scene. He had to submit to blockade because he could not help himself. But this new development touches him even more acutely, and he protests. Now part of his protest is perfectly sound: trade between neutral and neutral must not be interfered with; nor is it. Free exit and entrance must be granted, and is granted, to ships in that trade, because "neutral trade is free." But we have already got the measure of the subtlety of the neutral merchant's mind. We know what he means by "neutral trade," and how the doctrine of "continuous voyage," with its attendant principle of "common stock," gradually emerged to check his version of it, which was that it covered his trade in contraband with the enemy through neutral countries. It is the same old story once again: the same attempt to treat the merchant's interest in his contract with the enemy as distinct from the enemy's interest; to maintain that though the belligerent may stop the enemy receiving commodities from the neutral, yet he must allow the neutral to send them to the enemy. The American view of the "long-distance blockade" is that it is merely a development of defence against the growing power of the enemy which must not affect the neutral merchant. The sounder view is that it is a development of offensive power necessitated by the new circumstances in which neutral trade with the enemy is carried on—the increased importance of contiguous neutral countries in regard to conveying supplies to the enemy; the increased danger to the belligerent of a meaningless doctrine which got itself into, and has now been got out of, the Declaration of London, that the doctrine of "continuous voyage" does not apply to blockade. Such a development must affect the neutral merchant's indirect trade with the enemy, because it is in fact a deliberate check to the enemy receiving supplies indirectly from the neutral merchant. The doctrine of "continuous voyage" is an integral part of the new blockade; it is its meaning and intent; it would have been sheer madness had it not been made part of the Order in Council.

The doctrine of "continuous voyage" must apply to the stopping of *all* supplies as it does to the stopping of *some*, because, in plain language,

it is a check to devious trading. The sum and substance of the American claim is that the American merchants may trade with the enemy deviously although we have declared that the enemy shall not receive *any* supplies. You see how that idea that the doctrine of "continuous voyage" does not apply to blockade hampers us; you see now, I think, clearly why a regular blockade has not been declared, and why Article 19 of the Declaration of London has now been discarded.

The point I have endeavoured to make good so far is that blockade and contraband are in their essence only different manifestations, varying in degree, of belligerent power, and that whatever rules apply to the one cannot be arbitrarily excluded from the other. The test whether goods destined for a neutral country shall be allowed to pass through the "long-distance blockade" must, therefore, be whether they are destined to go into the "common stock" of the neutral country.

I now take up the thread of the question of contraband.

I have on two occasions quite recently explained how what the text-book writers are pleased to call "the law" stood at the outbreak of war. But it is of such infinite importance that the difficulties which faced the Government, and still face them, should be understood, that I venture for a third time to refer to it. It was not so much that in preparing the Declaration of London the theorists played havoc with the rights of war; it was their occult interpretation of the terms used which cramped belligerent action.

Article 30 of the Declaration of London declared that absolute contraband is liable to capture if it is shown to be destined to the enemy, whether the voyage be direct or indirect. But the commentators, with whom the protection of the rights of neutral merchants had become an obsession, who ignored altogether the existence of belligerent rights, had spun a web of theories round the term "enemy destination" which, in spite of the respect in which we hold some of their names, can only be described as fantastic. Here is what Westlake writes in the second edition of his book on "War," published in 1913: "When goods on a ship destined to a neutral port are consigned to purchasers there, or to agents who are to offer them for sale there, they have only a neutral destination; they have gone into the common stock of the country. If they ultimately find their way to a belligerent port, or to a belligerent army or navy, it will be in consequence of a new destination given them, and this notwithstanding that the neutral port may be a well-known market for the belligerent in question to seek supplies in, and that the goods may notoriously have been attracted to it by the existence of such a market. The consignors of the goods to the neutral port may have had an expectation that they would reach the belligerent, but not an intention to that effect, for a person can form an intention only about his own acts, and a belligerent destination was to be impressed on the goods, if at all, by other persons. Therefore it is not contended by anyone that on the way to the neutral port there will be a right of capture, *whatever the character of the goods.*" I beg you to note that all this applies to contraband of war!

It is impossible to imagine that any such fine-drawn rule will bind a nation at war; it is preposterous to suppose that a nation at war, when its existence is at stake, will sit quietly by and see these things going to the enemy, and console himself with the reflection: "Ah, well! he is entitled to them." On the face of it such a rule could never be accepted. *Placuitne gentibus?* Have the nations agreed to this indirect supplying of the enemy with munitions of war? Surely, No. The life-law of States, the right of self-defence, negatives the possibility of such a rule coming within the range of International Law—would justify its disregard even were the possibility admitted. Some things are lawful for belligerents to do, and some things are not lawful; yet there is an imperious necessity which impels nations, and men too, to do them and stand the racket.* If there is no other way out of the difficulty, the thing will be done and the consequences taken so long as the imminent danger be averted. The history of every country abounds in them. There is the case of Amelia Island and the adventures of the bold buccaneer McGregor in 1817, when Buenos Ayres and Venezuela were insurgent colonies of Spain; there is the case of the "Caroline," which in 1838 was seized by the Canadian authorities in a United States port, set on fire, and sent over the Falls of Niagara; there is the punishment of the Pensacola Indians in 1815, and the destruction of the forts on the Appalachicola River; and the case of Greytown, and of the British Orders in Council of 1807; and

* The right of self-defence, which Gentilis recognises as the foundation of all interference with neutral trade with the enemy, but which modern commentators persistently ignore, holds so paramount a position in the subject that I have ventured to incorporate at this point a passage from my letters to the *Times* in 1893, which summarised Sir Charles Russell's argument in the Behring Sea Arbitration.

there is the case of Mason and Slidell on board the "Trent." All these were as wrong as wrong could be, judged by any rule of International Law, and yet fulfilled the test of legitimate self-defence which Mr. Webster laid down in the case of the "Caroline"—that the necessity must be "instant, overwhelming, leaving no choice of means and no moment for deliberation." These are the things that a nation will do when it is forced by circumstances and yet remain on the side of the angels, nor lose one particle of its national honour. I maintain that if there were such a rule as is claimed by the authors, then the Government of a State would be mad if it sat quietly by and acquiesced in the enemy getting the supplies it urgently needs from neutral merchants, whether they be contraband of war or not.

But I need not take such high ground in defence of the Order in Council. I maintain that this imaginary rule is bad because it is impotent to bind, because it invites disobedience at the first stressful moment of war, and that it will not stand the most elementary test even as a principle of guidance. I maintain that it is illogical, that it divorces plain words from their most plain meaning. "Enemy destination" means that the goods are going somehow to get to the enemy.

The Order in Council swept these theories into the limbo of forgotten things, and from March 11th, 1915, the British Government with the Allies asserted the wider, bolder, truer doctrine—truer, because there are a dozen ways in which the good intent of the "common stock" principle could be evaded, and under cover of it goods be sent deliberately to the enemy. "Enemy destination" means exactly what it says, and says exactly what it means; and what it means is this—that if there is an intention, or a hope or certain expectation, I care not in which of the many parties who may be interested in a cargo, that the goods shall get to the enemy, then "enemy destination" is impressed on them. If the enemy himself, or anyone acting on his behalf, has any part or share or interest in the contract, then the destination needs no further proof.

Bear with me a few moments longer while I remind you how the game stood when we last saw the neutral merchant facing his opponent, the Prize Court. He was losing heavily; every stroke had gone against him. Evasion after evasion had been countered, not by arbitrary decision, but by a remorseless logic which followed him step by step. Yet it seemed as if he had a chance of winning the last stroke, the chance being that logic should cease to work and the Prize Court fall a-napping. The odds, too, you will remember, were in his favour: the learned authors and the theorists had backed him to win, and that unhappy Article 19 of the Declaration of London was equal to a stroke in hand. But now we have come to analyse his play, what have we found? Nothing but the same old trick; always the endeavour to get in below his opponent's guard. And as the Prize Court has defeated him in the past so I believe it would have defeated him in the present. As I have already said, my faith in the law of evolution is such that, even if there had been no Order in Council, I am certain that the Prize Court would have arrived inevitably at the conclusion that the doctrine of "continuous voyage" is and must be applicable to the "long-distance blockade," and that it would be able to say, as Sir William Grant said in the case of the "William" in 1806: "On the whole, I trust, I have demonstrated . . . that we do not in the case before us depart from any principle which we have ever adopted."

So much for the case which is made against us by the Government of the United States on behalf of its traders who use its name and its flag in vain. There still remain two classes of critics among our own people—those who say we are trampling on neutral rights, and those who contend that our policy is not vigorous enough.

To those who say, "Are, then, neutral merchants at the mercy of belligerents?" I answer, No. That old formula, "neutral trade is free," is still a live principle even of the most belligerent action. And it follows from every word I have said that the test of "rightness" by which that action is to be judged, and will be judged by history, is the respect which the belligerent pays to it. Between the neutrals A and H there is a vast amount of normal trade which does not touch even the fringe of war, because it does not in any way, however indirect, aid the enemy. That trade must be left inviolate, and is so left.

And now for those who cry aloud for a still more vigorous policy, and declare that many things are getting through the blockade to Germany. It would be most injudicious, to say the least — it would be a flagrant disregard of the rules of this ancient and Royal Society, to say the highest—were I to plunge into the controversy of figures which the unofficial asserts, and which the official

denies, show that there is an amount of goods getting through to Germany in spite of the blockade because of its weak enforcement. But there is so much genuine misunderstanding of the whole subject that I think I may, consistently with the rules of propriety, point out the theoretical aspect of this thorny question.

Between the two extremes—on the one side, purely genuine neutral trade; and, on the other, the trade which by many devious devices is in fact benefitting the enemy, but to which the doctrine of "continuous voyage" may legitimately be applied—there are a multitude of doubtful cases in which both elements are more or less present. I have tried to indicate them on my map by these two sets of lines which show what the "common stock" principle really means, and how at a given point the doctrine of "continuous voyage" must fail to help us. All those lines from **A** which stop at the coast-line of **H** represent genuine neutral trade which must not be interfered with; and all those lines between **H** and **G** represent lawful trade, even though it be in contraband of war. And, further, there is the mass of normal and abnormal trade shown by the lines between **H** and **E** which it is essential to ourselves to preserve. These are the ingredients of the problem with which the Government of the belligerent **E** is faced. It must, if it can, destroy the trade between **H** and **G**; it could do it unlawfully by cutting off all the trade between **A** and **H**; but—and this is the point which is so often forgotten—trade is in the hands of the neutral merchants, and not of the neutral Government; it is essential to preserve friendly relations with those merchants. They are not bound to continue either the trade between **H** and **E** or between **H** and **G**. It is a question of bargaining, of offering advantageous terms; it is a question for arrangement, for agreement, for "rationing," if they will acquiesce in it. There is a point at which the exercise of power fails the belligerent; the only way to achieve his purpose is by fair means. He must no longer be the strong man armed; he must agree quickly, and while there is yet time, with the neutral merchant within his gates.

DISCUSSION.

Mr. Arthur Hudson, K.C. (late Attorney-General of the Gold Coast), in opening the discussion, said the author had given an excellent exposition of the subject with which he entirely agreed. No one, whether layman or lawyer, who had listened to a story told with such graceful wit and lightened by such delightful imagination, could fail to derive great pleasure and benefit from it.

Mr. John Leyland thought the author had shown in the clearest possible light the conditions which existed between belligerents and neutral powers. Much was heard in every war of the rights of neutrals, but very little of the rights of belligerents, and Sir Francis had most clearly dealt with that point of view. Like the last speaker, he agreed entirely with everything the author had said.

The Chairman (Dr. Dugald Clerk, F.R.S.), in proposing a hearty vote of thanks to the author for his most instructive paper, said he had listened to many interesting papers of a similar type, but he had never heard a more clear and logical account of a very thorny subject than that delivered by Sir Francis. The clever attempted evasions of neutrals were clearly dealt with, and it was possible to see at once how wrong the American contention was. The American objection to the belligerents stopping trade with neutrals, and the assertion that belligerents had no right to assume that goods were on board a ship without actually knowing it beforehand, appeared, at first sight, very plausible, but on analysis they were proved to be absurd. The author had clearly shown how justifiable the Order in Council was in dealing with such trade in the manner it did.

The resolution of thanks was carried unanimously, and Sir Francis Piggott having briefly acknowledged the compliment, the meeting terminated.

GENERAL NOTE.

Tobacco Fertiliser from Indigo Plant.—The residue of the indigo plant, after the extraction of the indican, known commercially as indigo, is used in the Karachi district, and probably also in other parts of India, as a fertiliser for the tobacco plant, says the United States Consul at Karachi in a recent report. This substance is known locally as "seeth." The roots of the tobacco plant require free access to air, and seeth breaks up the ground in a way which allows the air to penetrate. Experiments have been made recently by the Agricultural Research Institute at Pusa with the object of securing better results from the use of seeth. The substance has been used for years by the natives, but little scientific work has been done in India until the last ten years. The experiments so far indicate that tobacco soil in which seeth and bits of broken tile or broken chatties (baked clay water-jars) are mixed produces better crops than soil under no special treatment. The cost is moderate, and the results achieved warrant the

extra expense. A plot of tobacco land near Pusa was treated in this way nine years ago, and has shown marked superiority over adjoining plots ever since. Indigo, adds the Consul, has had a remarkable "boom" since the war began, and the amount of seeth available as fertiliser has increased accordingly.

MEETINGS OF THE SOCIETY.

Ordinary Meetings.

Wednesday afternoons, at 4.30 p.m.:—

May 17.—George Percival Baker, "Hindu Hand-painted Calicoes of the Seventeenth and Eighteenth Centuries, and their Influence on the Tinctorial Arts of Europe." Sir William Martin Conway, M.A., F.S.A., F.R.G.S., will preside.

May 24.—John Collett Moulden, A.R.S.M., M.Inst.M.M., "Zinc, its Production and Industrial Applications." (Peter Le Neve Foster Prize Essay.) Dugald Clerk, D.Sc., F.R.S., Chairman of the Council of the Society, will preside.

Indian Section.

Thursday afternoon, at 4.30 p.m.:—

June 1.—Professor Wyndham R. Dunstan, C.M.G., M.A., LL.D., F.R.S., "The Work of the Imperial Institute for India." The Right Hon. Lord Islington, G.C.M.G., will preside.

June 23 (Friday).—Sardar Daljit Singh, C.S.I., "The Sikhs."

Cantor Lectures.

Monday afternoons, at 4.30 p.m.:—

J. Erskine-Murray, D.Sc., F.R.S.E., M.I.E.E., "Vibrations, Waves, and Resonance." Four Lectures.

Syllabus.

Lecture III.—May 15.—*Waves in the Ether.* Free and conducted—Light, heat, and electric waves—Alternating currents—Telephonic transmission—Wireless telegraphy—Submarine cables—Inductance, capacity, and resistance—Limits of known wave-lengths—Röntgen rays—Light—Heat—Reflection, refraction, and diffraction of wave motions—Stationary waves—Attenuation and distortion of travelling waves.

Lecture IV.—May 22.—*Resonance.* Mechanical and electrical—Superposition of periodic impulses—Universal importance of the selective absorption of wave motions—Mechanical resonance or revibration—Screening of vibrations, absorption, and filtration—The acoustics of buildings—Sound resonators—Absorption of light waves—Coloured glass—Vision and photography—Absorption of electrical power by resonance—Tuning in telegraphy.

MEETINGS FOR THE ENSUING WEEK.

Monday, May 15...Royal Society of Arts, John-street, Adelphi, W.C., 4.30 p.m. (Cantor Lecture.) Dr. J. Erskine-Murray, "Vibrations, Waves, and Resonance." (Lecture III.)

Tuesday, May 16...Statistical Society, 9, Adelphi-terrace, W.C., 5.15 p.m. 1. Sir J. Athelstane Baines, "The Recent Trend of Population in England and Wales." 2. Mr. J. W. Nixon, "War and National Vital Statistics, with Special Reference to the Franco-Prussian War."

Institution of Petroleum Technologists, at the Royal Society of Arts, John-street, Adelphi, W.C., 8 p.m. Mr. A. Campbell, "Petroleum Refining."

Royal Institution, Albemarle-street, W., 3 p.m. Professor C. S. Sherrington, "Unconscious Nerves—their Functions in Internal Life." (Lecture I.)

Anglo-Italian Literary Society, 22, Hyde Park-square, W., 5 p.m. Signor Gino Calza-Bedolo, "Con l'esercito italiano alla fronte di Gorizia."

Economics and Political Science, London School of, Clare-market, W.C., 5 p.m. Mr. C. D. Burns, "World Relations and World Organisation—the Political Aspect."

Wednesday, May 17...Royal Society of Arts, John-street, Adelphi, W.C., 4.30 p.m. Mr. G. P. Baker, "Hindu Hand-painted Calicoes of the Seventeenth and Eighteenth Centuries and their Influence on the Tinctorial Arts of Europe."

Meteorological Society, 70, Victoria-street, S.W., 4.30 p.m. Mr. L. C. W. Bonacina, "On the Re-adjustment of Pressure Differences: Two Species of Atmospheric Circulation and their Connection."

Microscopical Society, 20, Hanover-square, W., 8 p.m. 1. Mr. J. W. Purkiss, "Some Suggestions regarding Visual Efficiency in the use of the Microscope and other Optical Instruments." 2. Mr. A. T. Watson, "A Case of Apparent Intelligence exhibited by a Marine tube-building Worm, Terebella conchilega." 3. Rev. H. Friend, "Alien Oligochaets in England: Dichogaster lageniformis sp. n."

Literature, Royal Society of, 2, Bloomsbury-square, W.C., 5.15 p.m. Professor W. L. Courtney, "Dramatists and War."

Thursday, May 18...Chemical Society, Burlington House, W., 8.30 p.m. Lecture by Professor F. Gowland Hopkins.

Royal Institution, Albemarle-street, W., 3 p.m. Sir E. Ray Lankester, "Flint and Flint Implements." (Lecture III.)

Historical Society, 7, South-square, Gray's Inn, W.C., 5 p.m. Mr. B. Williams, "Minorities in War-time. A Study in Political History."

Friday, May 19...Royal Institution, Albemarle-street, W., 5.30 p.m. Colonel E. H. Hills, "The Movements of the Earth's Pole."

Mechanical Engineers, Institution of, at the Institution of Civil Engineers, Great George-street, S.W., 6 p.m. Mr. D. Adamson, "Spur-Gearing."

Saturday, May 20...Royal Institution, Albemarle-street, W., 3 p.m. Professor H. S. Foxwell, "The Finance of the Great War—New Problems and New Solutions." (Lecture I.)

London: Printed by William Clowes & Sons, Ltd., Duke Street, Stamford Street, S.E., and published for the Royal Society of Arts by G. Bell & Sons, Ltd., York House, Portugal Street, W.C., in the Parish of St. Clement

Journal of the Royal Society of Arts.

No. 3,313. VOL. LXIV.

FRIDAY, MAY 19, 1916.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICES.

NEXT WEEK.

MONDAY, MAY 22nd, 4.30 p.m. (Cantor Lecture.) J. ERSKINE-MURRAY, D.Sc., F.R.S.E., M.I.E.E., "Vibrations, Waves and Resonance." (Lecture IV.)

WEDNESDAY, MAY 24th, 4.30 p.m. (Ordinary Meeting.) JOHN COLLETT MOULDEN, A.R.S.M., M.Inst.M.M., "Zinc, its Production and Industrial Applications." (Peter Le Neve Foster Prize Essay.) DUGALD CLERK, D.Sc., F.R.S., Chairman of the Council of the Society, will preside.

Further particulars of the Society's meetings will be found at the end of this number.

SUMMER TIME ACT.

As this Act will come into force on May 21st, notice is given that after that date the hours of the Society's meetings will be announced in accordance with the provisions of the Act. As it may be necessary to alter the hour of some of the meetings, Fellows are advised to assure themselves by reference to the latest issue of the *Journal* as to the time at which any particular meeting will be held.

The Cantor Lecture on Monday, the 22nd inst., will be delivered at 4.30 p.m. modified time (3.30 p.m. true time).

PROCEEDINGS OF THE SOCIETY.

TWENTIETH ORDINARY MEETING.

Wednesday, May 17th, 1916; SIR WILLIAM MARTIN CONWAY, M.A., F.S.A., F.R.G.S., in the chair.

The following candidates were proposed for election as Fellows of the Society :—

Bates, Mrs. Adah Lilian, 16, Summerland Mansions, Muswell-hill, N.

Bates, Thomas Bradford, 16, Summerland Mansions, Muswell-hill, N.

Bates, Thomas House, 21, Summerland Mansions, Muswell-hill, N.

Gordon, William John, 83, Thurleigh-road, Balham, S.W.

Piggott, Sir Francis Taylor, M.A., LL.M., Little Woolpits, Ewhurst, Guildford, Surrey.

Tyrie, Colonel David A., V.D., A.D.C., 21, Strand-road, Calcutta, India.

Venables, William Henry, 129, Fordwych-road, Cricklewood, N.W.

The following candidates were balloted for and duly elected Fellows of the Society :—

Alcoff, William, c/o J. K. Robinson, Iquique, Chile, South America.

Apcar, John Gregory, 44, Chowringhee-road, Calcutta, India.

Barnes, Professor James Hector, B.Sc., F.I.C., Punjab Agricultural College, Lyallpur, India.

Black, Professor A. Bruce, State Normal School, Bloomsburg, Pennsylvania, U.S.A.

Goculdas, Narottam Morarjee, Shanti Bhavan, Pedder-road, Bombay, India.

Horne, William Edgar, M.P., 5, Tilney-street, Park-lane, W.

Isachsen, Halfdan B., Stavanger, Norway.

Janji, Suryabhan, Camp Keliweli, Akola District, Berar, India.

Mukhopadhyaya, Kumar Sree Panchanan, Uttarpara Raj, Uttapara, Bengal, India.

Newlands, Alexander, M.Inst.C.E., Highland Railway, Inverness, Scotland.

Northcliffe, Lord, 22, St. James's-place, S.W.

Oakden, William Edward, F.C.S., M.S.C.I., 11, Lonsdale-road, Barnes, S.W.

Saklatvala, Nowrojee B., Messrs. Tata, Sons & Co., Navsari Buildings, Fort, Bombay, India.

THE CHAIRMAN, in introducing the author, referred to the beautiful examples of hand-painted calicoes shown in the hall, and to the coloured lithographs, which he understood were specimens of the plates to appear in a work on the subject that Mr. Baker was preparing. It would be seen that the specimens were very frail, and it was not surprising that good specimens were now rare.

The paper read was—

EAST INDIAN HAND-PAINTED CALICOES OF THE SEVENTEENTH AND EIGHTEENTH CENTURIES, AND THEIR INFLUENCE ON THE TINCTORIAL ARTS OF EUROPE.

By George Percival Baker.

The late Professor Meldola, in his presidential address to the Society of Dyers and Colourists in 1910, very rightly laid down the desirability of technical societies including in their work research in the antiquarian side of their subject. He then went on to say that experts in any particular subject are assuredly the right people to undertake such work. It is more or less in that category that I venture to come before you this afternoon, identified as I have been for the last twenty-three years with a textile print works in one of the suburbs of London, where textile printing was carried on before the industry was driven north to Lancashire and to Scotland.

For many years past I have been an eager collector of early Oriental fabrics. At first I found the designs a source of much inspiration in the development of my own work; then followed the spirit of investigation as to their origin and the method of their production, and in this work I appear to have struck, as it were, a field somewhat neglected by my contemporaries; for although some few writers and chemists have contributed articles on the processes adopted by the Hindus, they have not dealt with examples of the goods produced by the very complicated and laborious methods employed by the natives of India. It is only by such study one can appreciate how much the print industry of the world is indebted to India.

The collection on the walls contains a few examples of this industry—long since passed away—mostly produced in India, and some few in Persia, in the remote past. From the perishable nature of the fabrics such specimens are fast being lost to the world.

Some of these hand-painted calicoes are still to be found in the art and technical museums of Europe, and there are more in the private collections of professional designers. From inquiries I have made in India amongst art museums, it appears that no good specimens have been preserved in that country.

I am hoping that my research, and the publicity which this Society will give to the subject, may unearth some specimens from the archives of collectors whose ancestors were connected with the East Indies.

My first task will be to deal with the historical side of printing. I find that it is generally agreed, amongst those who have studied the history of printing, that the art of impressing and imparting a design upon cotton or linen in colours which will withstand washing, originated in India, and that whatever science there may have been in the art, when Europe was so largely supplied with the painted and printed fabrics of India in the seventeenth and eighteenth centuries, the chemical processes adopted by the Hindus at that period were the same in principle as those described by the elder Pliny, who wrote A.D. 70. Pliny's writings are the bed-rock from which all research of this nature begins.

He says, in referring to Egypt (Lib. XXXV. chap. 11): "Garments are painted in Egypt in a wonderful manner, the white cloth being first stained in various places, not with dyestuffs, but with drugs, which have the property of absorbing colours. These applications do not appear on the cloth; but when the cloths are afterwards plunged into a cauldron containing the dye liquor they are withdrawn fully dyed. It is wonderful that, although there be only one dye in the cauldron, the cloth is dyed of several colours, according to the different properties of the drugs which have been applied to different parts; nor can the colours be afterwards removed. A cauldron which would of itself only confuse the colours on cloth previously dyed, in this way imparts several colours from a single dyestuff, painting (or dyeing) as it boils." From this passage it is evident that the drugs employed to stain the cloths were different mordants, and that some knowledge of calico printing or dyeing was known by the Egyptians, acquired no doubt from Hindustan.

I shall now, at this stage, pass over fifteen centuries and deal with my subject from about the time when the several rival East India companies were instrumental in making known to Europe, amongst other goods, these printed and painted cottons. The first in the field were the Portuguese, they having reached the East Indies by way of the Cape in 1498. This route transferred to them much of the trade then in the hands of the Venetians and Genoese, by way of the old trade route through the Persian Gulf to Bussorah, Bagdad, and Aleppo, from whence, *via* Alexandretta and Beyrout, the merchandise found its way to Venice and other

parts of Europe. At that time Bruges was the distributing centre over Northern Europe, afterwards Antwerp, and later on, after the destruction of that city by the Spaniards in 1576–85, Amsterdam became the centre. For nearly a century the Portuguese held undisturbed supremacy of the Indian trade *viâ* the Cape. The early Dutch trade with India was indirect, and came through their connection with the Portuguese, who had, as I have said, diverted the Eastern trade direct to Lisbon by water. By an interdict in 1580, issued by Philip II. of Spain, the merchants of Amsterdam were precluded from trading with Lisbon. The energies of the Dutch were, in consequence, devoted to more direct intercourse with India. Merchant adventurers making successive journeys to the Indies eventually amalgamated in 1602 into one corporation, under the title of the Dutch East India Company.

In 1587, among the ships seized by Drake when the Spaniards were about to invade England, was the "St. Phillip," a Portuguese carrack coming from the East Indies. The papers of this vessel afforded much information as to the value of the Indian trade. In 1592 another carrack, the "Madre de Dios," was captured by some English privateers, who brought her to Dartmouth, and it is mentioned that amongst her cargo were calicoes, lawns, quilts, carpets, and other rich commodities. It was the capture of these vessels that determined the English to establish direct communication with India, and led to the memorial of the promoters of the London East India Company to Queen Elizabeth in 1599, to be followed in 1600 by the granting of its Charter. The French do not appear to have been in the field quite so early, and it was not till 1664 that Colbert, the Controller of Finances, induced his Sovereign, Louis XIV., to grant the Charter to the French East India Company.

Coming now to the references made by travellers and merchants on the subject of the prints under review, I find that in 1498 Odoardo Barbosa, one of the Portuguese adventurers who visited India immediately after the discovery of the Cape route, refers "to the great quantity of cotton cloth admirably 'pintadoed'" (painted—the word was later adopted as a trade phrase by the factors and officers of the Dutch and English East India Companies).

In 1563 Cæsar Frederick, who travelled to India *viâ* Bussorah, described the "extensive trade carried on between St. Thomay and Malacca in fine bumbast cloth (cotton) of every sort, painted, which is a rare thing, because these kind of cloths show as they were gilded with divers colours, and the more they are washed the livelier the colours will show."

In 1657 Boullaye-le-Gouz writes: "Hitherto it is not known how the natives apply so successfully the colours to the 'foyes' and *toiles peintes* in such a way that they lose nothing in the washing. I showed some in France to several dyers who were filled with admiration at them, assuring me that the dyes in India are pure and quite simple, whereas those of Europe are sophisticated (*alterées*)."

In 1693 Dr. Havart, M.D., a Dutch botanist, in a work entitled the "Rise and Fall of Coromandel," writes with much detail on indigo dyeing, and in the same work makes meagre reference to "the chintsen, which are painted at Palicol, after designs which are given to the painters, which they imitate very well, for the natives are so stupid that they are unable to produce anything original; but they can imitate and produce a perfect copy; but one chintsen is not always as good as another, although both may have been painted by the same hand . . ." In another passage he says: "They have at this place four kinds of painters, who have each his special duty, connected with the painting establishment, among whom the work is shared; they in their turn sublet the work to their subordinates, who actually do the work. These latter are mostly people without means, so that, in order to pay their debts and yearly poll-tax, they are obliged to work very laboriously or else they would be reduced to beggary. For this reason more chintzes are produced in Palicol than in the south. The painting of chintzes proceeds in the most leisurely manner in the world, in a manner similar to the crawling of snails, which appear to make no headway. Anyone who would represent patience, and had no other model, could use one of the chintz painters of Palicol."

The writer in another place has a few lines describing the painting process, but it is so vague and incomplete that I forbear to quote it.

In 1777 Abbé Raynal, who is the author of a work entitled "Histoire Philosophique et Politique," says, amongst other things: "Quite a colony of Europeans of various nationalities are located at Masulipatam. They are engaged in the export of cotton goods. They also buy the painted cottons, which, however, European printers have not the enterprise to copy.

"It will be an abuse of the reader's patience to trace the slow processes used by the natives

of India in the art of painting these cloths. They say they are due more to the antiquity of the art than to the fertility of their genius. There is one thing apparent in this conjecture, and it is that they have not advanced a single step in the art for many ages."

I propose at this stage to introduce the most important information we possess of a technical nature on the methods adopted by the natives. This is to be found in certain letters written by a Jesuit missionary at Pondicherry, Father Cœurdoux, to another Jesuit father resident in Europe. They appear in "Lettres Edifiantes et Curieuses," and are dated 1742. Briefly, they are as follows :—

"Take a length of half-bleached cloth and immerse it in a bath of buffalo milk to which is added the dry fruit of a myrabolan, called kadou, reduced to a fine powder. When the cloth is thoroughly steeped, withdraw, wring and put it to dry in the sun. The next day lightly wash in plain water, dry in the sun, and afterwards leave in the shade. This internal preparation is followed by an external one, having for its object the smoothing of the cloth, so that no obstruction is offered to the brush when they come to paint. This operation is to fold the cloth into quarters or sixths and then beat it with a smooth piece of fine grained circular wood, about the thickness of one's arm, upon another similar piece. This operation we know as beetling, and imparts to the cloth the smooth surface so necessary in the operation of pencilling or painting. The pleats are reversed and the operation repeated. Two men, seated opposite each other, beat the cloth as they think fit until appearance and experience lead them to know that it is sufficiently polished and smooth.

"The painter or artist, having prepared his design upon paper, next has to transfer it on to the cloth. He begins by pricking the main outlines of the design with a fine needle, then lays his paper on the cloth, and passes over it a pad containing charcoal powder, which, penetrating through the pricked holes, by this means transfers the main features of the design on to the cloth.

"The black is the first colour to deal with, and for this purpose I should describe its preparation. They collect a heap of iron filings and dross, which they subject to the heat of a fire made of banana leaves—which they prefer to any other fuel, presumably on account of their reducing action—to reduce any oxide present. When cool, the filings are placed in a vessel and hot rice-water liquor is poured over them — it is probable that this rice had been boiled some time previously and allowed to ferment and become acid. The solution is then exposed to sunlight, and later the liquor thrown away, and the vessel containing the iron is refilled with sour cocoanut-tree wine. The solution thus obtained is acetate of iron. The preparation is again subjected to exposure in the sun for several days, and is then ready for use in the form of an iron liquor, care being taken not to give an excess of iron, which has destroying properties. A good black is formed with the tannin or astringent of the kadou, already applied with the buffalo milk.

"Having pencilled in the design over the charcoal tracing with the iron liquor, wherever needed for black, the next stage is to subject the cloth to boiling water, to which some of the astringent kadou is now added in order to form a good deep black. The next step is to prepare the cloth to receive the blue, and for this purpose it is required to be freed from the astringent already applied, by inserting the cloth in a maceration of goat's or sheep's dung, well washing and drying in the sun; failure to do this would cause the blue when dyed to become black. Furthermore, the cloth at the beginning was half bleached, and the properties of the dunging are to help to whiten the cloth. The beating process already explained is repeated very profusely. The blue is not painted on with a brush, but a wax resist is painted over the whole cloth, except only in the places appropriated to blues and greens. Liquid wax is put on with an iron pencil, and when done the cloth is exposed to the sun and care taken that the wax penetrates to the other side of the cloth. The cloth is then sent to the indigo dyer to be dipped. When dyed the wax must be thoroughly removed by boiling the cloth in water, and when cool the wax which floats on the surface is skimmed off with spoons. Then follows dunging, hot-water washing with a sort of impure soda, or fuller's-earth, renewed steeping in dung, and beating about 400 times on a stone. The cloth is then strongly wrung out, and left for twenty-four hours in a maceration of cow's dung, to be followed by the usual washing and boiling processes. In this way it is rendered ready to receive the kadou and buffalo milk treatment as given in the first instance. The cloth is again beetled by beating, and in this way is gradually being prepared for the next dyeing operation—that of red. Then it is that wax is pencilled in,

as a resist, on all such places where fine tracery of white appears over reds and pinks and lilacs. The cloth is now ready to receive the red, pink and lilac mordants, and this is done, by applying Pliny's method of painting or pencilling in the various mordants, and afterwards dyeing the whole cloth in a red liquor bath. In this case the mordants employed, as described by the Jesuit father, were drugs composed of alum and certain kinds of hard water, obtained in Pondicherry, to which would be added japan wood, just enough to stain the emulsion when painting, as alum alone is invisible. The places on the cloth for reds would require to be painted with a stronger emulsion of alum than the places for pinks; whilst the violets would require to be painted with a mixture of alum and iron liquor, composed of the iron rust and the sour rice-water.

"The three varied mordants having been applied, the next step is to subject the cloth to a severe washing in water (which I conclude had alkaline properties, because he remarks this is the principal thing in sight, having for its object, so far as I can judge, the fixation of the alumina and iron). Then beat on a stone in order to remove certain of the greasiness occasioned by the buffalo milk, and to prepare it to more evenly imbibe the red dye liquor, which now forms the next operation. This bath is made up of tepid water with the roots of a plant called chay (*Oldenlandia umbellata*), reduced to a powder which has been treated with bitter water, and whilst the cloth now inserted is in the dye liquor it is brought to the boil; then it is taken out in order that the dyer may remove any stains or splashes of red which may be developing in their wrong places, owing to the carelessness of the painters when applying the mordants; for this purpose they use lemon juice. When this operation is done they return the cloth to the dye bath, increase the boiling, completing the operation by a gradual cooling down. After this the cloth is subjected to the same severe treatment of washing in various baths of dung and soap, exposed to the sun and watered occasionally until the whites are a good bleach, and the stain from the reds removed from such parts where it is not required.

"Yellow has next to be applied, and this is made up with a solution comprised of alum, myrabolan and the rind of pomegranate, which is painted or pencilled over places where yellow is required, and also where the blue already dyed is to be turned into green. The yellow, you will observe, is directly applied, and in consequence is the weakest of all their colours."

Before concluding, a word must be said as to the Indian pencils. They are nothing more than a small piece of bamboo, sharpened and split at the end for a distance of a finger-point.

These letters from Father Cœurdoux exhibit remarkable patience; he seems to have followed every process communicated to him by the natives with infinite detail. In concluding his letter he says: "What I have to tell you, my Rev. Father, has been acquired from various neophytes skilful in this sort of work with whom I have conversed since baptism. I have questioned them frequently and separately, and their replies I now send you."

A certain M. Poivre reviewed these letters, and, writing to Father Cœurdoux, says: "Amateurs in the art, not calico printers, but amateurs or beginners, should willingly acknowledge these new discoveries, which you have been able to furnish them with"—and then, asking for further information, he suggests that: "If you could possibly divest yourself for a short period of your apostolic zeal, you would render a real service to our *curieux* in Europe." He concludes his letter by saying that "it is surprising that no Europeans have striven to enrich their country on the subject of an art from which much advantage would accrue, and that it should be the desire of our travellers, in quitting their country, not to be forgetful that there are no people who are not in possession of some particular art, the knowledge of which would be useful to Europe, etc., etc. Up to the present, you, Rev. Father, and those who work amongst the Chinese missions, are the only travellers who have given an example of work so useful. The pains they have taken to discover the methods of the Chinese workers of porcelain, the cultivation of the mulberry and the nurture of the silkworm, have merited the thanks of all their countrymen, whom they have so well served. Why is so brilliant an example so little followed?"

Although I have been unable to find that these communications were made public till nearly twenty years after they were written, we may with safety conclude that certain printers had the benefit of the information imparted by the Jesuit missionary.

Although the letters I have quoted from Father Cœurdoux were rendered somewhat incomplete, either by reason of the Hindus not understanding the principle underlying the

success of the operation of dyeing the reds or else the difficulty the Jesuit father would have in interpreting their description of the processes, the general operations were undoubtedly of great service to the calico printers of Europe, as is evinced from the many text-books on the industry published between the years 1760 and 1800. Furthermore, the general operations formed the key to the process of madder printing, and, as madder was known in Europe at this period, this was the dye root used by European printers and dyers in the place of the Hindus' chay root.

Thus it will be seen how important a part does chemistry play in the production of these Indian painted cottons, and one might well ask, how came the natives of India to possess the knowledge of the art ? Were the secrets handed down to them from father to son, through those twenty centuries of civilisation which are credited to them ? Or was the art originally acquired by "some lucky chance, or from a slight and contemptible beginning," or have they "by long experience and curious observations and various improvements, matured and brought the art to perfection" ?

Whatever the beginning, certain it is that the art since evolved step by step in the manner recorded by the observant Jesuit father no longer exists; in fact, the Hindu dyer and printer to-day is entirely dependent on synthetic dyestuffs.

From the communications I have quoted, no less than twenty-six separate operations at least were needed to complete a chintz cloth, employing in its production a complement of such colours as black, red, pink, blue, green, puce and yellow, and this whatever size the piece of cloth.

The special feature in their production which must be emphasised is the fact that they were produced by the method technically known amongst textile printers as madder printing, and although the process was a long operation, the colours employed were few, and no modern method of printing in direct colours can produce them, so far as I am able to judge, so fine, so solid, and so beautiful.

It will now be my purpose to trace the influence of the Indian methods of calico painting on the print industry of Europe at the period under review, and in dealing with the word "painting" I should include printing as well, for although I have no specimen of these printed goods, we may safely conclude that the early cotton prints of two or three colours, particularly of small repeats in the design, which came to Europe through the agencies of the various East India Companies, were produced by block printing. Furthermore, it should be noted that in the Middle Ages the industry was well established throughout Asia Minor, where it is said to have been introduced from India by Armenians and Greeks. This I consider very probable, because Asia Minor offered every opportunity for a calico print country; it possesses its own cotton, alum, madder, yellow berries, pomegranates, galls, and other dyes. Furthermore, the Armenians were amongst the more important traders of the foreign communities in Madras, Calicut, Masulipatam, Guzerat, Ormuz, and other places. In the literature of the Levant, in the Middle Ages, and also amongst the records of the Dutch and English East India Companies, one is constantly coming across these traders, the following being a typical case taken from Mr. Foster's work on the English factories in India. Henry Barnford records an account of his journey from Agra to Tatta Mar, 1639: "Agra is little frequented unless by Armenian and Persian merchants, the commodity that took them there being only chints which are here made in good quantities, well collored, in appearance little inferior to those of Masulipatam, all of which commodities are by the Persians and Armenians transported to Spahan, and other parts thereabouts by the way of Candahar."

Amongst the examples now on the walls in this room we have evidence of the Armenians in the specimen entitled "Altar Frontal." You will observe an inscription at the base. This is in old Armenian characters, and from its translation we learn that it was dedicated "In memory of (the priest) Der Hohanes (John) and his parents Mikael (Michael) and Getsemani (Gethsemane) and his grandfather Hohan, and of Kafar, and his son Garabed, the Forerunner (that is, St. John the Baptist) and Bedros (Peter). In both bottom corners is to be seen the trade-mark of the H.E.I.C.

The history of the Armenian kingdom in the thirteenth and fourteenth centuries, with its colonies on the Mediterranean coast and Acre as its seaport, is full of interest. They were the commercial link between Europe on the one side and Asia on the other.

In like manner the Greeks introduced into Europe the Turkey-red process of dyeing, brought originally from India, and in this way we may readily understand the possibility of the art of printing filtering through Asia Minor westward into Europe, through the medium of

the Armenians and Greeks. The opening up of the East Indies round the Cape in 1498 would introduce a number of new dye products, and with them came also information as to their methods of use, which we may surmise were treated as trade secrets and not published to the world—in fact, there are indications in the communications from the Jesuit father that such was the case. We may also believe that amongst the first to communicate the processes would be the Dutch, for I find that amongst the earliest text-books are those of Holland.

As to England, I find that in 1619 a special privilege was granted to George Wood for twenty-one years, who has found "a waie to printe upon lynnen cloth." This process I regard as printing in oil or pigment colour for wall decoration, and my reason is that there is evidence that the earlier printings in England, Germany and France were such.

There are also the following letters patent—in 1624, to William Shipman, "sowing, selling and planting of the herabe, roote and plant called Madder."

1676, Will Sherwin, "new and speedy way for printing broad cloth, being the only true way of East India printing and stayneing such kind of goods."

1715, Peter Dubison, "printing, dyeing, or staining of calicoes in grain," which "shall equal if not exceed in beauty and use those stained in the Indies."

I think we may take 1676, which was the date of the patent to William Sherwin, as about the time to fix the date when the art of printing was introduced into England. Sir Josiah Child, a director of the E.I.C., in a pamphlet published in 1677, mentions that goods then coming over from India were for the purpose of being printed upon in imitation of Indian chintzes.

More direct evidence gives 1690 as the date of the first printing factory established in England, at West Sheen, now known as the Old Deer Park, Richmond, and about 150 ft. from the Thames. It is said to have been started by a Frenchman who came over from Holland, where he had taken refuge after the revocation of the Edict of Nantes in 1685. A large number of persons were employed at this establishment, both male and female. It is recorded that they were "a saucy and independent lot," and that Richmond was overrun by the calico printers.

Very soon after the Richmond establishment, we find a considerable printing works being carried on at Bromley Hall, on the Lee in Essex, followed by many others on the outlying streams around London.

Wherever there is good water and an abbey, there would also be found the whitster or bleacher, to be followed by the calico printer.

I find records of printers at Waltham Abbey, Merton Abbey, Mitcham, Wandsworth, Isleworth, Lewisham and Crayford.

The new industry of calico printing was just growing in importance, and had "taken on"; the chintzes produced by our people were for the home trade as well as for export. The industry was encouraged furthermore by the prohibition in 1700, by Act of Parliament, of the importation of the real article from India. This Act of William III. was intended to protect the English woollen and silk manufacturers from the competition of Indian goods. The weavers had all along manifested the greatest hostility to the use of printed calicoes from the East. In the year 1680 they mobbed the India House, in revenge for some large importations then made of the chintzes of Malabar. In spite of the prohibition and the excessive penalties of £200 imposed on smuggling, the imported goods found their way into the country. Fashion had to be gratified, and the greater the restrictions the more determined were the ladies to have their own way.

About this period quite a number of pamphlets were published on the subject. Some of these afford amusing reading, and from certain of them I will quote:—

The following passage occurs in "A discourse concerning East India Trade, showing how it is unprofitable to the King of England," by J. Cary; with observations by Sir Josiah Child, 1699. The writer is very furious against the trades in calicoes, as "India does not take our goods nor encourage navigation," etc., mingled with much doubtful political economy.

"Calicoes and wrought Silks are the things I chiefly aim at, and hope to make it plainly appear that those two Commodities do us more prejudice in our Manufactures than all the Advantage they bring either to private Purses, or to the Nation in general, and it were to be wisht the Wisdom of our Parliament would prohibit their been worn in England, else like the ill-favoured lean Kine they will destroy the use of our Manufactures. Few think themselves well drest till they are made up in Calicoes both Men and Women. Calico Shirts, Neckcloths, Cuffs, Pocket Handkerchiefs for the former, Head Dresses Night, Hood Sleeves, Aprons, Gowns, Petticoats and what not for the latter.

"As if the dead could not rest easie in their Graves if wrapt in our Native Commodities.

"One thing which I aim at in this discourse is to persuade the Gentry of England to be more in love with our own manufactures and to encourage the wearing them by their example and not of choice to give employment to the poor of another nation whilst ours starve at home."

A pamphlet entitled "The Naked Truth in an Essay upon Trade," published in 1696, informs us that—

"The commodities that we chiefly receive from the East Indies are Calicoes, Muslins, Wrought Silks, peper, saltpetre, indigo, etc. The advantage of the Company is chiefly in their muslins and Indian silks, and these becoming the general wear in England. Fashion is truly termed a witch; the dearer and scarcer any commodity the more the mode; 30*s.* a yard for muslins and only a shadow of a commodity when procured."

As Baines remarks in his "History of the Cotton Manufacture: "So sagacious and far-sighted an author as Daniel De Foe did not escape the general notion that it was not merely injurious to our weaving industries, but also a national evil, to have clothing cheaper from abroad rather than to manufacture it dear at home."

In his weekly review he thus laments the large importations of Indian goods:—

"The general fancies of the people run upon East Indian goods to that degree, that the Chints and painted calicoes which before were only made use of for Carpets, Quilts, etc., and to clothe children and ordinary people, became now the dress of our ladies; and such is the power of a mode as we saw our persons of quality dressed in Indian carpets, which but a few years before their chambermaids would have thought too ordinary for them; the chints were advanced from lying on their floors to their backs, from the cloth to the petticoat, and even the Queen herself at this time was pleased to appear in China Silks and Callico.

"Nor was this all, but it crept into our houses, our closets and bedchambers; curtains, cushions, chairs, and at last beds themselves were nothing but callicoes or Indian stuffs; and in short almost everything that used to be made of wool or silk, relating either to the dress of the women or the furniture of their houses was supplied by the Indian trade. Above half of the (Woollen) manufacture was entirely lost, half of the people scattered and ruined, and all this by the intercourse of the East India trade.—Jan. 31st, 1708."

The Act of 1700 did not preclude the plain cloths of India from being admitted into the country, under a duty; to which was imposed, in 1702, an excise tax of 3*d.* per square yard on all home-made printed calicoes, afterwards increased in 1714 to 6*d.* per yard. In spite of all these taxes our people had become accustomed to the use of printed calicoes; they were cleaner, offered a greater choice for the women of this country, they made dainty garments, and it is natural that the prevailing kerseys, serges and camlets, which formed the staple goods of the country, would suffer.

A new alarm was raised amongst the manufacturers, with the result that the legislators of that day, intimidated as would appear by the East London mobs, enacted in 1720 an absurd and summary law prohibiting the wearing of all printed calicoes whatsoever, either of foreign or domestic origin. The enactment proved a terrible blow to the rising industry, in that it confined the operations of the printers to the printing of linens and cloths with a linen warp and cotton weft.

The business continued to flourish though in a lesser degree, and was carried on almost exclusively in the suburbs of London, till after the middle of the eighteenth century, when a greater commercial revolution was in progress—that of Arkwright's spinning jenny, and Watt's improvement of the steam-engine. Gradually it had the effect of driving the industry to the North, to cheaper fuel centres, where, in conjunction with cotton-spinning and weaving, that new and brilliant era of machinery was in store for this country, which in time gave greater scope to the activities of the rising generation of calico printers.

About the period of 1714 to 1760 our printers had reached a degree of such excellency as to merit the praises of Jean Rhymer of Bale. He wrote a very valuable record of the earliest days of calico printing in Switzerland. He was a merchant and printer in Bale, and bought Indian goods in Holland and England, to be afterwards printed by himself in his own country and by others in Holland. He was of all men eminently qualified to judge, and his testimony I regard as most interesting, as it helps to place this country in the foremost position as printers at about the time he wrote. Amongst other things he says: "It was only at Neuchatel that the printers sought to combine glory with profit, and to make goods imitating the English

and Indian prints. Now the English had closely followed the Dutch in printing, and soon surpassed their teachers in excellency." In another passage he says: "It was reserved for the English to attempt an imitation of the best Indian work in prints, and to arrive at a degree of perfection which no one would have thought possible. All the world knows this people, whose industry and plodding patience in overcoming every kind of difficulty exceeds all imagination. This nation cannot flatter itself with having made many discoveries, but it may glory in having perfected all that has been invented by others. Whence the saying to have a perfect thing it must be invented in France and worked out in England."

Turning to France, the influence of these Indian goods, to which must be added the gradual creation of a new industry, led to chaos and much disaster in the history of that country. At that period, viz., at the middle of the seventeenth century, textile printing was not known in France. I gather from certain writers that some such industry existed in the Middle Ages, but as I am by no means satisfied as to the style of work it may have been, I will refrain from offering an opinion. Whatever the process, it is evident it was very limited in palette of colours, and that little by little the industry sank into oblivion. The real article from India appears to have revived the ancient industry, and many works and small *ateliers*, I read, were installed throughout the country, encouraged by Colbert, the Minister of Finance. The production in the early stages of the revival in no way resembled the real article, though they bore the name of Indienne. They were in the most part, so far as I can gather, printings by block and paintings by hand on various fabrics in pigment colours, just as one would print in these days upon wall-papers.

It is very clear that whereas our printers in the early days of the industry, 1690 to 1720, were printing on the lines of Indian methods, the French had not yet acquired any of those processes known as the madder style. It is the more remarkable, and makes it difficult for me to comprehend, how such faked goods, plus the importations of the real goods direct from India, and also through the intermediary of the English and Dutch Companies, could possibly upset the equilibrium of France's national industries. That they did is certain, and to such an extent that one writer, Edgard Depitre, says, in the preface of his work entitled "La Toile Peinte en France au dix-septième et dix-huitième siècles":—

"So much was written in the seventeenth and eighteenth centuries on the subject of *toiles peintes* as on the subject of cereals, that it occupied the central authorities, and inflamed the people; for three-quarters of a century it remained established a burning problem and created lively discussions; it was the object of two edicts, and some eighty decrees in council; at one time it became a State question; it divided France into two camps, gave birth to an abundance of literature, provoked passionate controversy, in which the best-known economists of those days took sides. It was, in fact, a question *furieusement historique*."

The question is interesting and requires that I should review the situation. Already in 1664, when the F.E.I.C. was founded, instigated as I have said by the Minister Colbert, the real goods were well established on the market. The French, we must understand, were in those days, as we know them in our time, the leaders of fashion, and the effect of these Indian goods having become not only universally fashionable, but also a necessity for purposes of decoration, the national industries of France suffered in consequence, in proportion to their export as well as to their home trade.

In 1683 the return cargoes of the F.E.I.C. comprised mostly *toiles peintes* and plain cottons, and produced £1,500,000, the company gaining 300 per cent. From 1675 to 1684 eight vessels returning to France with cargoes costing £1,870,000, realised in France £4,370,000; these *toiles peintes* being the most profitable of the company's imports. Already the silk and wool weaving industries had been provoked to great hostility, and now the article of another country (which in no way was reciprocal in its trading) had usurped, as it seemed to the French, their prerogative of supplying goods of fashion, and robbed the country of an export trade which had hitherto added to the national wealth of the country; furthermore, the importation of the Indian goods through the English and Dutch East India Companies aggravated the grievance. Drastic measures had to be taken to curb the increasing discontent of the manufacturers. For a long time past religious persecutions had precluded many skilled Protestant workmen from pursuing their regular vocations. It would appear that, in consequence, they occupied themselves in this new industry of printing Indiennes, which I have no doubt was not included in the barred occupations.

But a more severe blow was struck at the industry when, in 1685, the Edict of Nantes was revocated, since this industry, like so many other industries, was in the hands of the Protestants.

Notwithstanding the large exodus of workmen created by this enactment, it failed to improve the situation, and when at this period, on the arrival of a vessel at Rouen laden with large quantities of *toiles peintes*, the sale of home-made serges suddenly ceased, other measures had to be devised, and so a double decree was passed prohibiting the importation of all real Indian printed and painted goods, and also the production of all home-made prints, whether for wearing apparel or for decorative purposes. The decree further enacted that all printers were to cease work; printing blocks and all apparatus connected with the industry were to be destroyed. It also prohibited, under severe penalties, the wearing of chintzes.

The "Indiennes," as forbidden fruit, became the passion of the better class of women. They openly defied the law by establishing clandestine depots for the sale of these goods at Versailles and at Fontainebleau to serve the Court. The wives of Ministers who were expected to carry out the edicts were the first to break the law and wear the *toiles peintes*. Madame Pompadour, the Court favourite, furnished a chateau at Belleville with the contraband goods. The war lasted seventy-three years, and much property was destroyed and dire punishment enacted; but fashion in the end was the winner.

During all these years of inertia as calico printers, France had been slowly coming to the front as wool printers; and later, when the Government realised the uselessness of the struggle and decided in 1759 to annul the prohibitions, she was ready to take her place amongst the foremost calico printers of Europe, basing her work on the processes of the Hindus, and reproducing the designs of Persia and India. Very soon a hundred works were to be counted throughout the country, the best known and the one whose name was printed on the *toiles peintes* being that of Oberkampf at Jouy.

In Germany, in the seventeenth century, such printing as existed in that country was by block with pigment colours mixed with oil; gold and silver were also used. They printed on linens and pile fabrics for decorative purposes. The type of designs seem to have been Gothic and Byzantine. Owing to the strongly established German weaving industry, there does not at this time appear to have been a call for prints for wearing apparel. Towards the end of the seventeenth century English and Dutch prints began to be imported, and they threatened to swamp the German productions. About 1690 Neuhofer, a printer of Augsburg, seeing that his styles were being pushed aside, went to England and Holland to learn how printing was done in those countries. He came back, and after a certain amount of initial difficulty and opposition from the dyers, he made a success of these new methods and built up a large industry. The dyers opposed him when they saw that dyeing (madder dyeing) was part of his process; they said that he was infringing on their privileges. After him a great number of other concerns got to work on this, to them, new process of printing fast and washable colours. In 1759 Schüle, the most important of the Augsburg printers, was printing on cotton all manner of madder reds, browns, and violets, on white and coloured grounds, and he imported large quantities of cotton piece-goods from the East Indies *viâ* Holland for printing on. This incurred trouble from the local weavers' union, which brought legal proceedings against him.

I must now close my story. The subject covers a wide field with most interesting matter, which cannot be told in the short time at my disposal. I must, however, express a hope that some native student of India, preferably one interested in dyeing and conversant with the literature of his country, will make an investigation of this subject and place upon record full descriptions of how the natives of India came to acquire the methods recorded by the Jesuit father.

DISCUSSION.

The Chairman (Sir William Martin Conway, M.A., F.S.A., F.R.G.S.) said that after the learned and interesting paper that had been read by Mr. Baker any remarks made by himself must naturally be those of a mere amateur and outsider. He had been very much struck by the philanthropic character of the paper; because, obviously, looking round the room at the beautiful collection of rare treasures Mr. Baker had acquired, he had had the market very largely to himself, but after the publication of his paper—and still more after the publication of the beautiful book he was preparing—he would have many competitors, and probably would never get another cotton cloth for himself again at any sort of reasonable price. The specimens were of a very high order of beauty as well as of very great rarity. With regard to the remark in the paper that the industry had absolutely died out in India, the horrible idea had occurred to him that it must have died out in consequence of contact with European civilisation. Still worse, it was awful to think that people who might be learning in their youth to make such beautiful objects were now being taught reading, writing and arithmetic, three useless things to those who were capable of such wonderful handicraft. The foundation of the art was obviously Persian, but probably tradition went very much further. He had seen in some of the museums in London, Paris, and elsewhere examples of coloured linens going back to the eighteenth Egyptian dynasty, or about 1500 B.C., and there were Coptic cloths of perhaps the fifth and sixth centuries A.D.; these he believed were not printed in colours but were all in monochrome. Fragments of printed linens, he believed also in monochrome, had come down from the Middle Ages, and there were examples to be found dating back to the fourteenth century, and possibly earlier. But none of those productions possessed the wonderful qualities produced by the elaborate system of dyeing which Mr. Baker had described. It was almost painful to hear the quotation of the writer who said that in the seventeenth or eighteenth century a thing had to be invented in France and worked out in England, because, as was well known, the process had been reversed in later years, great inventions being made in England and then being worked out in Germany—as, for instance, the aniline dye industry; the scientific part of that work was done in England, but the Germans reaped the harvest. After the war it was to be hoped that that condition of affairs would not be revived.

Mr. Alan S. Cole, C.B. (Member of Council), drew attention to the fact that the designs shown by the author were chiefly of a botanical or floral nature. A little while ago he was reading in Evelyn's Diary that he went to Ashstead to visit a certain Lady Mordaunt and found her room hung with "pintadoeds," in which were depicted Indians working at various trades and crafts. The idea of having incidents instead of floral designs was carried out very largely by the French in their *Toile de Jouy*. The author had made no reference to the difference between what was called *kalamkar* and *palampore*. He believed the word *kalamkar* came from the Persian word *kalam*, meaning a pen, and *kalamkar* referred chiefly to things done with a pen or pencil, while *palampore* he believed to be a generic term for things produced from stamps.

Colonel T. H. Hendley, C.I.E., asked the author whether he had examined the chintzes made near Jeypore, in Northern India. There the manufacture of chintzes had been going on for hundreds of years; there were specimens in the museum at Jeypore certainly two hundred years old, and a dress worn by a Maharaja in the seventeenth century. The designs were in great variety, and mostly done by block printing in different colours, but partly by the process described by the author of using various kinds of mordants and pigments. Some of the designs were very elaborate, and were both floral and figurative. The virtue of the chintz, its rosy groundwork, depended a good deal on the cloths being dipped in the river outside the town and dried on the banks. Some time ago a German, agent for a large firm in Manchester, went to Jeypore and studied the question, even taking away some of the water from the river; and a year or two later the markets were flooded with imitation chintzes, and the Jeypore industry was very much damaged. He did not believe the faculty of invention in the Hindu dyer had been lost; it had been overpowered, possibly, by commercial methods and the use of aniline dyes. In 1894 a conference in Lahore passed a resolution asking the Government of India to regulate the production of aniline dyes in the country, and it was pointed out at that time that Persia had been already ruined, but the Government never saw its way to doing anything in the matter. It seemed to him that the account given by the author applied also to a number of other processes in different arts, such, for instance, as enamelling. It was well known that India had borrowed from all the world from the earliest ages, picking up processes and bringing them to perfection. He would draw the author's attention to the fact that some very interesting articles on dyeing had appeared in the

Journal of Indian Art, which might be useful to him, but certainly none of them were so valuable as the address that had been given that evening.

MR. GEORGE C. HAITÉ, R.I., wondered what sort of reward or recognition the author would obtain for the sacrifice of time he had made and the trouble he had taken in bringing together such a magnificent collection. He was glad to know he was going to continue the work by bringing out a book; but unless he was a lucky man he was not likely to profit much in a pecuniary way, though no doubt his pleasure in the work would be a great compensation to him. He remembered that in the rooms of the Japan Society, some time ago, a gentleman lectured on Japan and the art of Japan, and around him, on the walls, he showed a collection of drawings of still life in the very best methods of early South Kensington. He had the audacity to ask for subscriptions to help Japanese artists to come to England and take lessons at South Kensington! The British people were generous, kind and brave, but in some things very stupid, and their stupidity meant a great lessening of their achievements in the world and a retardation of progress. He himself was a descendant of men who had been associated with the art of calico printing for many years, and he had been delighted to see the success which Messrs. Baker had made of the works at Crayford, where the very best printing was done, and which was really the Mecca of calico printers. He was glad to know that the subject was in such worthy hands, and to the author was due the thanks of all lovers of art and of the application of art to manufactures.

THE CHAIRMAN, in according the thanks of the Society to Mr. Baker for his paper and exhibition said a very great debt of gratitude was owing to Mr. Baker for what he has done.

MR. G. P. BAKER briefly described the specimens of printed calicoes on exhibition in the hall, and the meeting then terminated.

ARTS AND CRAFTS.

Artree Intarsia at the Medici Gallery.—The Medici Society has made somewhat of a new departure in opening its doors to a collection of Artree intarsia panels by Mr. A. J. Rowley. The work is not by any means unknown. It has been shown at various exhibitions within the last few years, notably at the British Industries' Fair, but this is the first time that it has been on view by itself at a well-known West End gallery. The panels are for the most part pictures—not painted with a brush, but formed of a mosaic of wood veneers of different colours and of great variety of grain. They are, of course, more or less in the nature of silhouettes, a few of them as frankly so as any picture cut out of black paper by the scissors of the silhouette artist. The most important pieces shown at the Medici Gallery were the three large compositions, "The Storm Cloud," "Homewards," and "Ghent," designed by Mr. Frank Brangwyn, A.R.A., all of which were planned with simplicity on definitely pictorial lines, and formed very effective pieces of decoration. Amongst other interesting and satisfactory pictures were some figure panels by Mr. W. A. Chase, suggesting French eighteenth-century work, which would be admirably in keeping with rooms of a certain type. It is not indeed as isolated units, that one feels these works must be judged, but as panels designed to fit into a scheme of decoration. One conceives of them, in the main, as forming part of the room, or gallery, or whatever it may be in which they will find themselves, rather than as pictures to hang on the walls—in other words, they are primarily decorative. That being so, one is conscious of some feeling of disappointment with the more obviously decorative of the works in Grafton Street. There was, it is true, a series of little mirrors ornamented rather in Japanese fashion which showed a good deal of taste, as well as a real appreciation of the qualities demanded by the method of execution, but some of the screens and trays adorned with flowers were rather garish in colour and not as satisfactory as they might have been, while the rolls of honour were none of them very good. This is the more to be regretted as the work would, if the right design could be found—not perhaps a very easy matter—be eminently fit for this use. Again, it would be interesting to see some of this intarsia which was not at all pictorial in aim. One can imagine that purely ornamental panels carried out in various colours, and with great attention to the grain of the wood, would be peculiarly beautiful in effect and would be useful in plans where more ambitious work would be out of place. Mr. Rowley's process has quite evidently not yet been made to do all that it can do. He is still feeling his way in order to find out how best it can be developed, but it promises well in many directions, and has already achieved good success. He certainly gets some pretty effects in the way of imaginative landscapes—it is noticeable that the places one knows best are always the least satisfying—and of simple figure work, and he has a real feeling for the quality of wood. It is to be hoped that his experiments will not lead him too far towards more elaborately pictorial rendering, but will take him in the directions of ornament, decoration, and severely simple silhouette work, where it looks as though a future awaited him.

Women's Work.—It seems as though since the outbreak of the war, while so many exhibitions and art classes have come to an end, there have been more exhibitions of women's work than ever before. That is not altogether surprising. To begin with, the increase is more apparent than real—it is only that the number is comparatively greater. Still, when hostilities first broke out

there was a good deal of dislocation in the employment of women, and consequently more need than usual to bring their work to the notice of the public, especially of that section of it with well-filled purses. Now that the dislocation has been in the main overcome, women are employed in all sorts of new callings and industries, and are anxious to inform the world at large of what they are doing and of the scope of their new undertakings; and so it comes about that shows of women's work go on being held in considerable numbers. The present-day exhibitions cover a very wide field of women's activities, and draw attention more particularly to such comparatively new openings as motor-driving and Red Cross work, but they contain also a surprisingly large amount of artistic and craft work. The British Women Workers' Exhibition, lately held at Prince's Skating Club, which described itself as an exhibition of the arts and crafts of the home-worker, was no exception to this rule. Side by side with more utilitarian work was to be found quite a quantity of artistic handwork, jewellery, needlework, weaving, basketmaking —and above all, toy-making. One of the points which these shows seem to emphasise most is the fitness of women for the making of artistic toys, and the exhibits at Knightsbridge—more especially the stall of Vale of Clwyd toys and that stocked by the North Warnborough Industry—were good examples of what women are doing in this direction. The most interesting embroidery was that sent by Mrs. Newall of Wylye, Wilts—mostly Greek or Oriental in type, some in plain white, some in black or red—which was excellent in execution and very tasteful in design. The cut leatherwork with an underlay of silk, by Miss M. E. Johnston was good; but it would have been rather more interesting had the leather and the material sometimes been in contrasting colours instead of practically matching one another. Weaving in excellent colour came from the Weaving School at Shottery, near Stratford-on-Avon, and good work from the Weaving Studio, Denmark Street, W. Competent rafia basketwork — as well as needlework—was sent by Queen Alexandra's School of Needlework, Sandringham, and the lamp-shades sent by one exhibitor made one realise that this work offered a field for really artistic work by competent women. While there was no work of striking and outstanding merit, the exhibition gave proof that women's work in the artistic crafts is going steadily on in spite of adverse conditions.

CORRESPONDENCE.

SUPPLY OF FOOD IN TIME OF WAR.

In your report of the discussion on Sir Henry Cunynghame's paper on "Supply of Food in Time of War," published in the *Journal* of May 5th, you omit the crucial point of my argument concerning the corn trade, and I would like to repair the omission.

After pointing out that dealing in grain is a very hazardous business, and that the amount of profit per unit of grain handled is exceedingly small, and after mentioning, as a rough and ready proof, that the price of bread in London before the war was only about half the price of that article in New York, I asked, who will be willing to trade in wheat on such terms or operate at all, if, immediately prices in the opinion of some authority are too high, a stream of wheat would be turned on from reserves accumulated in this country, with the object of reducing prices 5*s*., 10*s*., 15*s*., or 20*s*. per quarter? The argument may bring home to the readers of the *Journal* the danger of interfering with commercial operations conducted properly by individuals and firms. Any such action as that commended by Sir Henry Cunynghame must involve revolutionary changes in our methods of trading.

A. E. Humphries.

Coxes Lock Mill, Weybridge,
May 10th, 1916.

GENERAL NOTES.

Gum-Tragacanth in Persia.—According to a report by the United States Consul at Teheran, the various species of Astralagus, known in Persia as "kevin," from which gum tragacanth is obtained, grow on the mountain ranges which surround the Persian plain. The bushes producing the gum grow to a height of 2 feet. In the spring, when the sap rises, parts of the branches are cut away, thereby allowing the sap to flow out, which coagulates within a few hours on the surface of the stalk. The price of gum tragacanth has increased 5 to 10 per cent. since the outbreak of hostilities in Europe. The prices per lb. for the different grades of gum were at the date of the report (25th October last), as follows: First grade, 3*s*. 1½*d*.; second grade, 1*s*. 8*d*.; third grade, 1*s*. 2*d*.; fourth grade, 10*d*., and fifth grade, 6*d*. The principal Persian markets for gum tragacanth are Hamadan, Shiraz, Kerman, and Kermanshah. From 150 to 200 tons are exported annually from Hamadan alone. Before August 1st, 1914, half of this amount was shipped to Russia and the other half to America and the United Kingdom, but since that date the amount shipped to Russia has been reduced to one-fifth, the other four-fifths going to America and the United Kingdom.

Antimony Mines in Honduras.—Because of the advance in value of antimony incidental to the war in Europe, the profitable exportation of antimony ore or stibnite assaying about 70 per cent. has become possible from a mine in Honduras, said to be rich, but hitherto undeveloped because of unfavourable transportation conditions, and recently several small shipments of ore have been made from Puerto Cortes to New York. This ore is mined in the vicinity of the interior village of

Voro, and has to be transported six days by pack mule to the Sulaco River, thence two days by canoe down the river to Pimienta, where rail connection is made for Puerto Cortes. The mining and shipping of this ore under such difficult transport conditions, says the United States Consul at Puerto Cortes, is in accord with the claim that has often been made, viz., that the interior of this district was rich in minerals, and only needed railways for the development of the same.

MEETINGS OF THE SOCIETY.

(The times given are Parliamentary, not true.)

Ordinary Meeting.

Wednesday afternoon, at 4.30 p.m.:—

May 24.—John Collett Moulden, A.R.S.M., M.Inst.M.M., "Zinc, its Production and Industrial Applications." (Peter Le Neve Foster Prize Essay.) Dugald Clerk, D.Sc., F.R.S., Chairman of the Council of the Society, will preside.

Indian Section.

Thursday and Friday afternoons, at 4.30 p.m.:—

June 1.—Professor Wyndham R. Dunstan, C.M.G., M.A., LL.D., F.R.S., "The Work of the Imperial Institute for India." The Right Hon. Lord Islington, P.C., G.C.M.G., D.S.O., Under Secretary of State for India, will preside.

June 23 (Friday).—Sardar Daljit Singh, C.S.I., "The Sikhs."

Cantor Lecture.

Monday afternoon, at 4.30 p.m.:—

J. Erskine-Murray, D.Sc., F.R.S.E., M.I.E.E., "Vibrations, Waves and Resonance." Four Lectures.

Syllabus.

Lecture IV.—May 22.—*Resonance.* Mechanical and electrical—Superposition of periodic impulses—Universal importance of the selective absorption of wave motions—Mechanical resonance or revibration—Screening of vibrations, absorption, and filtration—The acoustics of buildings—Sound resonators—Absorption of light waves—Coloured glass—Vision and photography—Absorption of electrical power by resonance—Tuning in telegraphy.

MEETINGS FOR THE ENSUING WEEK.

Monday, May 22...ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 4.30 p.m. (Cantor Lecture.) Dr. J. Erskine-Murray, "Vibrations, Waves and Resonance." (Lecture IV.)

East India Association, at the Institution of Civil Engineers, Great George-street, S.W., 4.15 p.m. Mr. H. Marsh, "Famine Protection Works in British Bundelkund."

Geographical Society, at the Alpine Club, 23, Savile-row, W., 3 p.m. Anniversary Meeting.

Medicine, Royal Society of, 1, Wimpole-street, W., 8 p.m. (Odontology Section.) Dr. J. H. Mummery, "The Structure and Arrangement of the Enamel Prisms, especially as shown in the Enamel of the Elephant."

Tuesday, May 23...Economics and Political Science, London School of, Clare-market, W.C., 5 p.m. Professor Mantoux, "World Relations and World Organisation—the Economic Aspect."

China Society, Caxton Hall, Westminster, S.W., 8.30 p.m. Mr. W. R. Carles, "Some Pages in the History of Shanghai, 1842-1856."

Royal Institution, Albemarle-street, W., 3 p.m. Professor C. S. Sherrington, "Unconscious Nerves—their Functions in External Life." (Lecture II.)

Anthropological Institute, 50, Great Russell-street, W.C., 5 p.m. Dr. A. C. Haddon, "The Canoes of British New Guinea."

Zoological Society, Regent's Park, N.W., 5.30 p.m. 1. Mr E. G. Boulenger, Exhibition of living specimens of the African Lungfish (*Protopterus annectens*) and of their Cocoons. 2. Dr. R. Broom, "On the Structure of the Skull in *Chrysochloris*." 3. Dr. C. W. Andrews, "Note on the Sternum of a Bird from the Eocene of Nigeria." 4. Dr. A. Smith Woodward, "On a Mammalian Mandible from the Cretaceous of Alberta, Canada." 5. Mr. V. Lutshnik, (*a*) "List of Carabidæ (Coleoptera) collected in Chopersk District, South Russia"; (*b*) "A new Species of the Genus *Platysma* (Coleoptera) from China"; (*c*) "Notes on Species of the Genus *Platysma* from Australia."

Wednesday, May 24...ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 4.30 p.m. Mr. J. C. Moulden, "Zinc, its Production and Industrial Applications."

Geological Society, Burlington House, W., 8 p.m.

Literature, Royal Society of, 2, Bloomsbury-square, W.C., 5 p.m. Mr. E. Gosse, "Catherine Trotter: the Earliest of the Blue-Stockings."

Medicine, Royal Society of, 1, Wimpole-street, W., 5 p.m. (History of Medicine Section.) 1. Drs. J. A. Nixon and C. Singer, "Miniatures of the Bristol Guy de Chauliac MS." 2. Dr. C. Singer, "Some Figures bearing on the Practice of Blood-letting in the Fourteenth, Fifteenth, and Sixteenth Centuries." 3. Mr. R. R. Steele, "Note on the Scientific Work of Roger Bacon."

Optical Society, at the Chemical Society, Burlington House, W., 8 p.m. Dr. P. G. H. Boswell, "Sands used in Glass-making, with special reference to Optical Glass."

Japan Society, 20, Hanover-square, W., 3.30 p.m. Mr. J. C. Hall, "Teijo's Family Instruction: a Samurai's Ethical Bequest to his Posterity (1763)."

Thursday, May 25...Linnean Society, Burlington House, W., 3 p.m. Anniversary Meeting.

Royal Institution, Albemarle-street, W., 3 p.m. Sir Alexander Mackenzie, "The Beginnings of the Orchestra and its Instrumental Combinations." (Lecture I.)

Friday, May 26...Royal Institution, Albemarle-street, W., 5.30 p.m. Professor C. G. Barkla, "X-rays."

Physical Society, Imperial College of Science, South Kensington, S.W., 5 p.m.

Medicine, Royal Society of, 1, Wimpole-street, W., 4.30 p.m. Mr. J. L. Dick, "The Teeth in Rickets."

Saturday, May 27...Royal Institution, Albemarle-street, W., 3 p.m. Professor H. S. Foxwell, "The Finance of the Great War—How we stand to-day, and what lies ahead." (Lecture II.)

London: Printed by William Clowes & Sons, Ltd., Duke Street, Stamford Street, S.E., and published for the Royal Society of Arts by G. Bell & Sons, Ltd., York House, Portugal Street, W.C., in the Parish of St. Clement Danes, in the City of Westminster.—May 19, 1916.

Journal of the Royal Society of Arts.

No. 3,314. VOL. LXIV.

FRIDAY, MAY 26, 1916.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICE.

NEXT WEEK.

THURSDAY, JUNE 1st, 4.30 p.m. (Indian Section.) PROFESSOR WYNDHAM R. DUNSTAN, C.M.G., M.A., LL.D., F.R.S., Director of the Imperial Institute, "The Work of the Imperial Institute for India." THE RIGHT HON. LORD ISLINGTON, P.C., G.C.M.G., D.S.O., Under-Secretary of State for India, will preside.

Further particulars of the Society's meetings will be found at the end of this number.

PROCEEDINGS OF THE SOCIETY.

TWENTY-FIRST ORDINARY MEETING.

Wednesday, May 24th, 1916; DUGALD CLERK, D.Sc., F.R.S., Chairman of the Council of the Society, in the chair.

The following candidates were proposed for election as Fellows of the Society :—

Bilimoria, A. J., Navsari Buildings, Fort, Bombay, India.

Cropper, L. Cuthbert, F.C.A., Spencer House, South Place, E.C.

Waterbury, John I., 14, Wall-street, New York City, U.S.A.

The following candidates were balloted for and duly elected Fellows of the Society :—

Baddeley, Miss Mary, 113, The Crescent, Denmark-hill, S.E.

Banerjee, J. C., 21, Canning-street, Calcutta, India.

Driver, Robert Manning, Cowley, Horsell, Surrey.

Madden, S. Wilbur, 76, Sparks-street, Rangoon, Burma.

See Teong Wah, J.P., 10, Balmoral-road, Singapore, Straits Settlements.

Thomas, Miss Harriet E., 48, Clark-street, Newport, Rhode Island, U.S.A.

THE CHAIRMAN reminded the Fellows that the essay of which Mr. Moulden was about to give them a summary, since it was far too long to admit of its being read *in extenso*, was the result of a prize founded by Mr. Reginald Le Neve Foster in memory of his father. Mr. Peter Le Neve Foster was Secretary of the Society from 1853 down to his death in 1879, and though his own (the Chairman's) connection with the Society was of too recent a date for him to have any personal knowledge of Mr. Foster, he knew from the evidence of older members of the Council, who remembered his Secretaryship, that during his long tenure of office he had gained the respect and the esteem of the members. The Council had, he thought, been very well advised in their selection of a subject for the essay, because at the outbreak of the war the lack of supplies of the metal had been a grave difficulty in regard to the supply of munitions. They were fortunate in securing not only the admirable essay by Mr. Moulden but several other extremely useful compositions, one of which, the second best, was by Mr. Ernest A. Smith, the Deputy Assay Master of the Sheffield Assay Office, while another by an Indian Fellow of the Society—Mr. Ramji Das Vaishya, of Gwalior—dealt in a most interesting fashion with the treatment of zinc in the East Indies. He had very great pleasure in presenting to Mr. Moulden the medal which he had so deservedly won, and he hoped that the publication of so very complete a treatise on this important subject would have a beneficial effect in developing the production of zinc throughout the Empire.

PETER LE NEVE FOSTER PRIZE ESSAY.

ZINC, ITS PRODUCTION AND INDUSTRIAL APPLICATIONS.

By J. C. MOULDEN, A.R.S.M., M.Inst.M.M.,

Member, Australasian and American Institutions of Mining Engineers.

I.—THE PHYSICAL AND CHEMICAL PROPERTIES OF ZINC.

Zinc is a metallic element of bluish-white colour and strongly metallic lustre, capable, particularly in the rolled form, of receiving high polish.

At ordinary temperature it is rather hard and brittle, a cast ingot of the metal being fairly easily broken across under a blow from a heavy hammer. The fracture is crystalline-hackly and of strong metallic lustre. Between 100° C. and 150° C. it becomes malleable and ductile, and at over 205° C. so brittle that it may be pulverised in an iron mortar.

It has an atomic weight of 65·37, and a specific gravity of 7·12, slightly increased by hammering. It melts at 419° C. and boils at 950° C., the vapour taking fire in air, burning with a characteristic blue-green flame and the production of clouds of zinc-oxide smoke. The metal also, particularly if in the form of shavings or wire, will burn in air at a temperature as low as 500° C.

It is very strongly electro-positive, and precipitates most other metals from solution—gold, silver, lead, copper, mercury, etc. It finds application on the industrial scale for such purposes.

Its thermal conductivity (silver 100) is 28·1, and its electrical 16·9 (mercury at 0° C. being 100). Its specific heat between 0° C. and 100° C. is ·09555 (Regnault).

It crystallises generally in rhombohedral forms of the hexagonal system, the size of the crystals depending upon the degree of purity of the metal, the temperature at which it is poured, and the rate of cooling.

Exposed to perfectly pure dry air or oxygen the metal does not tarnish, but under ordinary atmospheric conditions it gradually acquires a film of the whitish basic carbonate which protects the metal from further corrosion.

Zinc expands 11·1 per cent. by volume between the cold solid and the molten condition.

As usually met with and used the metal is very far from pure, and for preparation in a chemically pure condition special materials, methods, and precautions must be employed. The electrolysis of a chemically-pure sulphate solution, if effected with scrupulous care in every particular, will afford zinc of 99·998 per cent. purity.

Zinc forms with the acid radicles the usual metallic salts. The haloid salts, as well as the sulphate and oxide, find some application in medicine.

It has great affinity for oxygen, and forms one very stable oxide (ZnO), which is the most important zinc compound from every point of view, commercially and metallurgically.

At a red heat zinc is strongly oxidised, even by carbon dioxide, with the production of zinc oxide and carbon monoxide. Emphasis is laid upon this in that it constitutes a decisive factor in the metallurgy of zinc, and confines the practically applicable methods of extraction from its ores within very narrow limits.

II.—The History of Zinc.

Whether zinc *qua* zinc was known to the ancients is a much debated point, and until recent years the balance of evidence and opinion tended towards the negative. In view of the discovery of bracelets made of it in the ruins of Cameros, which was destroyed 500 B.C.,* it appears that it was known, however local this knowledge may have been. That it was not in common use is indubitable, and we are entitled to say that it played no part of any importance in the economics of the ancients.

The alloys of which zinc forms a constituent, particularly brass, undoubtedly were not only known but important. This alloy receives Biblical mention in Genesis,† where Tubal-Cain is referred to as "an instructer of every artificer of brass and iron," and again, rather more specifically, in Deuteronomy,‡ where the words "out of whose hills thou mayest dig brass" occur. Too much reliance must not, however, be placed on these as necessarily indicating the copper-zinc alloy known in later times under the same name.

It is of course well known that the first metal worked by man was copper, and the time when it was first alloyed with other metals was long before the dawn of history. There are frequent references to copper, bronze and brass in the earliest classical writings, the metal and its alloys alike being generally designated by the same name. Hesoid and Homer both mention it. Aristotle,§ writing in the fourth century B.C., tells us that the Mossynoeci—an Asiatic race mentioned by Herodotus as living near the Black Sea, in the neighbourhood of Colchis — produced a brass which was very brilliant and white; it did not contain tin, but a certain earth which existed there was melted with it. He adds that as the inventor had not instructed anybody in the method of preparation, the secret of its manufacture was lost. Later on, Pliny ‖ (first century A.D.) described at considerable length the various bronzes which were used for artistic purposes, and says

§ Aristotle, "Mirabiles Auscultationes," 62. (See "Scriptores Rerum Mirabilium Græci," A. Westermann, 1839.)

‖ "Hist. Nat." XXIV. A sufficiently full account of Pliny's descriptions will be found in Smith's "Dictionary of Greek and Roman Antiquities"—article "Aes."

that they contained varying proportions of tin, lead, gold and silver. On the whole it can only be said that while it is known from various analyses that zinc, either accidentally or of set purpose, was a constituent of some of the alloys, there is little evidence, beyond that given above, to show that its existence in the metallic state was known in classical times. On the other hand it may certainly be assumed from the descriptions, vague as they are, that the method of cementation was employed in the production of some, at all events, of the copper alloys.

At the time of the Roman Empire it was well known that certain "earths" had the property of imparting to copper a golden yellow colour, corresponding to what would to-day be a low-zinc brass. The word "aurichalcum" has been considered to be evidence for this, but it seems certain that this is really a mis-spelling due to false etymology. The Latin word *orichalcum* comes from the Greek ὀρείχαλκος, "mountain-bronze," and has nothing to do with *aurum*, gold. It is indeed possible that the resemblance of orichalcum to gold led to the wrong spelling. It appears that the word came at last to denote brass, not bronze, and Cicero tells us that coins of it were indistinguishable in appearance from gold coins. That certain Roman coins were made of zinc-copper alloy is also known by analysis.

Dana* sapiently observes that "as the use of aurichalcum dates from before Pliny's time, we moderns may as well let it stand without correction." It may have been the case that the alloy was, in the primary instance, produced direct from the ore, the basic carbonate of zinc and copper aurichalcite, or that the mixed oxidised ores of the metals provided the source. We know that aurichalcite was a product of the lead-zinc mines of Laurium in Greece, not far from Athens, and that it also occurred in Sardinia and Cyprus—the latter a very ancient source of copper, and later of zinc. Since the Laurium deposits were worked in very ancient times, and on an extended scale, for their silver and lead, and subsequently for zinc, they may well also have provided the means for the production of brass at one operation.

Experimenting at Broken Hill, N.S.W., some years ago, the author had no difficulty in repeating the experience of Sage† by smelting brass direct from aurichalcite associated with copper carbonate, the mineral being ground, calcined, and then reduced with charcoal in a crucible heated by an assay wind-furnace.

Whatever the means adopted for its earliest production, there is little doubt that the only method of which any real record is handed down to us is that of cementation, whereby metallic copper was heated in the presence of calamine and carbon, and the zinc so reduced alloyed itself directly with the copper. This method survived until quite modern times, that famous and accurate observer, Dr. John Percy,* recording that he had seen the process in operation at Birmingham so recently as "a few years before 1861." He gives also what is probably the most accurate and detailed description, accompanied by cost details, of the manufacture of calamine-brass preserved in our metallurgical literature. Percy also quotes several analyses of brass coins of the Roman era.

Although Paracelsus, who died in 1541, wrote of zinc as a metal, it seems first to have been actually recognised in Europe in the metallic form by Georgius Agricola,† who, about the middle of the sixteenth century, discovered it accidentally in the wall-crevices of a smelting-furnace treating lead and copper ores at Goslar in the Harz.

Percy records a similar case, from South Wales, of the condensation of zinc in the wall-crevices of a blast-furnace smelting zinciferous iron ore, and the author has also personal experiences of two such occurrences—the one in a lead blast-furnace treating a highly zinciferous charge, at Cockle Creek, N.S.W., and the other in a large electric furnace smelting zinc ores, where the metal condensed in masses weighing many pounds, forcing apart the joints of the firebrick lining to an astonishing degree. Agricola's discovery, therefore, receives strong corroboration in modern experience. He called it "conterfey," but did not recognise any particular mineral from which it was derived, this being reserved for Glauber, who in 1657 announced that calamine was an ore of zinc.

Henckel in 1721 stated that zinc could be obtained from calamine; but he published no details beyond suggesting "phlogiston" as the reducing agent.

None of these discoveries resulted in any tangible outcome, and the indirect manufacture of brass by cementation became more and more

important. Thus we learn that about the middle of the seventeenth century calamine-brass works were erected in Surrey by Demetrius, a German, at an outlay of £6,000,* and that a "good profit was realised," whereupon British and foreign merchants combined against the proprietor, and involved him in heavy lawsuits, which caused his ruin and the abandonment of his works, "to the unspeakable prejudice of the kingdom." From all of which we see how really advanced, even in those days, the methods for "capture of trade" were.

Notwithstanding the use in alloyed form, therefore, from a very early period, the discovery and extraction of zinc itself were reserved for comparatively modern times, and we arrive at the latter end of the eighteenth century before we can credit Europe with tangible knowledge of the art.

For all this, it is generally recognised that the Chinese must have produced the metal at a substantially early date, although we have no specific details as to where or how. Specimens of Chinese and East Indian zinc were brought to Europe under the name of "tutanego," and we are even told that, some years prior to 1640, the Dutch captured a Portuguese ship with a cargo of zinc, which was sold under the name of "spiauter" or "spialter."† As to the extent of the cargo we have no record, and the story, if true, is an interesting historical forerunner of the extensive capture of zinc-ore cargoes effected by our Navy in the present great war.

Beckmann, who dealt with the history of zinc‡ rather fully, further records that the commercial company in the Netherlands between 1775 and 1779 caused to be sold on their account above 943,081 lb. of spiauter, and that in 1780 the Chamber of Rotterdam alone sold 28,000 lb. In 1781 the Danish company at Copenhagen purchased 153,953 lb. of "tutenage" which had been carried in two vessels, and which was sold "at the rate of 4⅛ to 4¼ schillings Lubec per lb." He states that it came from China, Bengal, Malacca and the Malabar coast, and one is tempted to wonder whether the whole of the quantities recorded comprised zinc. Robert Boyle coined the word "speltrum"§ from the term variously written as spiauter, spialter, spiautre, speautre or speauter, but he does not appear to have confined its use to zinc alone. Nevertheless we have obtained our English word spelter.

However all this may be, the metal introduced from the East does not appear to have been in sufficient quantity to exercise any substantial influence in the arts or commerce, but may possibly have had one far-reaching effect in that it is related that, during the first half of the eighteenth century, an Englishman journeyed to China and there learned the art, returning with his knowledge to England. It is frequently stated that the traveller was Dr. Isaac Lawson, but Percy* raises a doubt as to this. Bishop Watson† relates that in 1743 John Champion established at Bristol the first zincworks, having in 1739 taken out a patent, which although relating to metals had no reference to zinc.*

No doubt appears to exist that Champion was the first to erect zincworks of which we have any historical record, and to start the extraction of the metal on a substantial scale, nor that he, in 1758, secured a patent of great historical interest to us, for the winning of brass and zinc from blende as a substitute for calamine. Bristol had been a centre for the manufacture of calamine-brass since 1702,* and was also a producer of glass. Champion, availing himself of the calamine and a glass-furnace, worked out the zinc problem and established the so-called English method of distillation from large pots *per descensum*, keeping for a long time the actual details in that closely-guarded secrecy which persisted, with respect to the inner details of the metallurgy of zinc—more in reality as a pleasing fiction than an actual fact—right through to comparatively recent years.

There existed in the eighteenth century two very important known and worked deposits of calamine in Europe—one at Moresnet in Belgium, and the other near Beuthen in Poland. Both of these places were noted centres for the manufacture of brass by cementation, as also for the export of calamine for a like purpose, and it was more or less a natural corollary that the industry of zinc-smelting, as it became known, should follow.

Accordingly, towards the end of the eighteenth century the art, most probably learned in England, was carried eastward by Johann Christian Ruberg,‡ who, about 1799 or 1800—

some fifty years or more after the establishment of the Bristol works—established a smeltery at Wessola, in Poland, utilising, like Champion, glass-furnaces fired by wood for his earliest work. Ruberg did not, in the primary instance, avail himself of the calamine which lay so near his hand, but of the so-called "zinkstuhl," or rich zincy concretions which in those days—as indeed they still do—formed at the throats of the blast-furnaces smelting zincy iron ores, and incidentally caused a good deal of trouble to the ironmaster. He very soon found that the method of distillation *per descensum*, as practised at Bristol, was very defective, and thereupon evolved the system of treatment in horizontal muffles of large capacity,* thus laying the foundation of what was to become, in later times, the immense Silesian industry.

Almost coincident with Ruberg's work, zinc distillation from calamine was instituted by Dillinger at Dollach, in Carinthia, in 1799. This, although of some historical interest, had little influence on progressive metallurgy.

By 1805 the industry had advanced so little that in the year named the output of the Wessola works was 12½ tons of zinc only, the cost of production being £36 per ton, and the realised value £42.†

The calamine deposits at Moresnet passed in 1795 under the suzerainty of France, and Abbé Dony, a chemist of Liége, after many years of experimental work and the grant of the Moresnet concessions under the seal of Napoleon, seems to have quite independently discovered the distillation of zinc. There is no evidence that Dony had any knowledge of what had been done by Champion and Ruberg, and it is curious that, with Belgium separated only from England by a narrow strip of water, the secret should have been carried from Bristol so far east as Poland to commence with.

Various stories—pretty, even if not founded on strict fact—are related concerning Dony's discovery. One is that he received the "command" of Napoleon to evolve a method of extracting the metallic contents of calamine, and thereupon performed the rare feat of accomplishing a great metallurgical discovery "to order"; the other that, having inserted a flower-pot to act as a peep-hole in a reverberatory furnace treating a charge of calamine and coal, the zinc vapour condensed in the flower-pot and trickled down as fluid metal. It would be regrettable were we compelled to divest so technical a subject of its romance, and at that it were perhaps better to leave it. Certain it is that Dony, in 1807, established works at Liége, which formed the corner-stone of the Western European branch of the industry. He, by distillation in a number of small retorts set in a single furnace, gave us the Belgian method of extraction in contradistinction to the Silesian already referred to.

In 1805 the very important discovery was made by Hobson and Sylvester, at Sheffield, that between 100° and 150° C. zinc became malleable and ductile. This step forward was destined to exercise material influence by permitting of the utilisation in sheet form of large quantities of the rolled metal.

Nevertheless, the establishment of the means of commercial zinc extraction was one thing, and the fitting of the metal into its niche in the world of art and commerce was another. As might be expected, the brass-makers evinced at first indifference, and even hostility, to the new metal, averring that it produced brass inferior to that by cementation, and its use for this purpose extended but slowly.

The earlier of these objections were quite possibly well founded. It is by no means, apart from other considerations which enter into the matter, to be taken for granted that brasses of the same ultimate analysis, but produced in different ways, are necessarily of the same character or appearance. The method of preparation and the temperature at which the alloying is carried out, no less than the subsequent thermal treatment of the alloy, profoundly affect the characteristics of the resultant. Much of the calamine-brass was produced at a temperature sensibly below that of the melting-point of copper, while practically the whole of the modern brass made by the direct method is the result of thermal operations at a temperature well in excess of that point. The manufacture of the alloy by cementation does not, we realise, lend itself to the production of a high brass, nor is it economical; but, given pure materials, it has afforded some beautiful examples for the craftsmanship of the artist-worker in metals—well known to all who have handled many examples wrought from calamine-brass.

This chilly reception retarded progress, and for some years the industry remained a struggling one owing to lack of popular use for its product.

The good Abbé Dony suffered the fate which befalls many pioneers, in that he died a broken

* Lodin, "Métallurgie du Zinc," Paris, 1905.
† Liebig, "Zink und Cadmium," Leipzig, 1913.

man amidst penurious surroundings in 1819. He had, however, laid down the first rolling-mills at Liége in 1812, and three years prior to his death admitted as partner M. Dominique Mosselmann, a man of great energy and capacity, who took over the works, carrying them on until his decease in 1837. Even then the business was a tender fledgling, but his successors, with a capital of 7,000,000 francs, founded upon it the Société de la Vieille Montagne,* destined to become in modern times, with its world-wide ramifications, the greatest single producer in Europe.

It is recorded that the price of zinc in September, 1809, was 3.60 francs per kilo, falling the following year to 2.40 francs.†

The enterprise at Bristol, unsupported by any important local deposits of calamine, and handicapped by methods of working inferior to the Belgian and Silesian, languished and died out about 1860. Meanwhile, the well-known firm of Vivians had, in 1835, erected works at Swansea in South Wales, around which, as a nucleus, grew the Welsh branch of the zinc-smelting industry. This, limited as it is, remains to-day our Empire's greatest producer, and one may be permitted the hope that we are, for urgent national reasons, destined at no distant date to see radical changes in this respect.

The United States of America made no serious attempt to found zinc-smelting until 1850,‡ but once inaugurated it developed rapidly, and in 1909 placed that country at the head of the world's producers.

In so brief a review it is not possible to deal in any way exhaustively with every historical claim and detail, but an attempt has rather been made to indicate in logical sequence the salient features and successive steps which led up to the art as we to-day know it. Zinc has no history in the sense in which the precious metals, iron, lead, and copper, possess it. Practically unknown, save to a few, until the middle of the eighteenth century, it attained no great importance until certainly the first quarter of the nineteenth.

The nomenclature of zinc is a little confusing. The British usage, and also to a certain extent the American, is to apply the term "spelter" in designation of ordinary ingot zinc of commerce, the word "zinc" being usually reserved for the rolled metal and for chemical and mineralogical terminology. The miner thus sells ore to the smelter on the basis of its zinc contents, and the latter markets the extracted metal as spelter, which is not "a metal" *in sensu stricto*, but a commercial alloy produced by the smelting of zinc ores, and, although consisting mainly of zinc, containing usually sensible proportions of lead and other metals.

Recent usage, so far as Britain is concerned, has inclined towards the use of the word spelter for all grades of metal up to those containing 99·8 per cent. of zinc or thereabouts, those of higher quality than this being designated "fine-zinc." Although arbitrary, there are commercial reasons for the distinction.

III.—Zinc Ores, their Nature, Occurrence and Distribution.

Zinc is the proletariat of the common non-ferrous metals and, true to its class traditions, is by no means easy to extract from its baser surroundings.

Its ores are geographically very widely distributed—so widely indeed, that it is rarely that they are absent from any mining district which is a producer of the base metals. Particularly are they associated with the ores of silver, lead and copper, often forming huge deposits of considerable complexity, and presenting problems to the metallurgist, for the solution of which patents innumerable exist, still providing happy —or unhappy—hunting grounds for the fertile inventor of to-day.

The potential sources of zinc being so abundant it is certainly due to no scarcity of raw materials that its market value is, in normal times, relatively high. Between these potential sources, however, and the merchantable metal Nature has imposed a gulf, to be bridged only by the employment of very technical methods, in works requiring the expenditure of heavy capital for a relatively restricted output, and abundant supplies of skilled and semi-skilled labour for operation.

Many are the technical difficulties imposed upon the metallurgist by reason of the chemical and physical limitations of the metal, and the consequent necessity for the employment of ores relatively high in zinc content. Most of them have, therefore, to undergo some preliminary process of concentration before passing for metallurgical treatment strictly speaking.

The chief commercial ores of zinc are the sulphide—zinc blende or sphalerite—and the class of oxidised compounds usually designated under the generic term of calamine, such being used metallurgically for the oxidised ores of the

* "Official History of Vieille Montagne, 1837-1910."
† *Ibid.*
‡ Ingalls, "Metallurgy of Zinc," New York, 1903.

carbonate class (Smithsonite), hydrozincite and the silicates (Hemimorphite and Willemite). In the U.S.A. the native oxide (zincite) and the mangano-ferrate (franklinite) are also of importance as ores of zinc and sources of zinc oxide.

Zinc-bearing Minerals.

The principal zinc-bearing minerals and their content of zinc when pure are as follows:—

Mineral.	Composition.	Zinc.
		Per cent.
Blende . . .	Zinc sulphide	67·15
Smithsonite . .	Zinc carbonate . . .	52·00
Hydrozincite .	Hydrous basic zinc carbonate	57·10
Willemite . .	Zinc silicate . . .	58·10
Hemimorphite	Hydrous zinc silicate .	53·70
Zincite . .	Zinc oxide	80·25
Franklinite .	Zinc mangano-ferrate.	16 to 21

It is unusual to find any of the above alone constituting an ore of zinc, the latter most generally presenting a complex aggregate of zinc-bearing with other minerals and gangue, or worthless material, often requiring mechanical concentration for the removal of the undesirable constituents before a product of sufficient commercial value can be offered to the zinc-smelter.

Zinc-Blende — ZnS — contains, when pure, 67·15 per cent. of the metal, but is usually contaminated with iron manganese and baser substances, so that, in the form in which it is supplied to the zinc-smelter, it usually contains only from 35 to 55 per cent. of zinc. The more complex ores very commonly contain sufficient amounts of silver and lead also to render the residues, after extraction of the zinc, profitable commercial sources of those metals. Particularly is this the case with the ores from Broken Hill, N.S.W.

Smithsonite, the carbonate of zinc, was one of the earliest ores employed in zinc-smelting, and although the bulk of the metal is to-day derived from blende, it is still of considerable importance. It contains, when pure, 52 per cent. of zinc, but more generally, in the deposits in which it is commercially exploited, ranges much lower, owing to the admixture with silica, lime and iron. Ores containing as little even as 13 per cent. zinc are worked in Silesia by local smelters, such being too poor, of course, to bear the cost of transport. On calcination it loses the bulk of its carbon dioxide, and it is customarily calcined before distillation, the more particularly as it thereby loses considerably in weight, and becomes relatively enriched in zinc, this varying with the original composition of the ore.

Hydrozincite is a basic hydrated carbonate of zinc. Between it and Smithsonite there is, metallurgically speaking, little calling for comment.

Willemite is anhydrous silicate of zinc. The best-known deposits of it occur in New Jersey, U.S.A. In its pure state it contains 58·10 per cent. of the metal, but manganese and other base constituents are usually present and lower the value materially.

Hemimorphite is a hydrous silicate of zinc containing, when pure, 53·7 per cent. of the metal. It is not widely distributed in deposits of such economic importance as blende and smithsonite; but in Virginia and Missouri, U.S.A., and at Aix-la-Chapelle and Moresnet, in Belgium, it has been extensively worked, the latter two deposits being now practically exhausted. It is noteworthy in one respect in that the Virginian occurrence provided the source of one of the purest brands of zinc in the world, obtained by ordinary distillation methods direct.

Zincite (the native oxide of zinc), in a condition of purity containing 80·2 per cent. zinc, and franklinite (the mangano-ferrate), of variable composition, but with as a rule about 12 to 18 per cent., are important also, although of local significance, practically the sole worked deposits being in New Jersey, U.S.A.

Franklinite, owing to its composition, is worked mainly for the production of zinc oxide on the blowing-up grate, the residues being smelted for Spiegeleisen in the blast furnace.

Another source of the metal, although not an ore, consists of the zinciferous flue-dust which results from the smelting of iron and manganese ores containing small quantities of zinc. In available quantity it does not approach the ores previously referred to, but is an interesting metallurgical example of how the treatment of an iron ore, valueless as such from the point of zinc, results in a bye-product containing often as much as 75 per cent. of the latter metal and correspondingly valuable. It is produced by many of the iron blast-furnaces in our own country; and in the works at New Jersey, U.S.A., smelting franklinite residues it is a most important bye-product.

The geographical distribution of zinc ores in quantities of such magnitude as to warrant exploitation for their metallic contents is so

wide that reference to specific occurrences must necessarily be abbreviated, and then apply only to the more important of them.

In Great Britain zinc ores are being worked on a moderate scale, the best-known deposits being those in Flintshire, Cardiganshire, Durham, Cumberland, Derbyshire, and the Isle of Man, where they occur generally with those of lead, and are worked for both metals, being subjected after mining to crushing, concentration, and separation. Blende is the chief source of the metal, as exploited from our domestic deposits, the total production from which was, in 1913, 18,073 tons. It is not particularly creditable to our industrial organisation that a considerable part of this passed to the Continent for treatment, whilst our imports of zinc continued in ever-increasing quantities.

Australia has, in recent years, become a huge ore producer, although very little is smelted in the country itself; practically the whole is derived from the famous Broken Hill mines in New South Wales, the discovery and working of which provided one of the many romantic histories of mining. The material as exploited, from a huge lode deposit in places 300 ft. wide, consists of a complex association of galena (lead sulphide) and blende, interspersed through a gangue mainly composed of rhodonite (manganese-silicate), quartz, and garnet. It is also highly argentiferous. It is crushed and concentrated to remove the bulk of the silver-lead contents, the residue from this operation being dealt with by further methods for the production of zinc concentrates containing still some lead and silver. The real development of the zinc side of the industry was due to the discovery of the now well-known process of concentration by flotation, the similarity of specific gravity between valuable mineral and gangue having rendered abortive all previous attempts by the ordinarily accepted methods.

In normal times the Broken Hill deposits are capable of yielding within measurable distance of half a million tons of zinc concentrates annually, but, owing to the war and the consequent lack of available smelting-plants for their treatment, the restriction of output has been great. The quantity referred to would yield roughly no less than one-fifth of the world's annual output of zinc, and the enormous importance of this source, our Empire's greatest, may thereby be gauged. The ascertained life of the chief Broken Hill producing mines is also such as to assure the future production, although on a gradually reduced scale, for some years to come—probably ten as a minimum—even if no further ore bodies be developed. The whole of this is won from an area about three miles in length and less than a quarter of a mile wide, and this alone renders the deposit absolutely unique in the history of zinc-mining. A typical analysis of these Broken Hill concentrates as delivered to the metallurgist may here be given:—

	Per cent.
Zinc	46·50
Lead	8·50
Iron	7·60
Manganese	1·60
Sulphur	28·50
Lime	0·90
Cadmium	traces
Silica (insoluble)	4·50
Alumina	0·40
Copper	0·18
Oxygen / Organic matter and loss	1·30
	99·98

Silver, 15 oz. per ton.

Broken Hill produces no calamine.

South Africa possesses one known deposit—the Rhodesian Broken Hill—of some note, consisting largely as it does of a mixture of carbonate of lead with the carbonates and silicates of zinc, but transport and technical difficulties have so far prevented its appearance in the ranks of notable producers.

In Burma, active development operations are in progress, under which vast deposits of silver-lead-zinc ores of the sulphide class are being opened up at Bawdwen in the Northern Shan States, Upper Burma, some sixty miles only from the frontier of the Chinese Province of Yunnan. They are remarkable on several grounds, not the least being the high silver ratio and the comparative freedom from gangue, the crude ore as mined containing often as much zinc as the Broken Hill concentrates, with substantially greater quantities of lead and silver. While it is as yet too early for these deposits to have influenced the world's supply of zinc, the promise they bear of doing so in marked degree in the near future cannot be overlooked.

Canada and British Columbia have appeared in recent years as ore producers, although not in substantial degree. Such output as there is the American smelters have in the past absorbed, but recent proposals for the fostering by the State of the zinc industry in the Dominion of Canada invest the subject with a new interest, and render it highly probable that the exploitation of known deposits and the search for new ones will receive a marked stimulus.

The principal deposits of zinc ore situated within our Empire having thus been briefly outlined, the remaining countries of note in this connection may conveniently be referred to in alphabetical order.

Algeria (with which we may for convenience bracket Tunis) is a considerable producer of calamine, most of which, shipped from the ports of Bona and Sousse, found its way to Belgian, French, and German smelters.

Austria contributes modest amounts of zinc ore from her mines in Carinthia and the Tyrol, but in Hungary mining for the metal is almost unknown. The Austrian mines afforded, in 1913, 34,674 metric tons.

China—one of the earliest producers—has important deposits of both calamine and blende in the south-west provinces, chiefly Kweichou, and large quantities of zinc ores occur in the prefectures of Hêng-chou and Yang-chou. She also smelts to a limited extent, actual figures of output being difficult to ascertain.

France is a moderate producer, but much of the ore she smelts is of foreign origin. Her domestic production of ore in 1912 was 45,700 metric tons.

Germany.—In the case of this country the importance of domestic sources of ore is very great. The calamine deposits of Upper Silesia were among the most noteworthy in the world, whilst blende is the product of several districts, notably of the Hartz. The Upper Silesian deposits yield blende in the deeper workings. The production of zinc ore in Germany for 1913 was 637,308 metric tons, and from this its importance may be gauged.

Greece, with the mines of Laurium and some others, makes a good showing, her output of calcined calamine and blende being, for 1912, 68,497 metric tons.

Italy, with the mineral wealth of the districts of Bergamo and Sardinia, contributed 149,776 tons in 1912. She produces both calamine and blende, and one British company—the English Crown Spelter—operates important mines, and ships the ore for treatment at Swansea. The Sardinian calamine is famous.

Japan is a moderate producer.

Mexico came rapidly forward with her zinc ores, absorbed almost entirely by American smelters, but internal strife and political troubles have gravely retarded the expansion which offered such bright promise of future performance.

Russia is opening out, under the auspices of British capital, several deposits of the complex ore class in the Nerchinsk district of Eastern Siberia, and in the Altai Mountains, Siberia, in the Irtish River district, and her production, not very important now, may well prove a factor to be reckoned with when peaceful conditions permit of the development of her zinc resources on a scale commensurate with their importance. Russian Poland, in the districts bordering Silesia, produces calamine.

Spain, from the provinces of Murcia, Santander and Cordoba, is a contributor to ore supplies, both calamine and blende, her total yield in 1912 being 175,311 metric tons. Practically the whole of that produced was shipped to Belgium, Germany and France for treatment.

Sweden is a notable factor, her principal deposits at Åmmeberg being controlled and worked by the Vieille Montagne. From close investigations made by the author, many of her iron mines yield also no small amounts of blende, and under favourable conditions the potentialities of this country are undoubtedly considerable. Her output in 1913 was 50,036 metric tons, practically the whole being blende.

United States of America.—Alphabetically the last, we turn to this country with premonitory intuition that, in importance at least, it will not be so, and are not disappointed. It is the greatest producer of zinc ores in the world, the output for 1913 being no less than approximately 790,000 English tons — this not including ore exported, or that used in the manufacture of zinc oxide. Both calamine and blende are most extensively worked, and in addition the noted zincite and franklinite deposits. There exist, too, great reserves of the more complex lead-zinc ores, to a considerable extent untouched on account of the abundance of the simpler and purer sources. The chief ore-producing States in their order of importance are Missouri, New Jersey, Colorado, Montana, and Wisconsin, but as no less than nineteen of them figure as producers reference must be restricted to the more important. Of those cited, Missouri, with its famous Joplin district teeming with calamine and blende deposits of singularly docile character, comes easily first. Colorado derives 75 per cent. of its output from the Leadville mines. Montana's contribution comes largely from the celebrated copper district of Butte, and the potentialities are such as to cause confident prediction that this State will prove a serious rival for supremacy. New Jersey deserves special mention, owing to the fact that practically the whole of its ores are won by a single concern, the New Jersey Zinc

Company, from two localities in Sussex County —Franklin Furnace and Stirling Hill. The deposits are unique. Rated on its ore output, the State ranks second, but on the basis of spelter produced fifth only, on account of the enormous quantities consumed in the manufacture of zinc oxide direct from the ore. It is here that zincite, franklinite and willemite attain their high importance as ores, the two latter being often closely associated and separable only by magnetic means devised by Samuel Wetherill, whose name thus became intimately associated with the history and success of the district, as well as on the ground of his application and development of the blowing-up grate for the economic production of zinc oxide direct from the ores.

The State of Virginia yields ores of such character that on distillation they afford zinc of exceptional purity—fine zinc. They are silicate ores, and, as treated by the Bertha Zinc and Mineral Company, with special care pass into commerce as the world-famed "Bertha pure spelter," quoted by Ingalls* as containing 99·981 per cent. of zinc. It is thus nearly chemically pure.

Calamine and blende occur in both lode and bedded deposits, the latter frequently in limestone rocks, but the Broken Hill occurrence of lode type lies in somewhat schistose gneissic rock, and is of great antiquity in the geographical sense. The outline map of the world presented with this paper has been marked with the more important producing districts.

IV.—The Metallurgy of Zinc.

The extraction of zinc from its ores is divided metallurgically into two clearly-defined stages— the preparation for distillation and the distillation itself, the two operations being so distinct that they may be, and often are, carried out for commercial reasons in establishments widely dissociated from one another geographically.

Practically the whole of the world's supply of commercial zinc is obtained by distillation of the ores, in conjunction with carbon as reducing material, in relatively fragile externally-heated fireclay vessels or retorts. Before this can be effected, however, the ores themselves need preliminary treatment to fit them for it, particularly those of the blende class, which require a careful and almost complete desulphurisation. If this be not done, every unit of sulphur remaining behind has the power of retaining and rendering unrecoverable by distillation two units at least of zinc, besides introducing technical troubles in several directions. This rule, while not absolutely applicable to every class of ore, is, in the main, accurate, and with all sulphide ores, however composed, the more perfect the desulphurisation the better may the subsequent distillation be effected.

* "Metallurgy of Zinc," New York, 1903.

The calamines are calcined for the expulsion of the bulk of the carbon dioxide and combined water. The operation, however, is seldom complete, and as much even as 15 per cent. CO_2 may be left if the ores are very calcareous or magnesian.

Occasionally, indeed, calamine is distilled without such treatment, but few metallurgists will be disposed to accept this course as sound practice. Apart from any other reason, the economy in freightage between mine and smelter is usually sufficient to warrant calcination, this saving being more important where the two are situated widely apart. The operation is extremely simple, and is entirely analogous to the burning of limestone for lime, being carried out in practically similar manner, usually in kilns, in the presence of an excess of air and also of moisture, the two latter points being important for the attainment of good results. The use of kilns is restricted to lump ore, or a mixture of lump and fines, usually in alternating layers, while for calamines consisting wholly of fines it is necessary to use either a reverberatory type of calciner (hand or mechanically operated) or a circular revolving calciner of the well-known Oxland type. The fuel used for kiln work may either be alternated in layers with the ore, or burned on separate fire-grates. If the former, one is rather restricted to the use of charcoal or better-class coal with the corresponding disadvantage of contamination of the calcined material by the contained ash. Calamines containing high proportions of calcium carbonate are the most difficult to calcine with reasonable completeness, and such usually retain a sensible proportion of their original carbon dioxide contents. The chief carbonates associated with calamine, and the approximate temperatures required for expulsion of their CO_2, are as follows*:—

Zinc	carbonate	300° C.
Magnesium	,,	650° C.
Iron	,,	800° C.
Calcium	,,	812° C.

The hydrated zinc minerals need nothing more than simple heating to the dullest perceptible red for their complete dehydration. In

contradistinction to the comparative ease and simplicity which characterise the preliminary treatment of the calamines on the one hand, the blendes, and ores of the sulphide class generally on the other, offer considerable difficulties, and this is particularly true of those which are of complex nature, containing, as they commonly do, substantial amounts of iron, manganese, lead, lime, and sometimes baryta.

The problem calls for the replacement of the original sulphur by oxygen—and that to the greatest possible extent in every case.

Pure zinc blende contains 32·85 per cent. of sulphur, but it is uncommon in practice to find such constituting an ore except in the notable instance of the Joplin blendes. The usual ores may contain a greater or lesser percentage than the figure given according to the presence or absence of iron pyrites, lead, and gangue materials, but 21 per cent. to 30 per cent. would include the limits more usually encountered.

Desulphurisation is usually effected on the crushed ore by roasting in the presence of an excess of air in shelf furnaces of two or more rows. Where the resultant sulphur dioxide fumes are not liable to cause damage or nuisance, and where they are not required for the manufacture of sulphuric acid, the furnaces are of open type, and the fire-gases passing over the ore, together with excess of air, escape to the atmosphere. It is, however, now the practice in most European and many American works to carry on the roasting in conjunction with the manufacture of H_2SO_4, and this for two main reasons—the restriction imposed by legislation in most thickly populated countries upon the discharge of sulphurous gases to the atmosphere, and the value of H_2SO_4 in such localities due to the fact that they are usually also of industrial importance and consumers of the acid, and it therefore pays to utilise the sulphur. It is not uncommon in Europe to find the roasting and manufacture of H_2SO_4 being carried on in one district where the call for the acid is considerable, and the roasted ore distilled in another where conditions as to fuel, clay, and labour are the more favourable. Economic considerations govern, of course, each individual case, and this system has reached its most pronounced development in Belgium and Germany, largely owing to the abundant and cheap facilities for transport afforded by the various canal systems.

Where the manufacture of H_2SO_4 is one of the objectives, certain conditions are imposed upon roasting, the most important of which is the carrying out of the work in muffled furnaces, whereby the fire-gases never come in direct contact with the ore, the fumes from which are led by an independent flue system to the leaden chambers which are most generally used for H_2SO_4 production.

It may be here remarked that the contact system of acid manufacture has found but little application in connection with zinc-ore roasting.

The muffled roaster consists typically of three superimposed muffles on to the hearth of the uppermost of which the ore is charged. It is stirred and moved along by means of tools inserted through a series of working doors, which can be closed by slides, along the side of each muffle and passes to the second muffle through a drop opening at the end of the first hearth. It is moved in the reverse direction along the second hearth, drops to the third, and by a similar process of transference reaches the end of the latter, and is drawn intermittently in desulphurised form. The heating system, which may be arranged for direct coal firing or producer gas, passes under the lowest hearth and away, or under the lowest and then by a reverse turn under the middle hearth thence to the chimney system. There are endless modifications of these furnaces, but the basic type remains the same. They are often built in blocks of four, one fire system serving two roasters, and the conservation of heat being also secured to some extent by the lessening of radiant surfaces. This method of construction also effects an economy in capital cost and a reduction of the material necessary.

The operation of roasting furnaces may be effected manually or mechanically, the tendency in recent years, particularly in the United States, being towards the latter, and a number of such mechanically operated roasters are in use, amongst the most noteworthy being the Hegeler, Brown, Merton, and De Spirlet. On the simpler types of ore they have been most successful, particularly when they are of the non-muffled construction, which permits of simplicity.

The muffle furnace for mechanical operation is another matter, however, and in this form, and for the complex ores particularly, it has not yet reached the development and application which every zinc metallurgist devoutly hopes it may do. Of its economy, if successful, under the special conditions named, there can be no possible doubt.

The basic principles underlying the roasting of zinc ores in general are theoretically simple enough. In the presence of heat and air the

sulphur and oxygen change places according to the following equation—

$$ZnS + 3O = ZnO + SO_2.$$

This reaction is strongly exothermic, the sulphur acting as fuel.

At the same time a certain amount of sulphating takes place in the following way—

$$ZnS + 4O = ZnSO_4.$$

These reactions proceed under normal circumstances with the evolution of sufficient thermal units to render any external application of heat unnecessary. The ore is, once it is heated up, self-roasting to a point roughly corresponding to that attained when the total sulphur contents have been reduced to 8 per cent., the actual figure depending upon furnace construction and composition of ore. Beyond this, the application of heat becomes more and more necessary in order to split up the sulphates, and the process of sulphur expulsion, which began as an exothermic one, ends up by being strongly endothermic, the final finishing temperature in the ore bed lying between 900° and 950° C.

In muffled roasting for the manufacture of H_2SO_4 the roaster gases have necessarily to contain a minimum percentage of SO_2, which may be stated as 5 per cent. by volume. Below this figure the acid-chamber reactions are prejudiced, and if it rises sensibly over 7 per cent. the roasting is retarded. The result is that for conditions satisfactory alike to acid maker and roaster a compromise has to be arrived at which may lie, in average practice, between 5·5 per cent. and 6·5 per cent. SO_2.

However simple theoretically the roasting reactions in the case of the purer zinc blendes may appear to be, the more complex ores give us material for quite different consideration, and it is doubtful whether in the case of many of them the actual steps which lead to the ultimate result are really known.

The ferrous compounds for instance, behave quite differently, according to whether the iron exists primarily as a free iron compound, or as an isomorphous replacement of the zinc, as in certain ferriferous blendes—similarly with manganese.

Lead tends to sulphate in roasting, and as such forms a stable compound difficult to split up save in the presence of free silica and at a high temperature. Calcium and barium when present form also their very stable respective sulphates, which, however, are usually regarded as having a minor prejudicial influence in subsequent distillation.

Copper, in small amounts, introduces no complications.

The net result is that, while certain of the purer ores may, and do, lend themselves to a desulphurisation so complete that no more than from 0·5 per cent. to 0·8 per cent. total sulphur remains, others equally carefully dealt with retain from 2·5 per cent. to 3 per cent., and even more in special cases, particularly those where lime and baryta are present. It is generally conceded that the latter, when constituents of the roasted ore as sulphates, do not exercise the prejudicial effect during distillation that might be expected to result from their reduction to the respective sulphides by carbon in the retort, but the composition of the ore influences, naturally enough, the subsequent thermal reaction in the retort, and each case has therefore to be judged as a separate entity.

Although zinc ores are rarely absolutely free from lead, the trouble introduced by the presence of this metal in substantial amounts prevented to a large extent the smelting of such ores (usually classed as complex) until later years. It is now, however, by no means unusual to find those with 8 and even 10 per cent. of lead being dealt with successfully by ordinary methods, while the writer has had experience in roasting and distilling some thousands of tons containing from 14 to even 20 per cent. lead. The position arrived at is that, with due exercise of care and the selection of appropriate retort materials, the difficulties may be overcome to such a degree as to allow of entirely profitable commercial working. This is of far-reaching importance, as vast additional potential sources for the augmentation of spelter supply have thereby been rendered available, with the prospect of further ones now well within sight.

The presence of lead, usually in the form of sulphide, leads at first to the formation of sulphate, which afterwards becomes partially, although never wholly, split up into lead oxide, sulphur dioxide, and oxygen, which latter no doubt in its turn reacts with the other sulphides of zinc, iron, etc., present. This splitting up, if carried out by main force of thermal units alone and in the absence of silica, is not easy. The really excellent desulphurisation of Broken Hill flotation concentrates—containing say 45 per cent. zinc, and even as much as 10 per cent. lead, which is daily achieved by well-designed muffled roasters—is so remarkable as to be

inexplicable on these latter grounds and merits closer consideration. These concentrates are very low in silica—sometimes, indeed, it is almost absent—and contain their zinc not as true zinc blende, but rather as marmatite, a mineral in which the zinc is partially replaced by isomorphous iron and manganese. During the progress of roasting the iron and manganese form their respective oxides, and from close observations made over a considerable period of time the author puts forward the view that such oxides, under suitable conditions as to temperature and air supply, become strongly catalytic oxidisers. In the presence of these, and of the respective sulphides and sulphates of lead and zinc, complex mass-reactions go on which end in a removal of the sulphur so complete, that at a finishing temperature not exceeding 950° C. the roasted ore of composition above cited may contain as little as 1 per cent. sulphur. The temperature must, in fact, not be allowed to become excessive, otherwise the losses of metals by volatilisation, particularly silver and lead in the form of sulphate, attain quite serious proportions.

The writer has observed also that these results do not seem to follow in the case of ores in which the iron and manganese have no defined chemical association with the zinc, such as mechanical mixtures of blende and pyrites, or blende and rhodonite. Further, the reactions appear to reach their maximum effect in muffled roasters, and are not nearly so noticeable in roasting carried out in furnaces of the "open" type. The thoroughly well-roasted ore of the description referred to has a typical appearance, being of a bluish-black colour, with glistening particles quite different to those of badly roasted material. The colour seems to be due to zinc manganoferrate. Indeed, in muffled roasters under the author's control this compound (artificial franklinite) accumulates on the lowest hearth in impure fibro-columnar aggregates, often in columns of minute octahedral crystals, to such an extent as to render periodic removal by scaling very necessary. It forms, as a rule, in impure masses along with a good deal of lead sulphate, zinc silicate, and lead sulphide finely crystallised. Its formation is indubitable, and an analysis of the separated material gave a result closely approximating to the composition of franklinite, and practically lead and silver free. The analysis referred to is given below, with an example from Dana of the natural mineral for comparison.

Constituent.	Roaster Furnace Product from Australian Concentrate.	Natural Mineral from Stirling Hill, U.S.A. (Dana.)

Insol., Lead, Sulphur, etc.	2·37	—
	99·99	100·04

It has been wittily, if somewhat caustically, put* that—"It is a time-honoured custom to throw bricks at the zinc man. The accusation is that he has borrowed a lime-kiln and a gas-retort and part of a sulphuric-acid plant, hitched them together and spent the last fifty years in regarding with holy veneration the reactions which take place in that retort. The copper man, who thinks of zinc as something with which copper is adulterated to make brass, the iron man who regards it as a sort of paint for corrugated sheets, and the lead man whose opinion as to zinc is not fit for publication, have long felt that when two or three of the minor details of their respective metallurgies were put in order they would take a few days and fix up zinc on a modern basis. But somehow they still seem to have some unsolved problems at home."

It is true that we have to-day in operation methods of extraction which differ little from those used by the veterans Abbé Dony and Johann Ruberg, progress having been achieved rather along the lines of more efficient working and mechanical details, furnaces and fuel consumption, lower costs and higher recoveries, than of any spectacular and radical changes, such as have occurred in the modern metallurgical history of iron, copper and the other common industrial metals. That this is the case is due solely to the chemical and physical limitations of the metal, and in no wise to lack of research, the application of brains and the expenditure of vast capital sums.

The fundamental facts underlying the matter are:—

(1) That zinc oxide is not sensibly reduced by carbon and carbon monoxide below a temperature of 1125° C.†

* *Trans. Amer. Inst. Mining Engineers*, "Metallurgy of Zinc," Jan. 1914.

† Ingalls, "Metallurgy of Zinc and Cadmium."

(2) That at this temperature the reduced metal is in the condition of vapour, not only extraordinarily susceptible to ordinary oxidising influences, such as air and water vapour, but capable even of being oxidised by carbon dioxide.

(3) That the reduction of zinc oxide is a strongly endothermic reaction, necessarily carried out at high temperatures (modern practice calling for 1400° C.) in fragile externally heated fireclay vessels. Thermal efficiency cannot therefore be high.

(4) That the vapour so obtained has to be efficiently condensed to liquid metal, and this in a clay condenser the temperature limits within which must be so narrowly controlled as to lie within points well under the boiling-point and over the melting-point of zinc.

(5) That the operation is not continuous, but has to be carried out on small tonnages in furnaces of strictly limited capacity.

(6) That a loss of metal in the form of vapour, once sustained, is practically impossible to retrieve,

(7) That zinc vapour, for efficient condensation to fluid metal, must of necessity be above a certain density—relatively rich in zinc, thus limiting the profitable distillation of ores to those comparatively rich in the metal.

These are sufficiently formidable reasons to indicate clearly why it has not been found possible to smelt zinc ores in blast or reverberatory furnaces such as are used for iron, lead, and copper. The oxidising influence of carbon dioxide alone on zinc vapour is such that in distillation operations, at the temperatures ordinarily employed in practice, a tenor of 0·25 per cent. CO_2 would be hopelessly inadmissible.

The calcined calamine, roasted blende, or zinc-bearing material containing practically the whole of its metal as oxide—or silicate in the case of the silicate calamines—is mixed with reducing material in the form of coal, coke, or a mixture of both, and heated in fireclay retorts whereby the zinc is reduced to metallic vapour which distils over, and is condensed mostly as fluid metal, and partly in a finely divided pulverulent condition known as zinc dust, blue powder or *poussière*. In South Wales it is customary to use fine anthracite coal as reducing agent, and, when obtainable at a favourable cost, this material is both advantageous and efficient.

A modern distillation furnace consists of a large number of such retorts arranged horizontally in two or three superimposed rows and heated by producer-gas firing. The Belgian furnaces may contain even up to six or eight such rows of small retorts, but modern practice tends to the lesser number. They are arranged usually in two sets, back to back, with an intervening space for the gas and air-ports, the laboratory space in which they are set being a more or less elongated rectangular firebrick chamber with arched roof. The substructure of the furnace is usually arranged for recuperation or regeneration on the Siemens system, whereby the waste heat of the furnace is utilised to heat either the incoming air or gas, or both. The retorts are permanently closed at one end and open at the other, the latter resting on a shelf just outside the lateral furnace wall. To this open end is fitted a fireclay condenser, and to the open end of the condenser is fitted a sheet-iron drum or prolong, which serves to catch as powder the residual zinc not condensed to metal in the condenser, or " pipe " as it is sometimes termed.

Several main systems of distillation practice are in existence, evolved at the main centres of the industry—the Belgian, Silesian, Rhenish, Rhenish-Belgian, and the so-called Welsh-Belgian, which offers nothing novel or distinct as compared with the Belgian proper. They differ mainly in the size and shape of the retort, the number and arrangement of the retorts in the furnace laboratory space, the type of condenser and the system of firing, but the main principle applies to all.

Silesian practice employs the largest retort (or muffle), and Belgian the smallest. Variations between these extremes in working practice and details are so many that a treatise would be necessary to discuss them.

The older furnaces were direct-fired by coal and were very wasteful of fuel. Semi-gas firing on the Bœtius principle followed, and that in time gave way to the Siemens producer with regeneration. The most modern practice is to employ highly efficient steam or air-blown producers with fire furnaces of much higher recuperative or regenerative design.

The adoption of these more efficient thermal methods has resulted in the lowering of the fuel consumption per ton of average ore distilled from two or even three tons to, in favourable circumstances, one ton or rather less, presuming that the fuel consists of a good average coal suitable for gas-producer use.

In the United States a powerful advantage has been turned to account in the form of the immense supplies of natural gas existing in certain localities. The fuel question is so

important a factor in zinc production that these natural gas resources have permitted of the establishment of zinc distilleries in districts which offer otherwise no special advantage, the capital required and the working costs being so lowered thereby as to offset any disability attaching to transport of ore, clays, reducing material and finished product.

The manufacture of retorts and condensers is always carried out at the smelting-works, and forms a most important branch of the art. The retorts vary greatly in cross-section and dimensions, the former being circular, oval, or parallel-sided with semi-circular ends, the main governing factor as to cross-section being that it is not so great as to cause low efficiency by reason of incomplete transmission of thermal units to the central portion of the charge. Circular retorts for this reason seldom exceed 8 in. in internal diameter, while the internal width of the oval and parallel-sided, particularly when used for refractory ores, is seldom over 7 in., and is better when not exceeding 6½ in. The internal dimensions of the retort are—maximum height, $13\frac{9}{16}$ in.; width, $5\frac{11}{16}$ in.; and length, 5 ft. 5½ in. The thickness of the butt or closed end is 2 in., and that of the side walls 1 in.

Remembering that all the thermal units have to pass the poorly conducting walls of the retort, the latter are kept as thin as compatible with strength and impermeability. They seldom vary in ordinary practice up or down of 1 in. in thickness, but the bottom may be 2 in. or even 2½ in. to resist the corrosion of slag and matter formed in distillation.

The requirements for a good retort are refractoriness, strength, density, and impermeability to zinc vapour, freedom from cracking, and maximum resistance to the cumulative corrosive effect of the impurities in the charge. The clays therefore utilised in the manufacture must be of special nature adapted to meet these conditions, which are best covered by a mixture composed of burnt clay, or chamotte, and sufficient raw clay to act as an efficient binding agent.

In modern practice finely-ground coke is often used to replace part of the chamotte, as it assists in retaining the shape of the retort under great heat and gives density and impermeability.

A typical retort mixture would consist of:—

Crushed burnt clay (chamotte) . .	50 parts
Raw clay	40 ,,
Finely ground coke	10 ,,

The chamotte is crushed to pass a screen of eight holes to the linear inch, and the raw clay and coke as finely as possible. The mixture is damped so as to contain 15 per cent. moisture, passed through a pug-mill and allowed to "mature"—the maturation developing plasticity possibly owing to the formation of "gels," or films of gelatinous silica, on the particles composing the raw clay. After maturation, the duration of which may be a matter of days or weeks, the mixture is repugged and is ready for retort manufacture.

Retorts were originally manufactured by hand, but are in modern practice almost exclusively machine-made in a hydraulic press. The mixture is either pressed or stamped into the form of a cylindrical ballot which is pressed or squirted in a hydraulic press in very similar manner to that in which earthenware drain-pipes are made.

Maturation is dispensed with by certain works and the freshly pugged mixture pressed forthwith. Variations in composition of mixture to secure the desiderata already enunciated are very common, and some retort mixtures may contain four or five different clays to obtain the sought-for condition. A tabular list of eight typically suitable clays and their analyses is appended.

The green retorts are stood upright in rows in chambers to dry, the process being accelerated by artificial warmth conveyed by warm air or steam-pipes towards the end of the drying. The manufactured retort may contain 12 to 14 per cent. moisture, and this at the end of three months is reduced to 1 per cent. or under, when it is ready for distillery use. The final drying chamber temperature may run from 120° to 130° F.

The condensers are of various forms according to the retort capacity, type of furnace and system of distillation. They may be plain clay cones, conical-bellied to act as a metal receptacle, or D-shaped. Made of common clay mixtures by either hand or machine, they need little of the meticulous care necessary in retort manufacture, as they are not called upon to resist the same high temperatures or other destructive influences. After careful drying, with or without baking, and sometimes a coat of lime-wash, they are ready for use.

The retorts before being used for replacements in the distilling furnace are tempered by being gradually heated in a tempering oven or stove, until they attain a full red. In this condition they are transferred to the furnace and luted in position.

VII. Swedish burnt shale for chamotte.
Analyses I., II., and III., by S. J. Tweedy, Central Zinc Co., 1912.
VIII. Is an English clay of fluviatile origin, very plastic and dense when burned. The alkalies and titanic oxide are unusually high for so refractory a clay.

The process of distillation is not a continuous one, but consists in a well-defined cycle of operations repeated every twenty-four hours.

The roasted ore or zinciferous material, always in oxidised form, is mixed with from 45 to 60 per cent. of its weight of reducing material—coke, coal, or anthracite. This mixing, formerly done by hand, is in all modern plants performed by mechanical means.

The proportion of reducing material requisite is enormously in excess of theoretical requirements—in point of fact, from four to five times the latter or even more.

The retorts emptied of their exhausted charge are cleaned, patched, or changed if necessary, and the mixed charge, slightly damped, charged in by hand-scoops—either thrown in, where removable condensers are used, or through the condenser in the Silesian fixed-condenser type. Condensers are luted up, cracks, etc., and leakages stopped with clay, and distillation proper begins. The moisture and volatile matters are first driven off, followed by the reduction of the iron, and this again by the reduction of the zinc. The resultant carbon monoxide at the condenser mouth is ignited, and burns with its characteristic flame tinged more and more by the bluish-green of zinc. The sheet-iron drums or prolongs are then fitted to the end of the condensers, and the temperature gradually raised over a period of hours until in about from twelve to fourteen hours from the inception of distillation it attains its maximum, and is maintained until the CO flames and the sinking of the retort charge indicate that the operation is practically complete. The oncoming shift of furnace hands then take charge, tap the condensers and prolongs for their metal and

zinc powder respectively, draw the spent residues, change the retorts and recharge. So the process goes on, one charge per twenty-four hours being worked off.

It must here be observed that the metal may be tapped three or four times during distillation into hand ladles, or once only into a mechanical ladle runinng along the furnace front, also that charging and discharging of retorts may be accomplished by mechanical means. The latter is, as yet, in its infancy, and the majority of works still employ manual workers for the purpose.

A typical time-table for the twenty-four hour cycle would be: 7 a.m. to 12.30 p.m.—Metal tapped and cast, residues drawn, retorts changed, furnace charged and luted up. 12.30 to 1 p.m.—Cleaning up, luting leaks, etc. 1 p.m. to 2 p.m.—Charge heating up, furnace house cleaned up, etc., and left for workmen who attend to furnace over distillation period. 2 p.m. to 7 a.m.—Distillation period. Prolongs attached to condensers as soon as zinc flame appears.

This cycle of operations has been illustrated graphically, and in greater detail, by means of a clock-chart, divided as to the one half from twelve (noon) to midnight and the other from midnight to twelve (noon). It will naturally be understood that this chart is an idealised view of the operations. Variations in practice and circumstances would cause variations in the time-table.

The progress of distillation can be observed and the charge in each retort watched through the open condenser. The metal is poured into cast-iron ingot moulds and forms, plates or cakes, rectangular in form, the dimensions of which are about 17½ in. by 8½ in. by 2½ in., each cake weighing from 45 to 50 lb.

The zinc powder from the prolongs is sifted through a sieve of seventy meshes per linear inch, and sold as such after packing in drums or barrels.

In its best form it contains from 86 to 92 per cent. of zinc as metallic zinc. The formation of some powder is inseparable from distillation, but the proportion varies according to the manner in which the work is carried out, and may also be deliberately controlled by the use of a haloid salt, such as common salt, placed preferably at the mouth of the retort or even in the condenser. In this position it fulfils its object perfectly, without the drawback of influencing the lead and silver contents of the charge, as it does if mixed with the latter in the case where complex ores are under treatment. This method is the subject of a patent by H. W. Webster and the author, and has passed into practical use with entirely successful results.*

The exhausted residues, as drawn from the distillery retorts, drop into cellars or pockets, and in the case of clean zinc ores are thrown away. When, however, complex ores with lead and silver are under treatment they are usually concentrated by simple water-concentration in jigs or on tables, and the enriched material passed to the lead smelter.

The old retorts are thrown to the waste heap, but the condensers are chipped for the crusts of metal and oxide, which are returned to the retort charge. After so chipping, there is usually sufficient adherent oxide to render crushing and concentration profitable, the concentrates with 60 per cent. zinc and upwards being also redistilled. The condenser scrapings, oxide, and dross from the metal ladle are all recharged to the distillers in addition, and the metal resulting from the treatment of these bye-products amounts to a very sensible proportion of the eventual total extracted from the ore.

The spelter as produced by distillation varies greatly in quality according in no small measure to the composition of the ore from which it is produced. The American willemite ores yield a very pure metal, but all spelter produced from leady ores contains lead. By simple liquation the latter may be reduced to 1 per cent., or rather under, but no further, and for purer metal a redistillation must be resorted to. The metal obtained direct at one operation from the ore is often termed "virgin spelter," and a typical composition of such is appended in the form of an analysis, specially made for the purpose of this paper, of a good English spelter produced from Broken Hill ore by the Central Zinc Company, Limited, at Seaton Carew. It is:—

Zinc (by difference)	98·642
Lead	1·205
Iron	·060
Cadmium	·089
Copper	·004
	100·000

Some commercial spelters contain 2 or 3 per cent. of lead, and even pass into the market in this form; but it is usual to treat the metal when so impure in large liquating furnaces holding twenty or thirty ton charges. The bath is drossed and kept molten at as low a temperature as possible. The bulk of the lead separates by gravity and accumulates at the bottom of

* British Patent No. 26,788, 1910.

the bath, while the better grade of spelter is ladled from the top and cast. It may be taken that, with the greatest care, large bulk of metal, and long time-factor, the lead cannot thus be reduced below 0·8 per cent., and the general practice is nearer 1 per cent.

The simple fact is that lead and zinc do not alloy at all, but lead is soluble in molten zinc in degree varying with the temperature, much as lead chloride is soluble in water. At a temperature just above the melting-point of zinc (the latter determining the ability to cast the metal) it is soluble to an extent represented by about 0·8 per cent. Metallographic research by the author, on polished and etched sections of spelter, indicates beyond doubt that, at the freezing-point of zinc, the still molten lead is rejected and forms minute globules, occupying often the cleavage cracks caused by the contraction of the highly crystalline zinc. This is further confirmed by microscopic examination of the residues left after dissolving commercial spelters containing various percentages of lead, in very dilute sulphuric acid, when the minute lead spheres are very apparent.

This question of lead in spelter is of the utmost importance, for in many cases the sole practical difference between ordinary commercial spelter and the much more valuable fine-zinc is represented by the lead. Any cheap and readily applicable method for its elimination (short of redistillation) would find both world-wide application and substantial remuneration. Never has the need been more pressing, so far as our country is concerned, than during the present times with the insistent demands for munitions of war.

Lead separated by liquation from spelter still contains 2 per cent. or more of zinc, but owing to the great affinity for silver and gold that the latter has it may be counted upon as being absolutely free of the precious metals. The zinc is readily removed from the lead by a current of dry steam or by scorification, and this fact presents a ready method for the preparation of absolutely gold and silver free lead, which is often a desideratum where the assaying of the latter metals or their ores is concerned.

Whilst practically the whole of the spelter of commerce is produced substantially in the manner described, great efforts have been made, and large sums of money spent, in the endeavour to simplify, expedite, and cheapen extraction, and in particular to render the process continuous.

The electrolysis of zinc solutions (both sulphate and chloride), reduction by blast-furnace methods, and the electrothermic method of continuous distillation, whereby the distillation is carried on by thermal units produced within the reducing-vessel or furnace itself, have all been devised and exploited.

Electrolysis finds some very limited application, blast-furnace methods for direct metal production have failed entirely, and the electrothermic method, or electrical smelting, offers probably the most promise. It is, however, necessarily limited to such localities as can offer heavy electric currents at very low cost. For this reason its exploitation has been confined wholly to countries where electric currents can be most cheaply produced in large quantities by water-power. The most notable and important works are located in Norway and Sweden, in the latter of which there is at Trollhättan a works equipped for 18,000 h.p. These are to-day in operation, and have produced many thousands of tons of zinc by electrothermic distillation. The author would express the opinion that, given favourable primary conditions and the inevitable improvement to be brought about by experience, this method will in the future substantially influence the production of zinc.

[The concluding portion of the paper, with the discussion, will be published next week.]

THE DEVELOPMENT OF THE TEXTILE INDUSTRIES.

Progress in Dye-Making.—Unavoidable delays in structural work are now holding back the enlargement of the supply of British-made dyewares. In particular, fuming sulphuric acid is scarce—at all events for other than military purposes—and some time must elapse before the supply can be appreciably increased. After the war this re-agent promises to be almost embarrassingly plentiful, and it is altogether probable that the chemical plants now being erected for the manufacture of explosives will enable colours to be produced at cheap rates later. Although the cost of erection is perhaps twice the normal, it should not be impossible to write off the excess out of current profits. Pending the completion of new colour works in this country, imports from Switzerland afford some relief to consumers, and it appears that there remain certain stocks of German-made dyewares to be had at exorbitant prices from China. It is said upon good authority that there is still not a single coal-tar dyestuff made in this country suitable for a calico printer to use, and the needs of that industry can be reckoned by the thousand tons. Nearly all textile activities are circumscribed by the shortage of dyestuffs and the progress

of preparations for manufacture is being most keenly followed. It is fairly certain that large sums of capital could still be found for colour manufacturing, although perhaps not without some pledge of assistance from the Government. Dr. Alfred Rée, the new president of the Society of Dyers and Colourists, whose past experience in the production of high-class dyestuffs lends weight to his opinions, sees no reason why with reasonable assistance the colour industry should not be established on really successful lines. Like the late Mr. Ivan Levinstein, whose recent death is to be regretted, Dr. Rée lays great stress on the need for reforming the British patent laws. Indeed there is no British colour manufacturer who has had a chance to remain oblivious of the restrictions laid upon him by the adroit use made of our laws by strangers.

Lordly Velvets.—Manufacturers of goods at pence a yard or shillings a yard are little given to thoughts of the aristocratic cloths that are manufactured to sell at pounds a yard. It is more or less open knowledge that such goods are made, notably in Lyons, upon looms of which the output is measured not in pieces per week, but inches per day. Business in them has not attained to its full height in England, where the opportunities have been even deplorably neglected. Mr. Frank Warner has satisfied himself that there is room for expansion upwards, and his patient efforts in the production of fabrics worth large sums of money have led to the gradual perfecting of figured velvets of a unique richness, suitable for upholstery. A description which reduces the articles to the barest technical terms that will describe their nature does poor justice to them. The element of novelty in the fabrics consists in the weaving of a pile in three separate heights, and the difficulties of this achievement have been triumphantly surmounted by the inventor. However, neither the structure nor the composition of the finest silk is enough in itself to justify the high values set upon the cloths by connoisseurs. Their merits require to be taken as a whole in the light of the facts that the designs and colourings are perfect expressions of a classical taste, and that the cloths will appreciate rather than depreciate with the passage of time. England has something solid to add to the treasure of textile art, and the pity is that so few other manufacturers than Messrs. Warner & Sons are concerning themselves to make fabrics for the admiration of posterity.

New Relays of Labour.—Textile operatives as a whole are of a stationary disposition, ready to remain in the locality in which their lives have been cast, and to resist the temptation of higher wages which might be obtained by a removal of only a few miles. They are perhaps even more apt to remove to long distances, such as America, than to go shorter ones. The mills are fed pretty consistently with labour drawn from the immediate vicinity, and only in exceptional times is there an appreciable influx from the outside; in which case the importation of families from the rural parts of the country has been known. There have in times of stress also been transfers of widows and their daughters from large cities in which female labour is poorly remunerated. The introduction of young women by the hundred is something new. They are brought through the agency of the Labour Exchanges to towns in which hostels have been provided for their reception, and they come as temporary workers replacing men who have joined the Forces. The experiments are of interest because they bring new ideas into play, and it is probable enough that permanent marks will be left by them. Work that has been traditionally treated as a man's job, although it is far from calling out all the faculties of a man, is being learnt by these women; and where the results prove favourable it is scarcely credible that the employments can be regarded in quite the same light as before. It is the way of these transmigrations to be lost to sight, but some movements of the past are at least recorded. Numerous Norwich weavers removed to Bradford when East Anglian trade failed them, and Coventry at one period supplied drafts to Lancashire. Kidderminster has furnished carpet-weavers to other centres fairly continuously for a century or more, and the centrifugal forces in Scotland have dispersed Scottish workers widely over this and other countries. A hundred years ago, in circumstances resembling those of to-day, no doubt the workhouses would have been emptied into the mills by the aid of the forgotten "poor waggons."

River Water.—The rivers in the densely populated industrial localities have not been improving in appearance during the war, although the inkyness that meets the eye is not the worst of their offence. The scarcity of common sulphuric acid has interfered with some of the regular processes of purification to which textile trade effluents are subjected, but this absence of acid is being repaired by the general employment of nitre cake, removed from the new nitric acid stills. The rivers have suffered from acidity proceeding from the washing of picric acid and trinitrotoluene, and their water has thus been treacherous both in dyeing and in steam-raising. The usual balance of conflicting impurities has been upset, and dyers have not been able to count upon the customarily strict neutrality of rivers that have received the sewage of several large towns and of hundreds of industrial works. Near the head of a stream the apparently clear and pure water is liable to vary in quality by the liberation of minerals and acids from the soil in the event of heavy rains. Lower down, after extensive fouling and certain opportunities of fermentation, the water acquires a more consistent character, and it is rather odd to realise that there are industrial users who greatly prefer water that has been freely blended to that which is seemingly fair and bright.

CORRESPONDENCE.

ORGANISATION OF SCIENTIFIC RESEARCH.

I have read with great interest the proposed plan for the Organisation of Scientific Research in England. It seems to me that the chief and requisite necessity has not been referred to.

It is generally conceded that the German organisation has produced excellent results. I think this was possible because of the co-ordinated support the chemist receives in Germany from the working-man right up to the head of the business. The chemist in Germany is respected, because it is recognised that his work is necessary for the proper extension of business.

By reason of the enforced conscription in Germany the people are taught obedience, and, as a rule, have good health, and you know how important those two qualities are.

The Government takes a paternalistic interest in seeing that the German enterprises earn enough money to permit them to go ahead along proper lines. At the same time, the Government insists that the workers are looked after. The people in Germany, as a whole, agree with the paternalistic ideas represented by their Government, and therefore, the German organisation and German capacity for production, which must be admired, are the results of the desires of the majority of the German people.

The thoughts and ideals of the majority of the people are usually crystallised and appear in the character of their civic and commercial organisations. Militarism, therefore, may be but a part and not the cause, although some people think that everything good in German organisation is the result of their military system.

The liberty of England, as well as that of America, is often abused. The mass of citizens do not appear to understand how necessary it is to limit one's personal desires for the benefit of all. This is better understood in Germany. I believe, therefore, that the whole economic system in England must be changed before an organisation can be built up on the lines of German organisation.

A. ALEXANDER.

New York.

In connection with Professor Fleming's most interesting paper, may I call attention to two important points which received inadequate attention in the discussion :—

(1) The desirability of each technical and engineering society "boiling down" previous results into such a form that any man (member or not) can at once obtain information which will enable him to avoid retracing old ground. In this connection each society should produce each year a very detailed report on progress in all subjects that concern it, something on the lines of the "Britannica Year-Book," but better than that.

(2) The advantage of deciding (*a*) what industries are necessary for independence, and are therefore to be practised as far as possible by each and every nation; and (*b*) what industries may be locally specialised so as to produce the highest economy and efficiency in international trading.

HERBERT CHATLEY, D.Sc.(Eng.), Lond.

NEXT STEPS IN EMPIRE PARTNERSHIP.

In the discussion on Mr. Hurd's paper one speaker is reported on page 428: "The reason South Australian copper had not been purchased was that the Home Government had been able to procure plenty from America. That betrayed a want of outlook in the official world which would, if continued, kill the possibilities of the Empire as Imperialists would like to see them develop."

Now, is it not a fact in history that the importation of Australian lead helped to "kill the possibilities" of English lead-mining?

Twyford, Berkshire. WM. H. MASSEY.

ROUTE-MARCHING BY THE STARS.

It is very flattering to Colonials to be told by Colonel Tilney, in his paper* about the use of stars for finding the way, that they have a special aptitude for navigation at night without the aid of a compass, using the stars as guides. Personally, I know of no Colonial who at any time guides himself by the use of the stars. I speak not only of New Zealand and Australia but also of South Africa. In country districts people move about very little after sundown, and then only over and by well-known tracks. It is quite a common thing for Colonials when travelling in unfrequented country to lose themselves in daytime, let alone at night. Last month the papers reported two search parties out attempting to find "bushed" men. I never heard of the Bantu people of South Africa using the stars in navigation. In the districts known to them they make good guides, but they seem to use that peculiar sense known as "locality," of which we used to hear so much from the phrenologists of earlier days. Leaving aside the few educated people in New Zealand, Australia, and South Africa, I do not think that one in twenty ordinary people could distinguish or name one star in the whole heavens. Here in New Zealand comparatively few know even the Southern Cross.

I feel sure you will pardon my little criticism of Colonel Tilney's statements respecting the Colonials' use of the stars. JOHN A. R. GRAY.

Auckland, N.Z.

GENERAL NOTE.

ENCOURAGEMENT OF FLAX AND HEMP-GROWING IN FRANCE.—To encourage the cultivation of flax and hemp in France a premium, at the rate of 60 francs per hectare (nearly £1 per English acre) has been offered to growers of these crops by the Government. This is the maximum yet granted, as authorised by the law of 1910. According to the statistics published by the Minister of Agriculture, the area under flax in 1915 amounted to 9,685 hectares (24,422 English acres) in the thirty-seven departments where this plant is grown, and 10,185 hectares (25,157 acres) in forty departments for hemp. The average areas under these crops annually during the ten years previous to the war, viz.; from 1904 to 1913, were: flax, 26,370 hectares (65,134 acres), hemp, 16,200 hectares (40,014 acres).

MEETINGS OF THE SOCIETY.

(The times given are Parliamentary, not true.)

INDIAN SECTION.

Thursday and Friday afternoons, at 4.30 p.m.:—

JUNE 1.—PROFESSOR WYNDHAM R. DUNSTAN, C.M.G., M.A., LL.D., F.R.S., "The Work of the Imperial Institute for India." THE RIGHT HON. LORD ISLINGTON, P.C., G.C.M.G., D.S.O., Under-Secretary of State for India, will preside.

JUNE 23 (Friday).—SARDAR DALJIT SINGH, C.S.I., "The Sikhs."

MEETINGS FOR THE ENSUING WEEK.

MONDAY, MAY 29...Surveyors' Institution, 12, Great George-street, S.W., 5 p.m. Annual General Meeting.

TUESDAY, MAY 30...Royal Institution, Albemarle-street, W., 3 p.m. Dr. T. M. Lowry, "Optical Research and Chemical Progress." (Lecture I.)

Economics and Political Science, London School of, Clare-market, W.C., 5 p.m. Mr. F. S. Marvin, "World Relations and World Organisation—Culture, Ethics and Religion."

THURSDAY, JUNE 1...ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 4.30 p.m. (Indian Section.) Professor W. R. Dunstan, "The Work of the Imperial Institute for India."

London Society, at the ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 7.30 p.m.

Linnean Society, Burlington House, W., 5 p.m.

Chemical Society, Burlington House, W., 8 p.m. 1. Messrs. R. Seligman and P. Williams, "Hydrates of aluminium nitrate." 2. Messrs. K. C. Mukherjee and E. R. Watson, "Dyes derived from phenanthraquinone." 3. Mr. E. Newbery, "Overvoltage tables. Part I.—Cathodic overvoltages."

Royal Institution, Albemarle-street, W., 3 p.m. Sir Alexander Mackenzie, "Chamber Music and its Revival in England." (Lecture II.)

FRIDAY, JUNE 2...Royal Institution, Albemarle-street, W., 5.30 p.m. Lieutenant P. H. Loyson, "La France dans l'Histoire comme Champion du Droit."

SATURDAY, JUNE 3...Royal Institution, Albemarle-street, W., 3 p.m. Professor Sir J. G. Frazer, "Folk-Lore in the Old Testament." (Lecture I.)

London: Printed by WILLIAM CLOWES & SONS, LTD., Duke Street, Stamford Street, S.E., and published for the Royal Society of Arts by G. BELL & SONS, LTD., York House, Portugal Street, W.C., in the Parish of St. Clement Danes, in the City of Westminster.—May 26, 1916.

Journal of the Royal Society of Arts.

No. 3,315. VOL. LXIV.

FRIDAY, JUNE 2, 1916.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICE.

INDIAN SECTION.

Thursday afternoon, June 1st, 4.30 p.m.; THE RIGHT HON. LORD ISLINGTON, P.C., G.C.M.G., D.S.O., Under-Secretary of State for India, in the chair. A paper on "The Work of the Imperial Institute for India" was read by PROFESSOR WYNDHAM R. DUNSTAN, C.M.G., M.A., LL.D., F.R.S., Director of the Imperial Institute.

The paper and discussion will be published in subsequent numbers of the *Journal.*

PROCEEDINGS OF THE SOCIETY.

TWENTY-FIRST ORDINARY MEETING.

PETER LE NEVE FOSTER PRIZE ESSAY.

ZINC, ITS PRODUCTION AND INDUSTRIAL APPLICATIONS.

By J. C. MOULDEN, A.R.S.M., M.Inst.M.M., Member, Australasian and American Institutions of Mining Engineers.

IV.—THE METALLURGY OF ZINC (*continued*).

Fine-Zinc.—The highest grades of zinc have to be produced by either the employment of special materials and distillation methods, by electrolysis, or by the redistillation of commercial spelter. The reduction of very pure ores (or zinc oxide) by ordinary distillation is carried out largely in America by the New Jersey Zinc Company, and in Europe by the Vieille Montagne. Electrolysis finds a limited application, and there are plants in England for the purpose; their output is, however, on a limited scale.

The redistillation of ordinary spelter is responsible for considerable quantities, and as carried out in the electric arc furnace in Norway and Sweden is particularly successful. Redistillation is really a fractional distillation of spelter, whereby the more readily volatile zinc is distilled and condensed, leaving the lead and iron behind in the distillation vessel.

Fine-zinc may be in general, if somewhat arbitrary, terms described as containing less than 0·1 per cent. lead and 0·1 per cent. iron; the balance is not usually wholly zinc, for cadmium is often present in quite sensible amount, but the total removal of this constituent by fractionation is quite impossible commercially, and in the quantities in which it is usually present it exercises no known detrimental influence for the purpose to which fine-zinc is customarily applied; these purposes include fine brass for spinning and drawing, fine-zinc alloys of all descriptions, and generally all cases where the introduction of lead or iron in such small quantities as occur in commercial spelter would be inadmissible. Specimens of fine-zinc with 99·95 per cent. zinc, and the purest possible metal produced by the electrolysis of zinc sulphate solution, are submitted.

The points of interest germane to the metallurgy of zinc are so numerous that, short of a treatise, it would be quite impossible to refer to most of them.

Wide variations in ores, methods, and practice create almost local "metallurgies" of their own, the basic principles remaining, however, unaltered.

Chinese practice is, for instance, a closed book to us as yet; notwithstanding this, quite a substantial quantity of Chinese zinc of really good quality has found its way to England since the war.

Such matters as thermal efficiency and consumption of fuel per ton of ore, the percentage extraction of zinc, working costs and capital cost of works' installation, cannot profitably be entered upon unless accompanied by such a wealth of explanatory detail as to remove them quite beyond the sphere of this paper. In very broad terms, however, it may be stated that the extraction of the zinc under modern European methods varies between 80 and 90 per cent., calculated upon the roasted ore contents, with a fuel consumption of from 1¼ to 2 tons of coal

per ton of raw ore. The extraction, under European practice, is very generally referred to in terms of the percentage calculated upon roasted ore contents, for the reason that the roasting is often carried out in establishments totally dissociated from the distilleries, and the latter, in receiving roasted ore for distillation, have quite often no exact knowledge of the original zinc tenor of the raw sulphide ore.

Among the specimens exhibited is a portion of the wall of a used retort showing the formation of zinc aluminate (zinc spinel) of a deep-blue colour. It is a definite chemical compound ($ZnAl_2O_4$) corresponding with the natural mineral gahnite, and is due to the reaction between the aluminous retort and the zinc. It at one time constituted quite a material source of loss in zinc distillation, but with the modern hydraulically-pressed retort of dense structure it has almost disappeared as a factor of any moment. Its formation in the case of very aluminous calamines is of serious import in lowering the commercially practicable zinc recovery from ores so constituted.

Of great metallurgical interest is another hand-specimen illustrating the complexity of reaction which may take place under certain conditions. It is the result of smelting in the electric furnace a zinc ore containing lead, copper and silver. It contains copper, zinc and lead, all in the metallic condition, copper matte with moss-copper and slag; more interesting still, it illustrates very clearly the direct production of brass from the copper-zinc ore.

Do we but pause to consider and appraise at their proper value the inherent difficulties attached to the art, we may fairly console ourselves with the reflection that the modern metallurgy of zinc, much as it leaves to be desired, is not substantially inferior in its methods and practice to that of the other metals in common daily use.

Subsequent to the writing of this essay there has appeared the digest of a paper on "The Economics of Zinc Metallurgy" by W. R. Ingalls,* written with all the clarity and directness of that well-known authority on the question. Its perusal may be safely recommended as an exposition of the sane truth, and as an antidote to much of the misleading nonsense to which we have been treated during the last twelve months.

Of recent years two potent factors have operated in the direction of rendering available much increased ore supplies from raw materials which would be *per se* too poor, or otherwise unsuitable, for the extraction of their zinc contents. These factors, whilst not, strictly speaking, of metallurgical nature, have nevertheless had such influence upon the metallurgy of the metal, and contributed so much towards the increase in the world's production, that they may quite properly be included here.

The first of these was the Wilfley concentrating table, which opened up new avenues for the effective recovery of rich zinc concentrates from mixed and low-grade crude ores, working along the ordinary lines of water concentration.

The second was the introduction of flotation concentration, whereby extraordinarily effective work can be done in the production of rich zinc concentrates from crude ore absolutely untreatable commercially by any other known method. It is applicable to the finest slime or pulp, and as it does not depend for its success upon questions of relative specific gravity, is adaptable with peculiarly profitable results to those cases in which the desideratum is the production of a high-grade concentrate from an ore containing as gangue other minerals—*e.g.*, garnet, rhodonite, or baryta—so close to blende in specific gravity as to be inseparable by ordinary water concentration.

It really found its first extensive application in the mills of the Broken Hill (N.S.W.) mines, and one may safely say that without it the ores of this district could never have attained the influence they now wield in the domain of zinc.

Its latest development has been in the United States, where, curiously enough, its importance received but tardy recognition. The Anaconda Company, best known as a copper producer, has now adopted flotation as the means for producing great quantities of zinc concentrates, which will be subjected to sulphate roasting, lixiviation and electrolysis for the production, it is stated, of no less than 35,000 tons of fine-zinc per annum. It is, therefore, a highly important venture.

Electrolytic zinc is no new thing, and its past record may be fairly summed up as a series of failures—due, be it observed, not to any inherent impossibility of the method, but rather to adverse circumstances, unsuitable ores and the like. There are, however, special circumstances connected with the case which render success very probable. Into these we cannot enter here, but those interested will find a clear statement of them in a recent memoir by

* *Chemical Trade Journal*, Dec. 11th, 1915. Digest of a paper by W. R. Ingalls, International Engineering Congress, San Francisco.

Ingalls,* who discusses not only this particular instance, but the prospects generally of electrolytic zinc in relation to the usually accepted methods of production.

V.—The Uses of Zinc and its Compounds.

Zinc has become so much a part of our modern life that there are few of us who do not daily handle it in some form or another. Every particle of brass or German silver contains its proportion, and the bronze coinage of the Realm is a triple alloy consisting of 95 parts of copper, 4 of tin and one of zinc.

Up to about the middle of the nineteenth century the industrial uses for zinc were confined substantially to the manufacture of alloys and to rolled sheets, largely used for roofing. With the spread of the so-called galvanising, whereby sheets of iron are dipped in molten zinc and receive a thin coating, a new avenue for its employment was opened up, and this industry is to-day the greatest consumer of the metal.

Alloys.—The manufacture of alloys constitutes certainly the most varied and interesting use of zinc, although in importance of actual tonnage of metal consumed it comes at least second to galvanising.

Zinc alloys with copper in all proportions to form brass. The ordinary brasses contain from 27 to 45 per cent. of zinc, with from 73 to 55 per cent. of copper, the colour and characteristics varying with the relative proportions of each. For the commoner brasses, particularly those for casting and turning, a small proportion of lead, such as is contained in commercial spelter, is not only admissible but even desirable; but for the finer grades, and those intended for spinning and drawing, it exercises a most detrimental effect by causing cracks and fissures. In such cases, therefore, a specially pure metal has to be used containing 99·8 per cent. of zinc as a minimum, with 0·1 per cent. of lead and 0·1 per cent. of iron as maxima.

These fine brasses are essential for the production of cartridge-cases, alike for rifle, machine-gun and the lighter types of artillery.

For turning, on the contrary, the alloy should contain a well-marked proportion of lead, together with relatively high zinc and low copper. This leaded alloy is often called "clock brass," the best all-round working properties being secured when the proportion of lead rises to from 2 to 2½ per cent. in an alloy in which the proportion of copper is as 60 to 40 of zinc. This turns freely and cleanly and, with due care, allows of rolling and drawing to a substantial extent.

The subject has been investigated by Sperry* with much care.

The greater the proportion of copper the greater the difficulty in machining, and for shell-brass the ratio may fall as low as 55 copper to 45 of zinc.

Muntz metal is a brass, formerly much used for the sheathing of wooden ships, being much cheaper than copper and not so liable to foul. The inventor prescribed 60 of copper to 40 of zinc.

Cartridge brass, subjected as it is to the severest of treatment, requires the use of both copper and zinc, as pure as possible, with commonly 70 of the former to 30 of the latter.

Brasses with a small content of iron ranging from 1·5 to 4·5 per cent., with 55 to 60 of copper, and 38 to 41 of zinc, give alloys which, when hammered or rolled, possess very great tensile strength, Sterro and Aichs metals being representatives of the class.

The colour of the copper-zinc series varies from the red of pure copper at one end of the scale, through infinite gradations of reddish-yellow, full and pale yellow to the bluish-white of zinc at the other end.

The alloys very high in copper and low in zinc have found their greatest use in decorative work for such articles as buttons, imitation gold jewellery, and the like. Tombac, Mannheim gold, Oreide, pinchbeck, mosaic gold, Dutch metal and some others under equally fanciful names, although of practically similar composition, are those most nearly approaching gold in colour and characteristics. They have for long been used, either alone in the cheapest class of jewellery, or as a basis for the deposition of gold by plating, owing to the fact that their colour allows of a real golden effect being obtained with the thinnest possible film of the precious metal.

In the latter part of the eighteenth and early half of the nineteenth centuries some really beautiful and artistic work was executed in pinchbeck—work exhibiting the craftsman at his best. To what base depths the alloy has sunk in our times is glaringly and garishly proclaimed to all who care to take a stroll from St. Paul's to Trafalgar Square and observe. A

typical pinchbeck would consist of 83·5 parts of copper and 16·5 of zinc.

German silver, so-called, is a triple alloy of copper, nickel and zinc; the composition is very variable and is adjusted to the quality desired, remembering always that the common grades contain the least of the most expensive constituent—nickel, which may graduate from the 34 per cent. possessed by the finest to the 7 per cent., or less, in the commonest. A typical fair quality would be composed of copper 60, nickel 20, and zinc 20. The alloy is excellently adapted as a base for the reception of silver-plating, and its use in Continental coinage is familiar to most.

It is interesting to note that a variety of German silver has long been known in China, whence it was exported to Europe in considerable quantities under the name of "pakfong." In 1776 this was recognised as a triple copper-nickel-zinc alloy. It is highly probable that it was the product of cementation, much as calamine-brass was, and wide variations in the percentages of the three metals which enter into its composition are therefore not surprising.

Platinoid is a German silver supposed to contain about 2 per cent. tungsten. It must be confessed, however, that analysis often fails to reveal the tungsten. It is much used in electrical work owing to the fact that its resistance, which is very high, does not vary with changes of temperature.

Antifriction alloys, so much in use for machine bearings, often contain large percentages of zinc, antifriction metal itself with 85 per cent. and Babbitt's metal with 69 per cent. being typical representatives.

Zinc and aluminium alloys, although not in so general use as they deserve to be, offer many points of usefulness, as also do the so-called aluminium-brasses—copper-zinc alloys with a small proportion of aluminium. The zinc-aluminium alloys vary in properties with the proportions of the components. Those relatively high in aluminium are very light and strong, and have found use in the manufacture of scientific instruments. Those in which the zinc is increased, and a small quantity of copper added, cast and machine well for motor-car work. The content of zinc varies from 10 to 20 per cent. as a rule, and in no case is an alloy of any practical value produced if the zinc rises to 40 per cent. or over.

The triple alloys usually referred to under the generic terms of gun-metal and bronze are many in number and extraordinarily varied in composition. They consist typically of high copper, relatively low tin, and lower zinc. Where the true bronzes end and the gun-metals begin is hard to define, the two terms being often very loosely used. A standard Admiralty alloy consists of 88 copper, 10 tin, and 2 zinc, and there are many gradations between the 1 per cent. of zinc contained in the bronze coinage of the Realm and the 10 or 15 per cent. in some other members of the class. The true bronzes are essentially copper-tin alloys, but by the addition of zinc in increasing amounts, and the elimination of the tin, a great series of alloys results which ultimately shades off into the brasses.

It would not be possible to refer in specific terms, however briefly, to all the useful alloys into which zinc enters as a substantial constituent. The part which it plays in such may be judged from recently published standard works* on the subject, which refer to them rather by the hundred than the score. The range covered by them is, perhaps, best indicated by expressing in tabular form some thirty typical examples (see page 521).

Neither lead nor iron form with zinc alone alloys of any use in the arts, but both gold and silver have a great affinity for zinc, this property forming the basis for the Parkes process, now in such general use, for the extraction of the precious metals from lead containing them, and to which more extended reference will be made later.

The physical properties, and characteristics generally, of zinc alloys are greatly influenced by the manner in which they are compounded, the order in which the constituents are incorporated, and the temperature at which they are poured. This is not surprising in view of the comparatively low melting- and boiling-points of zinc. Copper, for instance, has a melting-point considerably higher than that at which zinc volatilizes.

For such reasons the zinc is the constituent generally added last, and that immediately prior to pouring. In the preparation of all brasses the copper should be melted first and exposed to the air as little as possible, as it has the property of dissolving, not only the cuprous oxide formed by the consequent oxidation, but oxygen itself. These influence the character of the alloy, and further to that, if excessive absorption has been allowed to take place, the subsequent incorporation of the zinc may be attended by violent reaction and ebullition—sometimes even almost of explosive violence—

leading to loss of metal and variations in the composition of the alloy.

Much of the brass produced is drawn into wire, and an interesting example of a compound wire is presented by that wherein copper rods were subjected to cementation with pure calamine and carbon at a temperature slightly under that of the melting-point of the metal, which became thus transformed on its exterior portion into brass. The drawing of these rods produced a wire which consisted of brass with a core of copper, and allowed of the production of very fine filaments which formerly found considerable use in the manufacture of imitation gold lace.

All zinc alloys, and particularly the brasses, are extremely susceptible to thermal treatment, and in the drawing of important articles from plates of even the finest of brass frequent annealings and pickling, to remove the consequent scale of oxides, are necessary for proper and successful working. In no branch is this more important than in working brasses destined for the manufacture of munitions of war, such as heavy cartridge cases.

Galvanising.—The operation of galvanising consists in coating iron or steel sheets, wire, netting, or other articles with a thin pellicle of zinc which is sufficiently adherent to protect the metal underneath from rusting and decay.

The process was invented by Crawford in 1837, and is performed simply enough by passing the heated sheets or other articles, previously pickled in dilute sulphuric or hydrochloric acid, through a bath of molten zinc. The object of the pickling is to present a chemically clean surface of the iron for the attachment of the zinc, and the operation, if properly carried out, results in a more or less firm attachment by reason of the actual formation of a contact alloy of zinc and iron.

The temperature of the galvanising bath determines the thickness of the coating; the hotter the bath the thinner it is, and the sheets may be passed, after their passage through the bath, between rolls to remove superfluous zinc. Galvanised sheets often exhibit a beautiful *moiré-antique* surface due to the crystallisation of the zinc, as in the specimen plate submitted.

From the descriptive outline of the process it may be judged how misleading the term "galvanising" is. It has no connection direct or indirect with electricity.

It forms the basis of a huge modern industry which is by far the largest consumer of spelter to-day, and the galvanised wire netting and corrugated roofing sheets must be so familiar to all as to need no laboured description.

The latter third of the last century witnessed a great extension of the industry, which called for very large quantities of spelter. A reference to the chart (see page 528) giving the zinc production curve from 1845 onwards shows how, soon after 1870, the production leapt forward, the influence causing this being in no small degree the call for the metal for galvanising.

The passing of the articles through the galvanising bath gives rise to the ultimate formation in the bath of a zinc-iron alloy known as "hard zinc." Being less fusible than zinc itself, it forms hard crusts at the bottom of the bath, and has to be removed from time to time. Part passes into commerce for use where a zinc-iron alloy is required, and the remainder is redistilled.

Rolled Zinc.—Zinc lends itself well to rolling into sheet form provided that it be not too high in lead and iron, and that the operation be carried out at the temperature at which it is ductile.

In practice the usual custom is partially to refine spelter in large liquation furnaces of reverberatory type, so as to reduce the lead-iron contents to the minimum practicable by such methods, and to cast the metal into ingots or plates which, while still hot and at the correct temperature, are rapidly passed through rolls until the correct gauge is attained. Very little rolling is done in England, the bulk of it being carried on in Silesia and Belgium; there are also rolling-mills in the United States. Such zinc sheeting finds most extended use on the Continent, where it is used to a very large extent indeed for roofing, either in the original sheets, or in ornamental stamped tile form nailed on exactly as slates are.

As roofing, particularly in the inclined position, it is durable, light, and efficient, and although it has as yet found little application in the United Kingdom for this purpose, the reasons are certainly not due to the shortcomings of the material. True it is that it is inflammable, but that only under conditions likely in any case to destroy the building roofed with it. So important and extended are its uses for roofing in Continental countries that the spelter market may be very materially influenced by the prosperity or otherwise of the general building trade. Fine sheets in perforated form are used as screens and sieves; their use in thinner gauge and unperforated form for the lining of airtight wooden cases, hermetically

sealed by soldering, must be familiar to everyone who has been in tropical countries.

Thick rolled zinc plates, sawn to suitable sizes and drilled for bolting, are used to a considerable extent in marine boiler work to prevent corrosion of the boiler plates. The highly electro-positive zinc, fastened within the boiler, receives the attack, and can be renewed from time to time.

Rolled zinc plates of specially high quality find important use in the photographic reproductive process known as photo-zincography, and in photo-etching.

Thin zinc sheeting stamped with varied ornamental designs in relief has of recent years found a very considerable use for ceilings, and its uses for dozens of articles in ordinary domestic use, such as bath-tubs, pails, toys, etc., must occur to everyone.

We owe the satinised surface finish on many of our better-class papers to the use of hot zinc sheets with a fine homogeneous surface.

Under the heading of sheet zinc may very properly be placed the filamentous zinc or zinc shavings which are used in considerable quantities for the precipitation of gold and silver from cyanide solutions. This use of the metal plays a most important part in the metallurgy and supply of both of the precious metals named. Circular discs stamped from rolled zinc sheets are threaded on a mandrel, clamped, and placed in a turning lathe. By means of a fine tool traversing the cylinder so formed the zinc is removed in the form of very fine wire or shavings, which in proportion to weight expose a great surface area. These shavings are used in the extractor-boxes of plants employing the cyanide process for extraction of gold and silver from their ores, the highly electro-positive zinc decomposing the double cyanides of gold or silver and potassium or sodium, resulting in the deposition of metallic gold or silver, and the formation of the cyanides of zinc. For this purpose zinc containing a small percentage of lead is the most efficient, as the zinc-lead couple formed thereby accelerates the precipitation.

Zinc is also extensively employed in the metallurgy of gold and silver in the Parkes process for refining of base lead bullion produced from the smelting of gold-silver-and-lead ores. The base bullion, treated in softening furnaces for the prior removal of copper, tin, arsenic, and antimony, is melted in large cast-iron or steel hemispherical kettles; zinc is added and stirred in, when it forms a preferential attachment with some lead to the gold and silver. On cooling down the kettle contents somewhat this alloy rises to the surface as a crust, and is skimmed off, pressed to expel superfluous lead, and the resultant distilled to remove the zinc. There then remains a very rich lead-gold-silver alloy, which is cupelled for the precious metals. The desilverised lead bath still contains a small amount of zinc, which is easily removed by oxidation, either by air or dry steam, and there then remains the soft lead of commerce.

From the two examples given one may see what a really important part zinc plays in the supply of our precious metals, and consequently of finance. There are probably few of us who, when handling a sovereign, pause to reflect that at one stage of its evolution it was quite probably either being deposited from a cyanide solution upon zinc filaments, or alloyed with zinc in course of its dissolution of partnership with lead in a Parkes refinery.

Thus does the humble mouse of the metallurgical world free from its bondage the lion of Finance, and clothe the bare skeleton of Science with the warm flesh of Romance.

Zinc rods ½ in. in diameter and about 7 in. long are consumed in considerable quantities in the Leclanché battery cells used in the telephonic and electric bell installations. There are, indeed, few houses or offices of any importance where such do not exist, and although usually stowed away "out of sight and out of mind" in a dark and dusty corner, they do their work faithfully enough for us. These rods may be cast, rolled, or extruded, and from time to time have to be renewed as they waste away. It has recently been found that fine-zinc rods are much superior to and more economical than those manufactured from ordinary spelter, owing to the absence of "local action" induced by the presence of lead and other impurities. A sample of such a fine-zinc rod produced by extrusion is submitted. At present these rods have not found the universal adoption to which their undoubted economic merits entitle them.

No particularly novel avenues for the consumption of zinc in any great quantity have been opened up in recent years, nor can it be claimed that any are in sight. Galvanising, sheet-rolling, and brass-making utilise the bulk of the spelter produced, and, although no statistics are available, probably in the order named. Its application in the form of zinc sheet roofing has hitherto found but limited scope in England, and any extension in this direction will inevitably meet severe competition from the many new and efficient roofing materials

of the "Ruberoid" and other types which have now appeared upon the market.

Zinc Dust, Blue Powder, or Poussière.—This material has already been referred to as collecting in the prolongs attached to the condensers in distillation. When zinc vapour in dilute form in a reducing atmosphere is cooled, or when in enriched form it suffers a sudden drop in temperature, the resultant condenses, not as fluid metal, but in pulverulent form consisting of an infinite number of globules forming a powder. We have an entirely analogous case in the formation of dew as compared with rain. Microscopical examination indicates that each globule has an extremely tenuous coating of oxide which prevents its coalescing with its neighbour when heated to a point exceeding that of molten zinc, and unless this coating be removed by ammonium chloride, or a similar flux, the powder is most difficult to convert to molten metal.

In this form of dust or powder it presents an enormous surface area as compared with its bulk, and constitutes essentially metallic zinc in an extremely fine state of division. As such it exhibits all the properties we might expect, and is one of the most active metallic reducing agents known. It is oxidised readily, and decomposes water or steam; in fact, if wetted when in bulk it will fire, and the mere moisture present in the air will sometimes cause it to ignite. Serious fires and even explosions have been caused in this manner.

Its value for commerce depends upon its content of zinc in the metallic state, and the best of grades contain from 86 per cent. to 92 per cent. as such. It finds extensive use in the dyeing and textile industries as a reducer, and for the removal of copper, arsenic, antimony, etc., from electrolytic solutions contaminated with these metals.

It has latterly found increasing favour as a precipitant in the cyanide process in lieu of zinc shavings, and the small amount of lead it usually contains acts beneficially in promoting more rapid and complete precipitation of the gold and silver.

Probably the most interesting use to which zinc dust has been applied in recent years is to the process of "Sherardising,"* or dry galvanising. The articles to be coated are pickled to present chemically clean surfaces, dried, and packed into a clean drum or box with zinc-dust. The drum or other receptacle is put into an oven, gradually heated to the required temperature, and then maintained at that for the requisite period. It is removed, cooled, and, when emptied, the articles are found to have received an even coating of zinc. The temperature required varies with the size and nature of the articles, and may be stated in round figures as from 200° to 400° C.—well under the melting-point of zinc.

The zinc deposited in this manner forms a true alloy at the junction, and becomes really an integral part of the article. It will not, therefore, scale or peel off. The coating given may be varied at will from the thinnest up to 14oz. per square foot. Such articles as screws, nuts, bolts, and others of more or less complex description can be evenly and thinly covered with a protective coating, without lumps, and without filling crevices and corners. The coating can be highly polished, and is then as bright and attractive as nickel plate, otherwise it has rather a dull frosted-silver effect.

The zinc really roots itself into the metallic surface of the article treated, forming an alloy, and upon that appears to grow particle by particle in an almost molecular manner. The coating is, therefore, of an entirely different nature to the pellicle of zinc obtained by ordinary galvanising, and is much more like an electro-deposit.

The author has experimented in this manner with copper, and finds that the action is most successful, although for obvious reasons the application to this metal is not likely to be of importance, such as would attach to metals which so readily corrode when unprotected, as iron and steel. One very curious fact came out in the experiment—viz., that at quite low temperatures, far below the melting-point of the zinc even, the point of union of the two metals consisted of typical yellow-brass, indicating an interesting case of the diffusion of solid metals. A "Sherardised" penny-piece and other examples are exhibited as specimens.

It is greatly to be regretted that this really beautiful and efficient process has not received the wide use and recognition to which its merits undoubtedly entitle it.

Zinc Compounds.—By far the most important compound of zinc from every point of view is the oxide—ZnO. Zinc, or zinc vapour, burns readily in air, producing the woolly-white substance formerly known as *Lana philosophica*—philosopher's wool. It is an amorphous snow-white material with a soft greasy feel between the fingers. The oxide exists in other forms.

* "What is Sherardising?" A pamphlet descriptive of the process invented by Sherard Cowper-Coles.

such as the native mineral (zincite), which is in a totally different molecular condition. When ignited at a high temperature it shrinks and becomes hard and gritty. It is infusible at all ordinary temperatures, but distinctly volatile at a white heat. Upon heating it assumes a canary-yellow colour, which usually disappears on cooling, but may be retained to some extent with certain varieties.

As used in commerce it is usually prepared—

(*a*) By the combustion of metallic zinc; or

(*b*) By the blowing-up grate method, under which oxidised zinc compounds or ores—such as low-grade calamine, franklinite, etc.—are mixed with coke or anthracite coal and burned in a specially designed furnace on a perforated cast-iron grate with a blast of air directed underneath. The resultant zinc oxide, after passing a combustion chamber and settling flues, is filtered out in a series of linen or woollen bags, whence it is periodically removed by shaking.

As its value depends upon its purity of whiteness, lead, cadmium, and the presence of fuel ash detract largely from it. The first-named method of production is practised largely in Europe, and the latter in the United States, which affords such quantities of the eminently suitable raw materials already referred to. The blow-up oxide so obtained is usually considered as superior even to that resulting from the combustion of zinc.

Impure forms of oxide are obtained in other ways, as in the treatment of highly zincy slags produced in lead smelting, and these, when not too high in lead or cadmium, lend themselves to the production of special grades of spelter, or even fine-zinc, by the ordinary distillation methods. The specimen of zincy concretion from iron blast-furnace work which is exhibited in connection with this paper is no more than an impure form of zinc oxide.

Zinc oxide, with its purity of white and other valuable characteristics, finds to-day great use the world over in paints, pigments, and enamels. It has good body and covering power, is non-poisonous, and is not blackened by sulphuretted hydrogen. It blends well with barium sulphate, which, owing to its cheapness, is a widespread adulterant. The author has purchased certain specimens of guaranteed pure zinc oxide, which, on analysis, afforded 80 per cent. of barium sulphate. In the trade the oxide is often termed zinc-white. It finds considerable use also in rubber and linoleum manufactures, and in medicine it appears in the common zinc ointment.

Zinc Sulphate, sometimes known as zinc vitriol, is usually prepared by the solution of zinc or zincy waste in sulphuric acid and the crystallisation of the salt. So obtained it contains seven molecules of water of crystallisation, and appears as colourless needle crystals with a strong metallic-astringent taste. It is also prepared by the sulphate-roasting' of zincy ores, often in heaps, followed by leaching.

It finds use as a mordant in the textile industries and in the manufacture of glue, where its function is that of a clarifying agent and preservative.

In medicine it is employed as an astringent, and a very weak solution forms a common eye lotion. Apropos of this, the author remembers an amusing instance of years ago at Goslar, where an astute and enterprising man sold the ordinary water of the well-known Rammelsberg Mine, in the Hartz Mountains, for this (and other) supposed miraculous virtues. The ordinary water of this mine is well charged with zinc sulphate, and had his local patients only known it they could have had many thousands of gallons for nothing.

The greatest quantity of zinc sulphate finds its utilisation in the manufacture of lithophone, which is a mixture of zinc sulphide and barium sulphate produced by double precipitation employing barium sulphide and zinc sulphate. It is a stable pigment, much cheaper than zinc oxide, but suffers from one grave defect in that it is affected by light and does not retain its purity of white, turning grey, or even greyish-black, in strong sunlight. It recovers its whiteness on being retained in darkness for some time. The manufacture of enamel paints and linoleum absorbs a good deal of lithophone. The basic idea underlying its use at all is to obviate the necessity for the much more costly zinc oxide for which it is a substitute.

Zinc Chloride is a waxy, extremely caustic substance obtained usually by the dissolving of zinc-scrap in hydrochloric acid, followed by the evaporation of the solution; the latter is by no means easy if the whole of the water is to be eliminated. It melts easily at 262° C., and at rather over this sublimes with the production of peculiarly irritating fumes.

As a preservative for timber it is well known and has been much used for railway sleepers, either in combination with creosote or without. The textile industry absorbs material amounts, and it is used in "mercerising" or giving the appearance of silk to cotton goods. It is extraordinarily hygroscopic, and if the solid

chloride be exposed to damp it will gradually absorb enough moisture to go into solution. It attacks cellulose when in the form of a strong solution, and one of specific gravity 1·7 boiled with excess of zinc oxide gives an oxychloride which will even dissolve silk.*

Zinc chloride in solution is a powerful disinfectant and germicide, as also is the iodide, which is used in minute quantities. Those who have, at the dentist's hands, been unfortunate enough to receive an application of zinc iodide and iodine will have had every inducement to retain a permanent recollection of the occasion.

Of the evil and debased uses to which our good friend zinc may be put we have only recently had two examples. In the one an etched zinc plate was used to counterfeit the watermark in an extensive forgery of Treasury notes, and this so perfectly, as evidenced by the prosecution, that it was difficult to detect the difference on comparison with a genuine note. In the other, to no stranger or more historically interesting use has zinc surely ever been put than for coinage to replace the nickel currency withdrawn for munitions of war. Yet the Germans have done this in Belgium, and the author has two such coins in his possession, one of the nominal value of 10 centimes and the other of 25.

VI.—The Production of Zinc and its Position in the Metal Markets of the World.

Leaving out of account iron and steel, the metals in most common use are, in their order, lead, copper, and zinc. The world's supply of these three is such that in the year 1913—the latest for which figures are available—we had :

	English tons of 2,240 lbs.
Lead	1,070,000 (estimated).
Copper	986,500.†
Zinc	985,142.†

Stated in a ready way, therefore, for every 1,000 tons of lead produced there were 921 tons of copper and 920 tons of zinc. Analysis in this manner will perhaps afford a ready mental concept of the relative position occupied by zinc in the Arts and Commerce. The close coincidence between the figures for copper and zinc for the year cited is at least remarkable, as indeed between those for all three metals.

Owing to the disturbance caused by the war it is doubtful how far this ratio is to-day strictly preserved; what the position may be at the conclusion of peace, and for some time afterwards, is vouchsafed to none of us to predict in any terms beyond those of mere guess. Much will depend upon the condition in which those great European centres of spelter production—Belgium, Upper Silesia, and Rhineland—are left, coupled with the very considerable extension of the smelting industry which has already taken place in the United States, and is by no means at an end. Russia, Japan, and Holland will almost certainly also figure in material productive increase, although in lesser degree. So far as Britain is concerned we may confidently predict an increase in production, the degree being dependent upon the manner in which the proposition is approached and handled. If certain comprehensive schemes, which have recently been outlined, for the treatment of Imperial ores in the United Kingdom come to fruition, the increase may be great indeed. Imperial matters call for Imperial methods, and any attempt to deal with such in "penny numbers" usually brings its own reward. The commercial metallurgy of zinc is, as we have seen, closely interwoven with that of other base metals such as lead, and that of silver, also with the production of sulphuric acid on a considerable scale; its successful establishment in any given area necessarily takes keen cognisance of this material and fundamental basis.

How far these major schemes may succeed in their object, without the recognition that the subject is of national importance and calls therefore for the support of the nation, remains to be seen. The war has supplied the much-needed lesson, are we but in position to appreciate it at its proper value and profit thereby.

The world's annual production of spelter, as nearly as may be ascertained, is given on p. 527.

The imports of spelter into England, as taken from Board of Trade returns, totalled in 1913 to 145,004 tons, approximately 14·5 per cent. of the world's production for that year other than domestic, viz., 58,298 tons, of which probably not more than 31,290 tons were "primary" spelter in the sense of being extracted from ores, the balance of 27,008 tons being the result of treatment of by-products, galvanisers' ashes, hard-spelter, etc. The domestic production, including even as it does so abnormal a proportion of "secondary" metal, amounts to, at the outside, a mere 5·9 per cent. of the world's total annual supply. For the year cited the imports, at the average

† Based upon figures from "Mineral Industry," Vol. XXII.

ruling price for spelter "ex ship," reached a total value of no less than £3,291,772.

THE WORLD'S PRODUCTION OF SPELTER.

Year.	English Tons of 2,240 lb.	Authority.
1845 . .	29,000	Based upon figures as quoted by Ingalls, "Production and Properties of Zinc," New York, 1902, and Liebig, "Zink und Cadmium," expressed to nearest 1,000 tons.
1855 . .	70,000	
1865 . .	98,000	
1875 . .	166,000	
1885 . .	294,000	
1890 . .	342,000	
1895 . .	406,000	
1900 . .	471,460	*Mineral Industry*, vols. XIV.-XXII. These figures include "secondary" spelter produced from old material, galvanisers' ashes, and the like.
1901 . .	508,422	
1902 . .	544,193	
1903 . .	561,547	
1904 . .	612,687	
1905 . .	648,906	
1906 . .	688,821	
1907 . .	725,616	
1908 . .	711,514	
1909 . .	762,559	The United States, in 1913, produced 31·4 per cent. of the world's total.
1910 . .	797,336	
1911 . .	880,411	
1912 . .	955,398	
1913 . .	985,142	

The *Engineering and Mining Journal* of New York, in its issue of April 1st, 1916, contains an exhaustive review of the United States spelter statistics for 1915, and it makes extraordinary reading. The author is that well-known writer W. R. Ingalls, and he computes the spelter production of the United States for 1915 at 452,000 English tons, of which probably no less than 55 per cent. was the result of natural gas firing.

He says "the manner in which spelter production in 1915 was expanded is one of the romances of our industry." For 1916 an output of at least 714,000 tons seems assured, much of it, no doubt, from smelteries which exist only for the purpose of reaping the present harvest, but much also from plants of a very permanent description which cannot fail to exercise a potent effect upon the economics of zinc for years to come.

I would earnestly invite the attention of all interested in the metal to this article, in the reading of which it is not amiss to bear in mind that, in addition to being a great producer of zinc ores, the United States, amongst other advantages, enjoys complete immunity from munitions control and excess profits tax.

A chart is submitted (p. 528) upon which has been plotted a curve indicating, from 1845 to 1913, the world's zinc production.

Prior to 1845 the statistics are not very reliable, and in any case the tonnage was so small as to have little bearing upon the metal in relation to the part it to-day plays in our commerce.

From 1845 to 1900 the periods adopted are quinquennial, and this with the set purpose of eliminating yearly fluctuations and giving a truer mean curve of the productive increase.

From 1900 onwards yearly periods have been plotted.

The curve is a remarkable one, and indicates the ever-increasing relative rate of production, particularly marked points occurring about 1873 (due to the progress of galvanising), 1900 and 1908. The increase from 1900 to 1913 is truly astounding.

It is by no means easy to arrive at true figures for the yearly production of the world. The complications introduced by primary and secondary spelter, and redistilled hard and other spelters, are not to be neglected. The meticulous accuracy, therefore, implied by stating to the units, or even the odd hundreds, is probably more apparent than real. The tonnages stated have, however, been gathered from the best and most reliable sources available, and enable us to state beyond fear of contradiction that in the relatively short space of sixty-eight years the world's output has increased about 3,400 per cent.!

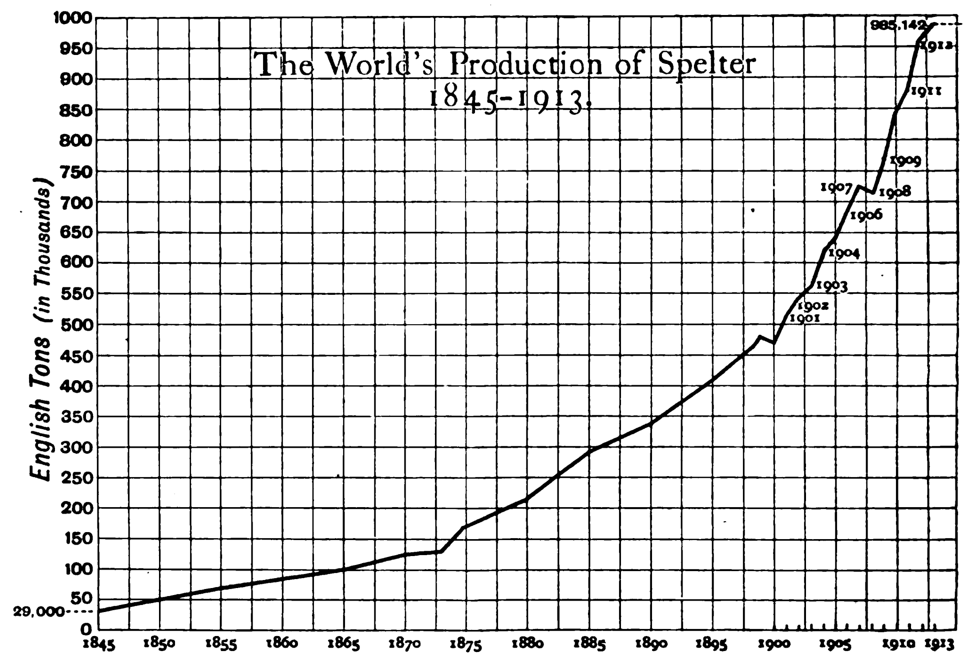
The market value of spelter has, not unnaturally, fluctuated considerably when viewed over a considerable period of years.

When first produced it realised a high price, which rapidly fell as production increased and no new output for its consumption opened out. In 1807* it was about £40 per ton, rose in 1808 to £84 per ton, and then fell steadily as production overtook demand, until in 1820 it stood at no more than £11.

* The prices quoted, 1807 to 1850, are based upon figures as given by Liebig: "Zink und Cadmium," Leipzig, 1913.

The extension of sheet-rolling caused the price to rise until in 1825 it reached £30; it fell again as production rose, and between 1830 and 1836 fluctuated between £10 and £19. It again fell to £10 in Breslau (the Silesian centre) in 1848. In 1850 it was quoted at about £16, and from that time onward to 1913 the yearly average fluctuated between £13 19*s*. 11*d*. (the lowest, touched in 1885) and £27 1*s*. 5*d*. in 1906.

The general tendency of later years has been towards a distinctly higher average level. For a very long time low wages, and easily won and treated ores, kept the price low. As wages increased and difficulties of treatment arose the improvements in metallurgical efficiency and extraction kept pace up to a certain point and compensated the producer. Beyond this point there was bound to be a rise in average value, and we see this clearly reflected in the facts that only twice since 1898 has the average yearly price been below £20, and never since the close of 1902.



Industrial conditions had reached such a point that, broadly viewed, a £20 market was unremunerative—distinctly unprofitable in particular for those concerns which did not themselves possess mines.

There is no gainsaying the fact that there is no branch of the metallurgical industry in which, considering the difficulties and risks involved, the invested capital has been so ill-requited as that of zinc. That this is not the popular impression the author is well aware. What profits there have been, however, were made largely by the ore and metal-dealing firms, and those who, in addition to smelting, turned out rolled and stamped zinc together with lead, and silver from complex ores—and possibly also zinc oxide.

Recently a great deal of unfortunate nonsense has been written and woven about the zinc position—obviously by people totally unqualified to express an opinion of any value—and as this has been widely published, it will be no easy matter to replace it in the public mind with a true perspective of the facts.

We have been informed, for instance, that the superior acumen, industry, and technical knowledge of the Germans enabled them to obtain control of and treat practically the whole of the huge output of Australian zinc concentrates. Obtain control they did, retaining it up to the outbreak of war, but treat the concentrates, except in relatively minor quantities, they did not. They utilised this control to make money, in which they were most successful, passing the major part of the concentrates on to the Belgian works for smelting. Of the total Australian output Belgium smelted at least 75 per cent., and Germany only 14 per cent. They had placed themselves in a position to force this on the Belgian works by acquiring at the outset a controlling interest in a number of them.

What we have now to see to is not so much

the hasty establishment of domestic zinc smelting works on an unprecedented scale, as the effective dissolution of Teutonic control once and for all. This, coupled with the energetic establishment of the smelting industry on well-thought-out and supported lines is, in the author's opinion, the soundest line of attack for the successful solution of the problem.

Until August, 1914, the European spelter market was controlled by an organisation known as the Spelter Convention, which regulated practically the whole of the metal output and price. War, of course, put an end to any question of our supply coming from Germany, and as Belgium fell into the hands of the enemy this source, too, was closed to us. The net result has been to throw the control, so far as the chief allied nations are concerned, into the hands of the United States—where it is likely to remain at least as long as the war lasts.

Germany has abundant spelter; her domestic ores and established smelting industries, to say nothing of those in Belgium, ensure this. Spelter is there to-day quoted at about £28 per ton. The Allies, on the other hand, have abundant ore supplies, and but limited facilities for treatment. We depend, therefore, on the United States for the bulk of our supply, and pay £100.

We are now in the anomalous position that, with the control of the seas and a plethora of the potential source of the zinc in the form of ores, we are driven to oversea countries for the metal at famine prices. Control of the seas, vital as it is, will not bridge the gulf between ore and spelter—and the moral is obvious.

It may be noted that the specimens of metallurgical products and manufactures exhibited are of strictly British origin in all save one or two instances.

The writer is deeply sensible of the shortcomings of this attempt to deal with a subject of such range and importance within necessarily limited compass. Written in the scanty leisure which the professional man employed in the production of munitions of war can to-day afford, it has been completed, such even as it is, with some difficulty. The generous indulgence of the reader is craved on these grounds. Not the least of the difficulties has been to decide, not what to include, but what to omit.

If, however, it may happily succeed, through the medium of this distinguished Society, in securing the wider appreciation of a national although comparatively little known subject, the author will feel that he has not entirely failed.

DISCUSSION.

Sir Gerard A. Muntz, Bt., in opening the discussion, said the paper was most instructive to men who had been engaged in handling this metal all their lives, and was even more instructive to the general public who had no previous knowledge of the matter. The author had given a very wide view of the possibilities of zinc production in this country, and had laid emphasis on the importance of it with regard to our present position in the war. As a manufacturer using a large quantity of zinc for munition purposes, he confirmed what had been said as to the difficulties experienced in the first instance in getting sufficient zinc to cover the requirements of the Army and Navy. It was felt in trade circles that it was quite time the zinc industry in this country was brought not only level with, but ahead of, other countries. The future of the zinc industry lay very largely in what had been described as "fine-zinc." Fine-zinc was more or less a modern product; ten years ago it was "fancy goods," and its possibilities in manufacture were very little understood even yet; people still looked upon it as a thing only of use in the manufacture of cartridges and high-grade brasses, but it had a great many more uses in the manufacturing world, and it would well repay any trouble taken with regard to it. In connection with supported industries, it was gratifying that at last the Government had awakened to the fact that its duty was to govern and not to look on; an Advisory Council on the subject of science and industry had been formed, and the Government were supporting researches in all sorts of directions, some of which had borne very good fruit indeed. Everybody in a position to do so should bring influence to bear upon the Government in that direction.

Mr. C. F. Courtney (General Manager in Australia, Sulphide Corporation) said the subject of the paper was particularly interesting to him, not so much from its scientific aspect as on account of his close association with Mr. Moulden for very many years in connection with the spelter industry in Australia. It being Empire Day, it was interesting to note that Mr. Moulden was born in South Australia. He joined with Mr. Moulden in hoping the matter would be considered by the Government, and that there would in the future be a far larger amount of spelter in this country than there had been in the past. Great difficulties had been caused in consequence of the very small production here. Regarding the question of concentrates, they were fully alive to the enormous leaps and bounds that had taken place in flotations of that method which had brought into use double and treble the deposits of the world that had been possible in the past. It was difficult to say what effect that would have on its price in the future, but if it was cheaper they would all benefit, and if it was dearer they would not be very much worse off.

Mr. Edward Brand said for many years he had taken a great deal of interest in the zinc question. It had been said by some, unjustly as he considered, that America had been keeping zinc products from coming to this country; the difficulty had arisen through the lack of shipping; otherwise the Americans would willingly have allowed their import here. The author had referred very casually to "plates of spelter," which was rather a confusing term. The best spelter was known as "fine spelter," for which the common trade term was "virgin spelter." The next grade was known in the trade as "remelted spelter," and that was where pieces had been cut and used, and then thrown back and remelted. After treatment in the galvanising bath the spelter run from the furnace was called "hard spelter," which was the cheapest and commonest grade. Unless one knew the difference between the various qualities, one was apt to go wrong in any experiments made. Zinc oxide could be made from the best quality spelter, and then the finest quality of zinc paint could be produced. On the other hand, if hard spelter was used a very common and inferior article was obtained.

Mr. W. E. Oakden asked the author if he could throw any more light upon the question of the failure of the electrolytic processes which had been carried on in England, and why they were likely to be more successful at the Anaconda Works?

Professor H. C. H. Carpenter, M.A., Ph.D. (Royal School of Mines), said that two years ago he had the pleasure of visiting the Anaconda works, where they were installing the plant to which reference had been made. It was rather difficult to test the electrolytic production of zinc by the Anaconda works; they were very large works, treating enormous quantities of copper ore on a big scale, and the production of zinc there would work in with that of other metals in the plant. It was questionable whether, even if it paid the Anaconda works to treat zinc ores in that way, it would necessarily be a solution of the problem for other districts where zinc ores existed. He desired to pay his tribute to the remarkable metallurgical skill of the staff at Anaconda; he had visited many works in America, and formed the impression that at Anaconda they had the high-water mark of technical skill. Another important question was: Were we going to have a greater production of zinc in the British Empire? Twenty-one months after the outbreak of war the position was very nearly the same as before. Mr. Holloway had recently said the production of zinc in this country was less now than at the outbreak of war. That was a serious state of affairs. Mr. Holloway had lately returned from America, and said there was no doubt that country was going to be a formidable competitor of this country. America had increased its production of the metal enormously, the rate of production being 800,000 tons a year at the present time; the works had been making very large profits and had used those profits wisely, spending the money on improving their plant, making it as efficient as possible, and accumulating great financial reserves. The competition of America would have to be faced at the end of the war. Being connected with the Royal School of Mines, it was a great pleasure to him to remember that Mr. Moulden, the winner of the medal which had been presented, was a Royal School of Mines man, and the second place had been gained by another Royal School of Mines man. They were proud of their associates from that institution.

Professor Thomas Turner, M.Sc., A.R.S.M., F.I.C. (University of Birmingham), said that for a number of years he had been using Mond zinc from time to time, and he knew the output of Messrs. Brunner Mond had increased steadily. He believed they had been turning out some thousands of tons annually of very pure spelter. Since the war had begun, Messrs. Chance & Hunt had commenced the supply of electrolytic spelter of the same quality; their output had gone on increasing considerably, so that there was ground for hoping that pure zinc would be produced in this country in increasing quantities. It would be noticed that the firms producing such zinc were chemical manufacturers who had a by-product with which to commence. The writer of the paper had pointed out an inherent difficulty in zinc manufacture, namely, that the heat of combination of zinc with oxygen was very high, so that there must be a great deal of power to separate the oxygen from the zinc, whatever process was adopted. The temperature at which oxide of zinc was first attacked by carbon was something like 1,050 degrees, whilst the spelter volatilised at something like 150 degrees below. That meant that a high temperature was necessary, and only rich ores could be used. Rich ores were also required for the electrolytic process using calcium chloride waste liquors. The other process for the electrolysis of zinc was applicable to poor ores, where sulphuric acid was available as a result of the roasting of the ore. So there were three problems to be dealt with: (1) the problem of electrolytic zinc from chemical works; (2) the problem of fairly rich ores, the zinc from which must be produced by distillation; and (3) the problem of complex ores containing relatively a smaller quantity of zinc from which one might hope to get electrolytic zinc by processes which would be at all events fairly remunerative when worked on a sufficiently large scale.

The Chairman (Dr. Dugald Clerk, F.R.S.), in moving a vote of thanks to the reader of the paper, said he had had some little experience in the use of zinc, having been a Director of Kynoch & Company for about seven years, during which time they had used a very large quantity of zinc. Even at that time they had electrolytic zinc as well as ordinary zinc, and he would like to hear from Mr. Moulden what was the nature of the process used

at that time. He had lately become aware of a process for depositing zinc electrically from zinc concentrates. A small works was started near Newcastle-on-Tyne, and was now making a good many tons per week at the present high price. That method depended upon pure electrolytic deposition in liquid, not upon the decomposition of a fused electrolyte, as in the case of aluminium electrolysis. That was the electrolysis of which the author had spoken as being more likely to succeed, but at present the wet electrolytic process was used to some extent. He often heard it said at meetings like the present that the English were very much to blame, not only in regard to zinc but in regard to almost every other subject. The curious fact remained that Britain had been very successful; they had all been very busy, and he generally found on examination that those subjects for the neglect of which they were blamed did not pay so well as the other subjects that they continued to work on. That accounted for the rapid increase in the wealth of Britain, which was going on at a very great rate even up to the time of the war. He quite granted that key industries were of essential importance, and Mr. Moulden had made a very good case with regard to the zinc industry being treated as a key industry. Undoubtedly this country ought to be in a position to supply its own spelter for its own munition works. Kynoch's, for instance, were even now turning out twelve million cartridges for the front every week, and every one of those cartridges required very pure copper and very pure zinc, otherwise they would be of no use for the quick-firing guns. Many attempts had been made to produce zinc in other ways. He had happened to become aware of the flotation process which was used by the Sulphide Corporation, a most interesting process of partly English and partly Australian invention. There were two methods: one was oil flotation and the other carbonic acid flotation. He did not know which had obtained the mastery; but some years ago he had occasion to go carefully into the acid flotation and he found many interesting facts about it. Undoubtedly these new processes would help very greatly in the production of zinc concentrates, and those zinc concentrates should certainly be dealt with in this country and not in Belgium or in Germany. He quite agreed with that view, and he believed a number of people were hard at work now on those lines. He could not see that this country was at all lacking with regard to the chemical side of the question, because there were Brunner Mond's and all the great North-East coast firms, Castner Kellner, and so on, many of whom had done good work in electrolytic chemistry.

Mr. J. C. Moulden, in acknowledging the vote of thanks, said that some of the points dealt with in the discussion would be found to be covered by his paper as printed, though he had not had time on the present occasion to develop them. He had been asked why the Anaconda people were likely to make a success of their electrolytic work when other people had failed to do so. He would answer that in the words of Professor W. R. Ingalls, the foremost writer on the subject in the United States of America, who said that there were special circumstances connected with the matter. The Anaconda Company was able to obtain its crude zinc ore very favourably, inasmuch as it worked its copper ore in conjunction therewith. The crude zinc ore lent itself to very successful treatment by the flotation process which gave a high-grade zinc concentrate. This again was of such nature that by roasting and leaching with weak H_2SO_4 the percentage of zinc extracted as sulphate was unusually high. That could not be said of ordinary ores containing, as they so often do, sensible quantities of iron and manganese which formed all sorts of troublesome compounds in roasting, and lowered thereby the percentage of zinc recoverable by lixiviation. The Anaconda process was based upon the electrolysis of zinc sulphate in weak sulphuric acid solution. He had been rather surprised to hear one speaker refer to the suitability of poor ore for electrolytic work, because Professor Ingalls made directly the opposite point, and said that the success of the Anaconda people was due in considerable measure to the fact that they were able to obtain high recovery of the original zinc contents of the ore in so enriched a form and so amenable to treatment that the greater part of the zinc could be easily obtained in the form of sulphate solution. Reference had been made to a number of firms in England who were producing electrolytic zinc to-day. That fact, however, did not touch the main metallurgical question, namely, the addition of British zinc to the world's supply in any considerable quantity from ores. It was true that electrolytic zinc had been produced in this country, but the quantity was very limited, and unless it could be produced in connection with some other chemical industry running side by side with it, the difference in the price between high-grade virgin spelter and fine-zinc had not been sufficient in the past in most cases to warrant people launching out into big works for the purpose of making fine-zinc in that way. Electric smelting had been referred to. He might say that he had been for three years consulting metallurgist to one of the largest concerns in the world, where a system had been employed of electro-thermic smelting, and he had some opportunity of observing what the prospects were likely to be. He was bound to say that the production of zinc by internally created electro-thermic units would in the future, where power was available, have a very far-reaching effect upon the metallurgical side of the question.

FRUIT PRODUCTION IN NATAL.

While fruit from Cape Colony is well known on the market in this country, the products of the Natal fruit industry are almost unknown here. It

may be said that Natal produces no deciduous fruits worth mentioning as compared with her citrus and tropical products. The fact that during the year past plums and pears are to be found amongst the list of exports indicates that there are possibilities for the building up of a trade in these fruits.

According to the report for the year ended March 31st, 1914, of the Department of Agriculture of the Union of South Africa, the advantage possessed by Natal is that all fruit grown in that province is, according to the character of the climate, earlier than that produced in other exporting areas.

Naartjes.—This fruit is placed first on the list because it stands at the head of the 1913-14 season's exports, some 11,000 cases having been sent away. Further, it is at the present time the best of Natal's citrus products. The class of naartje most largely exported is of the tangerine type and known generally in South Africa as "the Natal naartje." It is undoubtedly the best naartje grown in the Union, and is produced to a large extent in the coastal districts north and south of Durban. Export of this fruit lies to a large extent in the hands of dealers, to the exclusion of the actual grower, and it is possibly due to the fact that the largest dealers and exporters are a most painstaking and progressive body of men that such an amount of success has attended naartje export from this province.

Oranges.—Less than 1,500 boxes of oranges were sent away from Natal during the year under review. This is not an encouraging record, and is likely to prove the minimum mark in the history of this industry. The reason why this small quantity only should have gone forward is possibly to be found in the fact that coastal growers have in years past received little encouragement either in prices received or in the way their fruit stood transport. It has finally, apparently, been recognised that the export of coastal-grown oranges is not a reliable business, and so far the up-country grown article has not been available for export in sufficient quantity.

With the development of citrus culture within a radius of a few miles of Maritzburg, and in a few other suitable localities, it is only a question of time before Natal will take her place with her sister provinces as an exporter of good well-grown fruit. The higher uplands of Natal produce as good an article in the way of an orange as most other parts of South Africa, and with carrying qualities equally good.

Minor Citrus Varieties.— These include lemons, limes, grape-fruit, etc. No export of these has taken place; a good local demand exists for limes and lemons. Grape fruits should find acceptable surroundings in some part of the coast; arrangements were being made for testing them at Winkelspruit.

Pines. — Pineapple culture in Natal is an expanding industry. Certain circumstances connected with it will probably see it take second place to the Albany district of the Cape, but given greater attention by the right kind of white man the future should be a bright one.

Some 2,500 cases were exported in 1913-14, as against 923 from the Cape, principally of the Queen variety. These carry well and open up in good order; they are lighter in colour and less full in flavour than the Albany article, but have rather a better appearance, are more uniform and have better crowns. The standard orange-box has been used for shipping them in, holding some thirty-two fruits each. Although this makes a good receptacle and an economic one as far as saving of space is concerned, it is thought that shipping in boxes to contain one dozen will pay better. This is the system adopted by Cape exporters, and their product always fetches more than does the Natal article.

Cayenne pines formed 25 per cent. of the whole export. The large size of this fruit, its delicate skin, and large moisture content, render it difficult to transport properly. It is by no means certain that it should not be carried in the cold rather than the cool chamber on board ship. Experiments are being carried out with the object of discovering the best conditions under which to handle these fruits.

Bananas.—Natal is the province in South Africa, *par excellence*, for the cultivation of the banana. Climate, soil, and other conditions are nearly all suitable; the labour engaged in the industry is nearly all Indian; and whilst that may not be in accordance with certain principles, the fact remains that the banana industry of Natal is being well handled. The demand for this fruit is so great in the other provinces of the Union that no attempt has ever been made to extend the export beyond the confines of South Africa. Some few hundred cases were disposed of annually to German East and South-West Africa and also to Portuguese East Africa. Prices, whilst not exactly high, were remunerative. There is room for some expansion and development before the needs of South Africa are fully supplied, but it is not anticipated that any export of South African bananas to Europe, at any rate for many years to come, will take place.

Mangoes and Avocados are bracketed because, though both do well enough in Natal, neither has made a success, so far, in the export market. Climatic conditions, principally atmospheric, do not appear to be conducive to good carrying of the mango, and it is only of late that the avocado has given any encouragement to exporters. With increased care in growing and packing a business in this fruit may eventually arise. It is to be feared that the same cannot be said of the mango, until such time as the tree may be planted further inland.

ENGINEERING NOTES.

National Waste of our Coal Supplies.—Professor W. A. Bone, speaking before the Society of Chemical Industry, alluded to the economical

conditions arising not only from the war, but also from the restriction of output by the ordinary process of exhaustion. He pointed out that until recently our abundant supplies of easily obtainable coal gave us a position of great advantage, but we can now no longer claim any advantage in this respect over our two nearest competitors. According to the figures issued by the International Geological Congress of 1913, the world's total probable and possible reserves of coal of all kinds within 6,000 ft. of the surface amount to 7,397,553 million metric tons, or approximately 6,000 times the present total annual consumption. Of these reserves 61 per cent. are in the United States, 16·4 per cent. in Canada, 13·5 per cent. in China, 5·7 per cent. in Germany, and only 2·6 per cent. in Great Britain. The relative insignificance of the British coal reserves is a matter of which, it seemed to him, our commercial and ruling classes are profoundly ignorant, else effective measures would have been taken long ago to check the criminal wastefulness of all classes of the community in the use of coal; and he suggested that scientific and technical societies should urge the Government to take immediate effective action in the direction of establishing through a fuel control board some systematic supervision of fuel consumption in all large industrial areas, and of promoting scientific investigation on a large scale on the better utilisation of coal. He proposed the reimposition of the duty of one shilling a ton on exported coal, a portion of the revenue so obtained to be earmarked for investigations on the problem of fuel economy. A vast amount of coal is left in the pits because colliery companies can make bigger profits by working the better classes of coal only. This pit wastage represents, on the average, about 25 per cent. of the coal actually won in the mines. The inferior grades of coal now left in the pits should be brought up and transformed at the pit-head into useful forms of energy for public purposes. He estimated that possible realisable economies in the use of coal amount to at least 30 per cent. of the total home consumption, which is now nearly 200 million tons annually. Work has been done also in this direction by the Committee of Engineers, Chemists, and Technologists appointed by the British Association under Professor Bone's chairmanship.

Power Transmission under the Sea: Cable between Sweden and Denmark. — According to *Engineering*, this scheme is now an accomplished fact and has been in satisfactory operation for several weeks. The electric energy is generated by the South Swedish Power Company at four power stations on the Lagan, having an aggregate capacity of about 19,000 kw.; but as this power is almost completely utilised, three other waterfalls on the Lagan are to be exploited, which, with sundry supplies from steam stations, will bring the total available up to about 40,000 kw. in the near future. Three-phase alternating current at 50,000 volts is used for transmitting the power from the generating stations, but for the submarine cable the pressure is reduced to 25,000 volts. The transformer station used for this purpose is at Helsingborg, and the submarine cable actually starts from Palsjo, which is situated on the coast about three miles from that town. It reaches Denmark at Marienlyst, near Elsinore, the distance under the sea being nearly three and a half miles, and is laid on the bed of the sea at a maximum depth of nearly 21 fathoms. It is made of three copper conductors with a sectional area of 0·019 sq. in. and is insulated for 35,000 volts with impregnated paper, with an external lead covering. Galvanised Z-shaped iron wires are used for strengthening it, and the outside diameter is 3·6 in., the weight being about 56 lb. per yard. The cable was supplied in nine lengths of 656 yards each, and these are connected by means of iron coupling boxes nearly 5 ft. long, which transmit the strain from the sheathing wires. The connecting boxes have inner boxes of lead which are soldered to the lead covering of the cable. At present only one of the three cables contemplated by the design has been laid, but if the experience of two or three years' working proves satisfactory, the further installation will be proceeded with. The maximum supply at present is calculated at 5,000 kw. A protecting cable of steel wire rope having a breaking strength of 40 tons has been laid to the north of the cable to guard it against damage from dragging anchors of vessels drifting south, and landmarks have been erected on both sides of the Sound to show the position of this protecting cable and warn ships not to anchor in its vicinity. There is also a telephone cable, 2 in. in diameter, insulated with guttapercha, laid beside the protecting cable.

Concrete Floors for Machinery. — Mr. Davis, H.M. Inspector of Factories for the Kent district, remarks on the causes of failure. In addition to the obvious reasons, that builders often use too much sand in proportion to the cement, and an insufficient thickness and bad foundations, there are others due to ignorance, although the intention is good. Mixtures of sand and cement expand when they are wet, and contract as they dry, and within limits the greater the proportion of cement the greater the expansion and contraction. A common practice is to put down a first layer of material with a small proportion of cement, let this dry, and then put on top of it a thin layer with a large proportion of cement. This top part thus remains a separate layer, instead of bonding with the lower part, as it would have done had it been put on at once in the unset lower portion, while, being richer in cement, it expands and contracts more than in the lower part, with the result that it may be rapidly broken up. For large surfaces, however good the work and material, the expansion and contraction are almost certain to produce cracking unless the work is divided up vertically into sections with thin strips of wood between them.

Electric Engine-starter for Industrial Motors.—The *Electrical Review* states that since the fitting of an electric engine-starting outfit on American pleasure-cars became general, there has been considerable discussion as to the advisability of adding such equipment to industrial motor vehicles. An interesting contribution to the subject has just come to hand from the United States, where the engineering department of the Reo Motor Truck Company, of Lansing, Michigan, recently carried out a series of experiments with its 15-cwt. petrol motor delivery van. It is stated that the results obtained go to show that an engine-starting outfit will more than repay its first cost in the saving of petrol effected during the first year of its use, owing to the engine being stopped instead of being allowed to run while deliveries are being made. It is also claimed that it will have a marked effect on the cost of upkeep of the vehicles, due to the elimination of the wear and tear of the large amount of idle running. Finally, it may be stated that, as a result of the test, it has been decided to adopt an electric engine-starting set as a standard part of the equipment of the Reo vehicles.

Bridge over the Neva at Petrograd.—This bridge is rapidly approaching completion. All the spans are finished, and the machinery is so far assembled that the movable central span can be worked by hand mechanism already installed. The bridge has been constructed in accordance with the plans of A. P. Pshenitsky, which were tendered at the competition announced by the municipal administration in 1908, R. F. Meltser being responsible for the architectural portion. It is a five-span structure, with a length of 246·94 metres between the shore abutments. There are eight girders in the width of the bridge, the distance between them being 3·60 metres. They are calculated to bear a load on the tramway lines of cars weighing 22 tons, and accordingly the heavier ones are placed in the middle and the lighter ones at the sides. The movable central span consists of two equal leaves. For opening it two methods are available, viz., mechanical, by means of electric motor, and hand, with the aid of a capstan. In order to enable the bridge to be opened even in a strong wind, extraordinarily powerful mechanism is required. There are eight main motors of 80 h.p. each, with four auxiliary motors of 65 h.p. and two of 10 h.p. each. The process of opening or closing the span by motor takes one minute, and by hand four minutes when there is no wind, and about eighteen minutes in a wind. The piers rest on caissons sunk with the help of compressed air into the ground to a depth varying between 23·75 and 27·86 metres. Their working chambers, after they had been immersed to the required depth, were filled first with rubble and subsequently with concrete. The width of the thoroughfare is 22 metres. The footpaths are 2·91 metres wide, their projection beyond the girders being ·25 metre. The bridge has already been opened for pedestrian traffic.

THE DEVELOPMENT OF THE TEXTILE INDUSTRIES.

Industrial Dislocations.—The successive changes in the laws and regulations governing military service cause some modification of industrial plans. Men who were regarded as settled in their places have become liable in large numbers to serve, and the detail work in respect of their cases is a considerable tax upon managers' time. The bare task of keeping an exact record of their individual liabilities, and of complying with official forms in seeking exemptions on their behalf, is itself considerable. Then there is the business of finding or training successors, and of negotiating concerning them with the trade unions. The manufacturer feels himself to be living from hand to mouth in the matter of assistance, and his uncertainties react upon his power to enter into definite engagements of any kind. The successive changes, all bringing loss of men, are made more tolerable by the rude justice of the tribunals, which ordinarily allow certain men to be retained for a specified time upon condition that certain others are surrendered. Large numbers of temporary exemptions are falling in at the same time that the liability to serve becomes more general, and experience under these new conditions is awaited.

After the War.—It can be judged that conditions at large are not favourable to the making of individual preparations for trade after the war, but even these are not quite at a standstill. New buildings and machines are formidably dear, but there are departments in which they are being put into commission in readiness for the future. The effort will certainly be attempted to do directly with certain markets business in British goods that has been done hitherto through Germany, and the Russian market is especially in point. Rather to satisfy present than future needs headway is being made with mixed cotton and woollen yarns such as were formerly bought from Germany. Absorption in war work, and the limitations of the labour and colour supply, still tend to make current textile production less diversified than usual, and dear materials forbid any striking exhibitions of cheapness. The appointment by the Board of Trade of a Committee to consider the international position of the textile industries after the war has been passed over with less notice than so important a departure would seem to deserve. The position of the industries during the war is of absorbing interest, but it does not justify neglect of the future. As the Committee includes fifteen members associated in different capacities with the textile trades, it is constituted to understand the bearings of the problems, and presumably there will be consultations with representative bodies of traders.

The Dyestuff Manufacture.—The report of a re-combination of the German aniline dye companies is apparently well founded. The companies

had long been grouped by the exchange of capital and linked by intricate agreements controlling prices, but a firmer control will exist now that Bayer, Badische, the Berlin, Meister Lucius, Cassella, Kalle, and Weiler-ter-Meir are within a single syndicate. The new combination can scarcely lessen the objections to leaving the colour manufacture to a foreign monopoly, and it is significant that the measure should have been felt necessary. There are reports, less fully confirmed, of the purchase of a Dutch works by the German companies with the purpose of maintaining an export trade. In the United States a Bill to increase the present 30 per cent. import duty on dyestuffs has been rejected by the Senate, to the disappointment of the textile manufacturers who lent it their support. Two substantial concerns in this country have allowed it to be known that they propose to manufacture alizarine colours as soon as conditions permit. Dye—as everyone has discovered—is peculiarly essential to textile manufacture, and in bulk the cost of dyestuff is of importance. In relation to the other expenses of dyeing, the cost of the colour powder is small. The ratio varies, but in the case of a pink, costing 3½*d.* to dye, it was found that one-eighth of a penny covered the actual cost of colour. Dear colours are not so inconvenient in practice as dear steam and labour.

British Wool Resources.—Probably further attention will be directed soon to the commanding position occupied by the wools of the British Empire in the markets of the world. The leading manufacturer in the United States, fearing the introduction of an export tax upon the Imperial wools, gives their quantity as nearly two-thirds of the world's supply. Their quantitative importance is not the whole of the matter, but that aspect can be roughly illustrated by a reference to brokers' figures. There were imported into Europe and North America, in 1914, some 2,839,300 bales of Australasian and Cape wools. The River Plate and South American supply was approximately 1,160,000 bales of the same denomination. Simply on the score of quantity, the Australasian wools are highly necessary to the manufacturing trade of all countries, but in quality they are flatly irreplaceable. Wool may be likened to coal, except for the point that the supplies do not come from the Mother Country, and there are accordingly other opinions to seek before proceeding to make wool an instrument for providing the sinews of war.

Limitation of Prices.—State limitation of the prices to be paid for supplies to the Services may in some eventualities extend, but there is no cause thus far to anticipate an unreasoning attitude on the part of the authorities. They have the power to command but hardly the ability to enforce the cares of the unwilling. A spinner may be bidden to deliver yarn at a stated price, but he cannot in practice be compelled to apply the innumerable small cares that are freely exerted in keeping up to the commercial standard of excellence. A limit may be fixed to the prices of raw material, but the producer, above all when resident abroad, cannot be compelled to market his material, within that limit. Voluntary co-operation is of inestimable use in getting work done thoroughly, and the opportunities of eliciting the right spirit cannot be—and are not being—set aside. The vexed requisitioning of worsted yarn for the knitting of military underwear is in a fair way to resolve itself in a compromise. Spinners' margins will be limited to a certain excess over the cost of their raw material, but the margin, although less than that of the open market at present, will be substantially more than the minimum in other times. There will be a sacrifice, but the sacrifices will be distributed, for those owning the requisite types of machinery will each, according to his capacity, be called on to supply a proportion of the necessary yarn at the determined prices. The commands are transformed in this way into workable bargains, disadvantageous to neither side.

Industrial Starches.—The large consumption of starch in the textile industries is deemed to have had some influence in repealing the old Corn Laws. Within the last few days representations by textile traders have brought a modification of the recent prohibition upon imports of starch, dextrine, and potato flour. The consumption of farinaceous materials in binding, stiffening and smartening woven goods can be counted by the thousand tons a week, and in order to continue in the usual manner and provide a number of appreciably different "finishes," a full selection of materials is required. Flour, farina or sago in company with tallow are used in sizing the warps of cotton goods to prevent chafing in course of weaving, and by the addition of mineral ingredients the sizing mixture can be used to increase the weight of the cloth more or less considerably. Wheat, maize, rice and potato starches are employed upon cotton cloth and the manipulation of the mixtures is an art in itself. At an early stage in the war the German finishing industries were deprived of starch, and notices disclaiming responsibility for the finished results were issued to their customers. Without flour in its various forms it would be impossible to maintain the export of cotton goods, so that even that which is not eaten is in an indirect sense the food of the people. Little size is used upon wool goods, and it is more usual to apply a weak glue than a flour paste. The case was not always so, and it is recorded of a contractor in the Crimean days that he thought the troops would be able to eat his heavily starched woollens if they were unable to wear them. The incident is strictly of the past, and there is little to suggest that the fancy for stiff and heavy wool clothing is likely to return.

GENERAL NOTE.

Essays on Patriotism.—The Lundie Memorial Trust, with a view to encouraging the study of patriotism in secondary schools in the city of Liverpool, with which this educational foundation is connected, has decided to institute an essay competition which will be open to all pupils under eighteen years of age in attendance at a secondary school in the city recognised by the Board of Education as efficient. The subject of this year's essay is Robert Browning's couplet, "Here and here has England helped me; how can I help England?" The prizes offered include Lundie silver and bronze medals, with books to the total value of £2 10s. Further particulars of the competition may be obtained by forwarding a stamped (halfpenny) and directed postal wrapper to the Secretary of the Trust, Miss A. M. Davies, 27 Church Road, Waterloo, near Liverpool.

MEETING OF THE SOCIETY.

(The time given is Parliamentary, not True.)

Indian Section.

Friday afternoon, at 4.30 p.m.:—

June 23.—Sardar Daljit Singh, C.S.I., "The Sikhs."

MEETINGS FOR THE ENSUING WEEK.

Monday, June 5...Victoria Institute, Central-buildings, Westminster, S.W., 4.30 p.m. Professor E. Hull, "The Tides, with special reference to their Effects around the British Isles."

Royal Institution, Albemarle-street, W., 5 p.m. General Monthly Meeting.

Chemical Industry, Society of (London Section), at the Chemical Society, Burlington House, W., 8 p.m. 1. Report of the Session. 2. Messrs. R. Seligman and P. Williams, "The Action of Nitric Acid on Aluminium." 3. Professor W. B. Bottomley, "Bacterised Peat. I.—The problem in relation to Plant Nutrition."

Geographical Society, Burlington-gardens, W., 8.30 p.m. Sir Aurel Stein, "Further Explorations in Central Asia."

Tuesday, June 6...Economics and Political Science, London School of, Clare-market, W.C., 5 p.m. Professor Pollard, "World Relations and World Organisation—The Legal Aspect."

Aeronautical Society, at the Royal Society of Arts, John-street, Adelphi, W.C., 3 p.m. (Wilbur Wright Memorial Lecture.) Mr. G. Brewer, "The Life and Work of Wilbur Wright."

Royal Institution, Albemarle-street, W., 3 p.m. Dr. T. M. Lowry, "Optical Research and Chemical Progress." (Lecture II.)

Anglo-Italian Literary Society, 11, Chandos-street, W., 4 p.m. Dr. R. Piccoli, "Renato Serra."

Photographic Society, 35, Russell-square, W.C., 8 p.m. Mr. D. Cameron-Swan, "Some Hints on Photographing Paintings."

Zoological Society, Regent's Park, N.W., 5.30 p.m. Discussion on the Results published in the "Biologia-Centrali-Americana," with special reference to the zoo-geographical relations between America and Africa.

Gas Engineers, Institution of, at the Institution of Civil Engineers, Great George-street, S.W., 10.30 a.m. (Annual Meeting.) 1. Address by President. 2. Dr. H. G. Colman, "Report of the Refractory Materials Research Committee." 3. "Report of the Ventilation Research Committee." 4. "Report on Thermal Phenomena in Carbonisation."

3 p.m. "Report on the Life of Gas Meters Research Committee."

Röntgen Society, at the Institution of Electrical Engineers, Victoria-embankment, W.C., 8.15 p.m. 1. Professor J. W. Nicholson, "Homogeneity of Visible Radiation." 2. Exhibition of X-ray and Electrotherapeutic Apparatus.

Wednesday, June 7...Geological Society, Burlington House, W., 8 p.m.

Public Analysts, Society of, at the Chemical Society, Burlington House, W., 8 p.m. 1. Mr. A. D. Heywood, "Determination of the Reichert and Polenske Figures of Butter and Margarine, using small quantities of the fat." 2. Messrs. R. R. Tatlock and R. T. Thomson, "Potash and other Mineral Fertilisers and Constituents of Plants." 3. Mr. J. Rakshit, "Estimation of Acetone in the presence of Ethyl Alcohol."

Literature, Royal Society of, 2, Bloomsbury-square, W.C., 5.15 p.m. Lecture by Dr. M. A. Gerothwohl.

Royal Archæological Institute, at the Society of Antiquaries, Burlington House, W., 4.30 p.m. Sir William M. Conway, "Goldsmiths' Work in the Dark Ages."

Thursday, June 8...Mining Engineers, Institution of, at the Geological Society, Burlington House, W., 10.45 a.m. (General Meeting.) 1. Professor F. W. Hardwick, "The History of the Safety Lamp." 2. Dr. J. S. Haldane, "The Health of Old Colliers." 3. Mr. T. F. Winmill, (a) "The Estimation of Moisture in Coal"; (b) "The Absorption of Oxygen by Coal. (Parts VIII. and IX.)"; (c) "The Oxidation of Pyrites." 4. Discussion on following papers: 1. Professor W. G. Fearnsides, "Some Effects of Earth-movement on the Coal-Measures of the Sheffield District (South Yorkshire and the Neighbouring Parts of West Yorkshire, Derbyshire, and Nottinghamshire) (Part I.)" 2. Mr. S. Mavor, "Compressed Air for Coal-cutters." 3. Mr. M. H. Mills, "Gas-producers at Collieries for obtaining Power and By-Products from Unsaleable Fuel."

Royal Institution, Albemarle-street, W., 3 p.m. Sir Alexander Mackenzie, "Chamber Music and its Revival in England." (Lecture III.)

Optical Society, at the Chemical Society, Burlington House, W., 8 p.m. Mr. F. H. Glew, "Some Technical Applications of Radium and other Luminous Substances."

Friday, June 9...Royal Institution, Albemarle-street, W., 5.30 p.m. Dr. E. Clarke, "Eyesight and the War."

Malacological Society, Burlington House, W., 8 p.m. 1. Mr. J. R. le B. Tomlin, "Note on *Erato guttula*, Low." 2. Mr. G. C. Crick, "On an Undescribed Ammonoid from the Lower Greensand (Aption) of Kent." 3. Mr. G. K. Gude, "On *Helix scytodes*."

Astronomical Society, Burlington House, 5 p.m.

Sanitary Institute, 90, Buckingham Palace-road, S.W., 10.30 a.m. Conference on Sanitary Administration under War Conditions. Mr. H. P. Boulnois and Dr. J. Wheatley, "The Maintenance of the Standard of Municipal Sanitation during the Continuance of War Conditions."

Saturday, June 10...Sanitary Institute, 90, Buckingham Palace-road, S.W., 10·30 a.m. Dr. A. B. Ritchie, "The Mental Deficiency Act from the Social and Educational Standpoint."

Royal Institution, Albemarle-street, W., 3 p.m. Professor Sir J. G. Frazer, "Folk-Lore in the Old Testament." (Lecture II.)

and not scattered about. The most important necessity of all was improved agricultural education, because in his opinion more capital would be forthcoming, better organisation would be available, and better fiscal arrangements would be insisted upon when the agriculturist was better educated. Education—the right sort of education—was the crux of the matter, and he would like to have seen more attention devoted to that subject in the paper.

Sir Frederic S. P. Lely, K.C.S.I., C.I.E., expressed his sense of admiration of the silent but substantial work that had been done in India during the last few years by the Agricultural Department. Compared with earlier days, there had been an enormous advance in the manner in which the Government had dealt with the subject.

Mr. J. S. Beresford, C.I.E., said the agricultural conditions in Egypt were very much the same as in India, but there was a great difference in the results obtained and the rentals charged for the land. The difficulty in India was that the cultivator had a very small amount of capital, whereas in Egypt the farmer thought nothing of spending £2 an acre on imported artificial manures, without which the large crops grown could not be produced. He doubly recouped the expenditure by the greater yield. It was impossible for the best production from the land to be obtained without the expenditure of capital, and in any new schemes the Government of India introduced that fact must be borne in mind. It was of interest to mention that since the Agricultural Society of Egypt took in hand the purchase and distribution of artificial manure the consumption had largely increased. The import in 1909 was 21,000 tons, value £178,000; while in 1912 it had risen to 70,000 tons, value £668,000. Ninety per cent. of this was nitrate of soda. It was chiefly due to the judicious application of such manure that the high level of production in Egypt was now maintained, for the supply of nitrates from the numerous ruins in the country, on which the people formerly relied, was fast becoming exhausted.

Sir Daniel M. Hamilton, in proposing a hearty vote of thanks to Mr. MacKenna for his admirable paper, thought the last speaker had put his finger on the weak spot in Indian agriculture, viz., the want of finance on the part of the cultivator. It was impossible to build up any industry unless it had a sound system of finance at its foundation. Until the financial question was settled he was afraid Indian agriculture would not advance as rapidly as it should do. He recently read a paper by Mr. Howard calling attention to the fact that the surface soil of India, which was the best part of the soil, was being washed away. Mr. Howard advocated the erection of irrigation bunds to hold up the soil, but such work could not be carried out without money. So far as manures were concerned, he hoped a trial would be made in India of the bacterialised peat discovered by Professor Bottomley, of King's College. It had been proved to be a first-class manure, and was, he understood, being manufactured by the Manchester Corporation at £3 a ton. The Government had recently appointed a Commission to study the question of helping Indian industries. Everything possible should, of course, be done to help manufactures of every kind, but it was often forgotten that the agricultural population of India must always be the great purchasers of manufactured goods, and it therefore seemed to him that one of the ways in which the industrial development of India could best be helped was to develop her agriculture in every possible way.

Sir Frederic W. R. Fryer, K.C.S.I. (late Lieutenant-Governor of Burma), in seconding the motion, fully endorsed Sir Andrew Fraser's statement in regard to the willingness of the ryot to take up any improvement provided he could be convinced that it would pay him to do so. When he was Deputy-Commissioner of Hazara he introduced to the sugar-cane growers the iron mill made by Mr. Milne, and they adopted it in preference to their wooden mill, as it could be worked with one bullock instead of two; but they would not use the English plough because it necessitated the use of two men and two bullocks, compared with one man and one bullock with the native plough. The cultivators in India were always ready to adopt any improvements that were visible to their personal observation, and he was certain they would be only too pleased to avail themselves of the services of the Agricultural Department. That Department was evidently doing very good work, and the development of agriculture was, as Lord Curzon perceived, one of the first objects to which the Government should devote its attention.

The Chairman, before putting the motion, said that Sir Evan James's scepticism was not altogether unnatural, as cases had occurred in which the cultivators had thrown away the whole advantage they had gained from selection of seed by adulteration on a large scale. The Agricultural Department was now fully alive to that danger, and the organisation was so good that it was not likely to occur again. He also thoroughly agreed with Sir Daniel Hamilton's remark that finance was of the greatest importance to agriculture.

The resolution of thanks was then put and carried unanimously.

Sir Steyning Edgerley promised that the vote of thanks which had been so heartily passed should, in due course, be communicated to Mr. MacKenna. The suggestion was made in the paper that organised development was begun in Bombay by Mr. Mollison, but he was sure that gentleman would be the first to acknowledge the labours of a Bombay civilian, the late Mr. Edward

Ozanne. He went home to Cirencester in 1881, took his M.R.A.C., and on his return to India was appointed in 1883 the first Director of Agriculture in Bombay. Mr. Ozanne did much spade work between 1883 and 1890, and had successfully dealt with the dairy industry, the number of dairies run on scientific lines having been raised from one to about 800 by 1888, if his memory was correct. He thought it would be found that it was because of Mr. Ozanne's success that the business in Bombay outgrew his powers of dealing with it, and it became possible to convince the Government of India that there was a good case for bringing out Mr. Mollison as Superintendent of Experimental Farms in 1890. It remained only for him to express the thanks of the Committee to Sir R. Carlyle for kindly presiding that afternoon.

OBITUARY.

Sir Hay Frederick Donaldson, K.C.B.—Sir Hay Frederick Donaldson, who was drowned with Lord Kitchener in H.M.S. "Hampshire" on the 5th inst., had been a Fellow of the Society since 1889. Born in 1856, he was educated at Eton and Trinity College, Cambridge; and after serving in the shops of the London and North Western Railway Company, he was employed from 1881 to 1887 at Goa. From 1887 to 1891 he was engaged on the construction of the Manchester Ship Canal, and from 1892 to 1897 he acted as Chief Engineer to the London India Docks Joint Committee. In 1898 he was appointed Deputy Director General of Ordnance Factories, afterwards becoming Chief Mechanical Engineer, and eventually Chief Superintendent. In 1915 he became Technical Adviser to the Ministry of Munitions, and in that capacity rendered invaluable services to the country, services which were fully acknowledged a year ago by Mr. Lloyd George. He acted as President of the Institution of Mechanical Engineers in 1913, and was a member of the Council of the Institution of Civil Engineers. He received the honour of K.C.B. in 1911.

William Stanley.—Mr. William Stanley died at Great Barrington, Massachusetts, U.S.A., on May 14th last. He was a member both of the English and the American Institutions of Electrical Engineers, and had a considerable reputation as an electrical engineer in America. He was at one time Chief Engineer to the Westinghouse Electric Company, and later on he was connected with the Stanley Electric Manufacturing Company. He was the inventor of an alternating current system of long distance light and power transmission. Mr. Stanley was born in Brooklyn in 1858. He joined the Society as far back as 1887, and continued his membership for some years. In 1896 he resigned, but renewed his connection with the Society a short time back.

GENERAL NOTE.

Field Telephony.—The City and Guilds of London Institute has arranged for free courses of lectures at the Technical College, Finsbury, for officers and others, in training corps, etc., preparing for active service. The lecturer will be Mr. R. P. Howgrave-Graham, M.Inst.E.E. The college is already well equipped with apparatus for the illustration of the lectures by experiments carried out in the lecture room and in the laboratory, and a special grant for additional appliances has been made by the City and Guilds Institute for this purpose. Further courses on gunnery and gun-laying, etc., will follow if warranted by the attendance at these lectures. An inaugural lecture will be given on Wednesday, June 14th, at 7 p.m., after which convenient hours and dates for the future will be arranged. Those intending to be present are requested to send a postcard at once giving their name, military unit, and address to Lecturer, Telephone Course, City and Guilds Technical College, Finsbury, Leonard Street, City Road, E.C.

MEETING OF THE SOCIETY.

Indian Section.

June 23 (Friday), 4.30 p.m.—Sardar Daljit Singh, C.S.I., "The Sikhs."

SOCIETY'S OFFICES.

The offices will be open as usual on Monday next (Whit Monday).

MEETINGS FOR THE ENSUING WEEK.

Wednesday, June 14...Biblical Archæology, Society of, 37, Great Russell-street, W.C., 4.30 p.m. Dr. Platt, "Notes on the Religion of Ancient Egypt."

Thursday, June 15...Chemical Society, Burlington House, W., 8 p.m. 1. Messrs. G. Senter and S. H. Tucker, "Studies on the Walden Inversion. Part IV.—The kinetics and dissociation constant of phenylbromoacetic acid." 2. Messrs. G. Senter and H. Wood, "Reactivity of the halogens in organic compounds. Part IX.—Interaction of alkalis and alkali bromo-acetates and bromopropionates in ethyl alcoholic solution."

Historical Society, 22, Russell-square, W.C., 5 p.m.

Friday, June 16...Physical Society, Imperial College of Science, South Kensington, S.W., 5 p.m. 1. Mr. G. D. West, "A Method of Measuring the Pressure of Light by Means of Thin Metal Foil." (Part II.) 2. Dr. Edith Humphrey and Mr. E. Hatschek, "The Viscosity of Suspensions of Rigid Particles at Different Rates of Shear." 3. Captain C. E. S. Phillips, "Experiments with Mercury Jet Interrupters." 4. Dr. A. Griffiths, "A Correction of some Work on Diffusion by Dr. A. Griffiths and Others."

London: Printed by William Clowes & Sons, Ltd., Duke Street, Stamford Street, S.E., and published for the Royal Society of Arts by G. Bell & Sons, Ltd., York House, Portugal Street, W.C., in the Parish of St. Clement Danes, in the City of Westminster.—June 9, 1916.

Journal of the Royal Society of Arts.

No. 3,316. VOL. LXIV.

FRIDAY, JUNE 9, 1916.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

PROCEEDINGS OF THE SOCIETY.

INDIAN SECTION.

A meeting of the Indian Section was held on Thursday, April 27th, 1916; SIR ROBERT W. CARLYLE, K.C.S.I., C.I.E., in the chair.

The paper read was—

SCIENTIFIC AGRICULTURE IN INDIA.

By JAMES MACKENNA, M.A., I.C.S.,

Agricultural Adviser to the Government of India, and Director of the Agricultural Research Institute, Pusa.

There is probably nothing which more clearly marks the progressive and sympathetic character of our administration of India than the fact that, at this comparatively early stage, it is possible to speak of "scientific agriculture in India." Half a century ago the subject had awakened but little general interest in England. It is true that scientific agriculture in England may historically be dated back to Sir Humphry Davy's work on the "Elements of English Agricultural Chemistry," published in 1813, while to this period also belongs the work of Boussingault in France and of Liebig in Germany. It is true also that industrial development, increase of population, the enclosure of waste land and the abolition of common land, combined with greatly advanced prices, led to a considerable improvement in agricultural practice in the eighteenth century. But although a few earnest workers like Jethro Tull, Arthur Young, and Coke of Holkham, deduced general principles and tried to influence the agriculture of the country, they were, to a large extent, only "voices crying in the wilderness." The substitution of large for small holdings led to great improvements in agricultural practice and in labour-saving machinery, and the principles of agricultural method became standardised in particular localities. It was not, however, until the beginning of the nineteenth century that scientific agriculture, properly so called, came into existence in this country.

Progress at first was slow, nor did the general economic conditions permit of much attention being paid to the results recommended. The economic upheaval during the Napoleonic wars, with an inflated currency and an extravagant increase in the standard of living, led, when peace was declared and prices fell, to a period of the greatest depression. "Man learns in suffering," and these bad years turned thoughts to schemes of improvement—schemes which a subsequent long period of unexampled prosperity—from 1831 to 1875—gave ample scope for developing. The principal lines were the investigation of mechanical appliances for agriculture, stock-breeding, and the improvement of seed.

Meanwhile agricultural chemistry was coming into its own. The work of Liebig and Boussingault was yielding results. But the greatest practical advance was made when, in 1843, Sir John Lawes established his factory for the manufacture of artificial manures. For some forty years British agriculture flourished exceedingly, and under such stimulating conditions scientific research by Lawes and Gilbert at Rothamsted and by Voelcker in London made rapid strides. It was well that full advantage had been taken of these fat years, for by 1880 British agriculture was again in a state of grievous depression. Harvests were bad, while a new economic factor, that of foreign competition, was beginning to make itself felt.

Again, the development of our colonies and the increased facilities for emigration were alluring many of our small farmers and their sons to new fields of activity.

To this period of depression and to these altered economic conditions may be attributed the awakening of a real interest in scientific agriculture. The seriousness of the position

demanded a thorough investigation of possible remedies.

Agriculture insisted that science should come to its aid as it had done to that of industries. The best of the youth of our agricultural classes were emigrating to Canada and our other colonies. They desired to take with them, in addition to what practical knowledge they had acquired, a certain amount of theoretical knowledge—for in a new country they would be thrown entirely on their own resources. Again, our colonies—largely agricultural—early realised the importance of agricultural science, and turned to the mother country for its teachers. Such were the driving forces which, towards the end of the last century, induced the development of a systematic interest in agricultural science and research. Till this driving force made itself felt scientific agriculture had not been a particularly vigorous plant in England. The work of Lawes and Gilbert was best appreciated in its practical aspect—the supply of artificial manures. In the sphere of education also not much had been done. Cirencester turned out its young squires and its land stewards. A few of the old universities had endowments which involved the delivery of a certain number of lectures annually on the principles of agriculture or rural economy, but in few, if any, was there a regulated course of study of the sciences bearing directly on agriculture; in none, except perhaps Edinburgh, was there a degree conferred in agricultural science. It is only since about the year 1900 that agricultural science and education in England have bocmed. Colleges and research stations have sprung up all over the country, and the number of young men availing themselves of the opportunities which they offer steadily increases.

It can hardly be said that in India there was any similar demand. The youth of India was not clamouring for the application of science to its greatest industry, nor did the pressure of economic conditions demand that agriculture should be thus assisted. In England the development of scientific agriculture was forced by necessity and by the clamant voice of youth anxious to get the equipment of scientific knowledge and exploit it, in most cases, far from their native land.

Scarcely had this development in England begun before we brought this gift to India—a gift the meaning of which was not, perhaps, fully realised and the immediate necessity of which was not accepted by many, including not a few of the older type of Government official, whose opinions were conservative and who thought it a vain task to teach the cultivator his own business.

But what a scope Indian agriculture offers for scientific investigation! The variations of geological formation, of climate, of rainfall, of local customs—rigid and unyielding—and the vastness of the human problem—200 million people dependent on agriculture or the industries subsidiary to it.

The varying conditions, the immensity of the problem arrest the imagination. Over vast tracts of the country the only common interest is agriculture—the monsoon, the state of the crops, the health of the cattle. It is a fortunate thing for this great agricultural Empire that a very large number of the young men who have from time to time gone out to India in one capacity or another have taken with them an interest in rural life and rural conditions.

They find themselves in their new environment in congenial surroundings. They find that the one subject which interests the people amongst whom their lot is cast is their crops and their cattle. They are brought into contact with a peasantry whose interests seldom extend beyond the limits of their fields and their simple village life.

The appeal is irresistible, and, just as England had its early enthusiasts, so these young exiles, influencing the Government under which they worked, stirred up from the beginning an agricultural policy and directed the attention of Government to the improvement of agriculture. Thus as far back as 1788 the Government of Bombay was interesting itself in the improvement of its great staple crop—cotton. For just about a hundred years persistent and continuous effort was faithfully devoted to this problem, and although it was only when scientific agriculture had been developed that any great results were obtained, the labours of these years were not in vain and some definite results were achieved. In other provinces interest in agriculture seems to have awakened at a much later date. Madras began, in 1863, by ordering from England a steam plough, some harrows and cultivators, seed drills and horse hoes, threshing machines and winnowers, chaff-cutters and water lifts. It was the material aids of Western agriculture that appealed to them.

The Government of the United Provinces, when it embarked on its Agricultural Department in 1874, struck the right note. Its object

was defined as the establishment and proof, to native agriculturists, of the advantages to be gained from small improvements such as they were able with the means at their disposal to carry out, and the making of experiments with staples and industries which it might be possible to introduce, if new, or to familiarise and improve if already existing in the country. Sir Edward Buck, the Grand Old Man of Indian agriculture—if I may be allowed to call him so —was the first Director, and his name will always be held in affectionate remembrance as the pioneer of agricultural progress in India.

Similarly, in Bengal, from 1870 Government had taken some sort of interest in agriculture, while the Central Provinces had been working away at agricultural problems from about ten years earlier.

The real awakening of an interest in scientific agriculture in India coincided with the rapid development of the subject in England. Towards the end of the last century the revival in agriculture in England was finding its reflection in India. The science was being systematised at home and was being taken more seriously. India awoke to the importance of its great industry, and took a lively interest in what was being attempted and achieved in England and on the Continent of Europe. In fact, there was evidence of a demand for the scientific investigation of Indian agricultural problems before the facilities for giving effect to it were available. But in Bombay an attempt at organised development was seriously made when Mr. Mollison, later Inspector-General of Agriculture, was in 1890 appointed Superintendent of Experimental Farms. In Madras, Mr. Benson and Dr. Barber laid the foundation of what is now a very live and progressive department.

In the Central Provinces the need for a trained staff was felt, but it was not till 1901 that a Deputy Director of Agriculture was appointed. Similarly, in the other provinces the need for systematic development was gradually making itself felt. It was not, however, till the Indian Budget of 1905-06 that Lord Curzon's Government found it possible to place the scientific study of agricultural problems on a thoroughly sound basis by the provision of funds for the creation of a Central Imperial Staff, with an adequate supply of workers and farms in each of the provinces. In this Budget an annual provision of twenty lakhs of rupees (subsequently raised to twenty-four lakhs) was made for the improvement of agriculture.

On the Imperial side Lord Curzon seized the opportunity of a generous donation of £30,000, made to him for the benefit of India by Mr. Henry Phipps, of Chicago, to establish and equip the Agricultural Research Institute at Pusa. This is now the headquarters of the Imperial Department of Agriculture in India, and, in equipment and achievement, challenges comparison with any similar institution in the East. The principal concern of the institute has, so far, been research, but post-graduate courses are also given, and, although the necessity has not yet arisen, the educational aspect has not been lost sight of, and an adequate equipment has been provided. But as provincial colleges become better established there will be an increase of students from these colleges who desire a post-graduate course, and it seems not improbable that Pusa may ultimately become the training-ground for Indian students who desire to enter the superior grades of the Indian Agricultural Service, conferring an Indian qualification ranking on a par with a British one. In my opinion, if this stage is reached, a considerable addition to the Pusa staff will be necessary, so that the time of our best research officers may not be taken up with the drudgery of formal teaching.

In the provinces the development and reorganisation of agricultural effort were also seriously taken in hand. It is unnecessary to refer to the differences of opinion which arose as to the lines on which this development should take place. Suffice it to say that there are now fully equipped agricultural colleges—in Poona for the Bombay Presidency; in Coimbatore for Madras; at Sabour for Bengal, Bihar and Orissa, and Assam; at Cawnpore for the United Provinces; at Lyallpur for the Punjab, and at Nagpur for the Central Provinces. Burma has not yet its own provincial college for agricultural education, but it is, all the same, getting its men trained satisfactorily. The staff of these colleges consists of a principal, who is generally, though not always, the agriculturist, and professors of chemistry and botany, who also do the research work of the province. Madras has in addition an entomologist and a mycologist, and to each college is attached an adequate subordinate staff. Each college has a college farm for the training of students in practical agriculture, for the demonstration of collections of the cultivated plants of the locality, and for experimental work. In most cases the botanist also has an area on the college farm for research work, and the agricultural chemist a section, on which he

conducts manurial and other experiments, and tests in the field the results of his laboratory investigations.

In most provinces there is now a Director of Agriculture as adviser to the local Government, while under him deputy directors of agriculture, each in charge of a circle, are posted at different centres throughout the province, and, aided by a staff of Indian assistants, control the experimental, demonstration and seed farms. This, in broad lines, is the constitution of a provincial Department of Agriculture.

We have seen that the benefits of scientific agriculture were brought to India almost as soon as they had begun to make their effects felt in England. But the conditions in England and in India were vastly different. In England the farmer is generally a person of education and substance, farming large areas and capable of applying the results of his reading. The great mass of the agriculturists of India are small holders, and the standard of education amongst them is, as a rule, low. There are no agricultural papers to bring to their notice new manures or new machinery; in most cases they would not have the money to purchase them, nor the experience and knowledge to make much use of them when they had got them. I am well aware that in every province of India there are not a few highly educated and intelligent landlords and farmers; but, as a rule, the cultivator of India is a small holder. This, obviously, complicates the problem. Finally, the idea of seedsmen as we know them in England, with our Suttons and Carters, is practically unknown. Till a few years ago the village Bania added this to his various lines of activity.

It might seem somewhat strange and distinctly premature to bring the conclusions of science to bear on Indian agriculture when the subject was practically in its infancy in England. But a beginning was made, and the striking results already achieved have fully justified the wisdom of the policy. The investigation of the basic principles underlying the Indian system of agriculture required careful study, and these have engaged the attention of our scientific workers since their arrival in the country, and already results of far-reaching consequence have been obtained.

But, while this recondite and abstruse investigation into first causes has been going on, attention has also been given to means of helping immediately the local agriculture and the individual cultivator. As I have already said, the professional seedsman is practically unknown in India, and the crying need for India, as for all agricultural countries, is good seed, the best seed, and plenty of it. Thus, while India is waiting for the results of patient laboratory research, there is a problem at once to hand—an easy problem, the results of solving which are immediate and quickly applicable.

When the agricultural officers arrived in India they found in nearly every crop they studied an extraordinary number of mixtures. The cultivator whose interests were limited to his village saw no harm in this; but when the demands of outside trade set a standard, the disadvantage was brought home to him and was reflected in reduced prices. The Department introduced improvement by one or more of three methods: (1) selection of existing varieties; (2) hybridisation; (3) new crops and methods. In applying the first, before any improvement could be effected, it was necessary to make a careful study of the crops and varieties of crops that actually existed. Innumerable varieties and deteriorated samples were found, and it was necessary first to determine by selection which was the best. This was done by an examination of plants growing in the field. What appeared best was selected and plants grown side by side. Their characters and out-turn were studied, and when the superiority of one or two types had been demonstrated and proved the seed was multiplied and distributed.

This is the method of improvement by selection. It is an admirable method for India, as there can be little doubt that there are already in the country numerous crops of high quality if they are grown pure to the best type. It has the additional advantage that it can at once be taken up by an officer trained in the principles of agriculture and that the results can very rapidly be brought into general practice.

Secondly, there is the improvement of plants by cross-breeding or hybridisation. This is the second great method of plant improvement, but its results naturally are slower and the technique much more scientific. It is in fact the work of the botanist rather than the agriculturist, and the application of the Mendelian methods, principally by Mr. and Mrs. Howard, Imperial Economic Botanists at Pusa, and Mr. Martin Leake, the Economic Botanist to the United Provinces Government, has already achieved wonders, notably in wheat, tobacco, and, to a less extent, in cotton. Mendelian work

is slow and requires an infinity of patience. The difficulty is to isolate plants which are an improvement—that is, which contain within themselves a large number of desirable characters. The successful Mendelian worker must have a strong power of discrimination and the courage to abandon ruthlessly what does not suit his purpose. But even in the short time which has elapsed since the work began wonderful results have been obtained by the application of these methods.

The third method is, like the first, one by which rapid progress can be made. It is the introduction of new crops or varieties and improvements in agricultural practice. Both this and the first method require only what I may call agricultural experiment as opposed to deep chemical or botanical research. They are not highly specialised methods, and can be taken up at once by the agricultural worker who is trained in the technique of his profession.

Now, what has been achieved in India under these various heads? Firstly: Improvement by selection.

One of the most important crops of India is cotton, and the fact that for years it had engaged attention in a spasmodic and unorganised way may account for its being found in a very mixed state when real scientific work upon it began. When our agricultural workers first examined the existing crops they found admixtures almost everywhere. A survey of the indigenous cottons of India was made by the Imperial Cotton Specialist, and with the aid of this the provincial officers proceeded to isolate and maintain pure types, to improve their outturn and quality by selection, and to introduce the improved plant into general cultivation.

Rapid success followed. Soon Bombay could point to a selected variety of Broach cotton which yielded 500 to 600 lb. per acre with a ginning percentage of 32·5, against 450 lb. per acre with a ginning percentage of 31·9 obtained from unselected seed. The Central Provinces have found by selection a white-flowered cotton —*Roseum*—with a high lint percentage. This has been developed, and by an admirable network of seed farms and agricultural unions, all controlled by the department, over a million and three-quarter pounds of selected seed have been produced, which sells at more than twice the price of unselected bazaar seed.

By similar methods of selection the United Provinces have established the Aligarh white-flowered cotton with a high ginning percentage, the seed of which commands a premium of from twelve annas to Re. 1-4 per maund. The efforts of the Madras Department have been so successful with pure Karunganni cotton that the seed sells at 40 per cent. above the bazaar seed. The trade, in fact, have been so impressed with the results that they have urged the department to improve by selection local varieties district by district.

The earlier work on wheat also was conducted on these lines. But the subsequent history of work on wheat in India has been so completely influenced by the application of Mendelian principles that nearly all efforts by selection have sunk into insignificance. And yet the material was to hand, in this crop as in others, if the method had been known and applied. A preliminary examination of Indian wheats by Forbes Watson had shown that India possessed wheats of excellent quality. If she had also had a staff of economic botanists who could have followed up this opinion they would have set themselves the task of selecting these superior strains and developing them. But there was no one who could undertake this obvious line of work, and attention was directed to the eradication of rust by the introduction of rust-resisting varieties from abroad rather than to the improvement of indigenous wheats by the elimination of the most liable and susceptible. Improvement of indigenous wheat had, therefore, to wait for the advent of Mendelian workers before any real progress can be recorded. This work will be referred to at some length later.

The great rice crop of Burma is being dealt with on both lines of treatment. Mendelian experiment is being called in to try and produce a product with all the qualities desiderated in the perfect grain. But this will take time, and here again some useful and more rapid results could be secured by selection. Side by side, therefore, with these deeper researches intervarietal selections are being made. Half-a-dozen varieties which already possess an established reputation among millers and cultivators—types suitable for the export market—have been selected. These have been grown and studied, plants which show marked superiority being selected and the seed grown separately. The variation in growth period, resistance to disease, standing power and uniformity of ripening will be observed. Finally, the grain-weight and straw-weight of each will be studied. As a result of this a final selection of the best varieties will be made and the seed of these selected cultures will be propagated for

distribution on a large scale and as rapidly as possible. Each selection will be given a name and number, and these, as well as its history, will finally be entered in a pedigree register. It is scarcely necessary to add that before any variety is distributed it will be thoroughly tested on a field scale.

Yet another crop to which it has been possible to apply this rapid method of improvement is jute. An elaborate survey of the races of jute in Bengal was made by Mr. R. Finlow, Fibre Expert in Bengal, and Mr. Burkill, Assistant Reporter on Economic Products.

It was found that very wide and important differences existed between *Corchorus capsularis* and *Corchorus olitorius*. Some races have a considerably taller stature, and, therefore, other things being equal, a correspondingly greater yielding power.

A suitable basis for pure line culture, as regards yielding power, was thus found, and work on these lines is being continued. At the same time, in order to secure a better fibre, a careful chemical and microscopic examination of the fibres of different races was adopted as a second basis for pure line culture. So far no single plant has been found which combines in the highest degree the two most desirable qualities—high yielding power coupled with strength and durability. Some, however, approximate to this criterion, and it is hoped ultimately to obtain what is required by hybridisation. In the meantime the seed of pure lines has been isolated. Some of these pure lines have been multiplied, and seed is now available for distribution.

A campaign of considerable magnitude has been organised for the final testing of these pure lines against local races. It is quite certain that they are amongst the heaviest—if not actually the heaviest—yielders in the province, and the tests will soon show whether they are absolutely the best or not. In any case it seems clear that in the near future the best will have been obtained, and in the meantime it is quite safe to multiply the pure lines on a very large scale, in the certainty that this seed can advantageously replace the very large amount of poor bazaar seed which is at present bought for sowing over large areas.

It is a similar method that Mr. and Mrs. Howard propose to follow in their effort to improve the indigo crop of India, but in this case it is improvement by selection of an imported variety. A few facts about this crop may be interesting. When synthetic indigo came to the front in 1897, the plant grown in Bihar was the variety known as *Indigofera Sumatrana*. This plant was a low yielder of colouring matter, and it soon became apparent that if any fight was to be made against the synthetic substitute something better would have to be found. In 1898 Mr. H. A. Baily, a Bihar planter, visited Java and, as a result of his visit, introduced into Bihar what is known as Java indigo. The cultivation caught on, and by 1910 the area under Java indigo exceeded that under the old *Sumatrana*. The plant gave a very large increase of colour, and it was thought, not unreasonably, that this crop would save the industry. Suddenly, in the monsoon of 1907, an insect pest called Psylla attacked the plant. In addition the plant wilted away, as the result, it was supposed, of some unknown disease. The out-turn was much reduced. The disease steadily became worse. Java indigo could not be induced to form seed, as the disease killed the plant before the seed set. The industry was on the verge of extinction. Work on the crop was brought to a standstill, as selection, which has formed the main item of the programme of the Bihar Planters' Association, became impracticable when seed could not be produced. Further, in view of the great decline of the industry, the association could not face any further expenditure on their Research Institute at Sirsiah, and it was decided that the investigation should be taken up by the Howards at Pusa. As the salvation of the industry was held to depend on being able to produce seed of the Java variety, this was the first problem which the Howards set themselves. This is a purely agricultural question. They have proved that indigo must be grown separately for seed and for leaf. For seed, indigo should be sown about the middle of August on high-lying and well-drained lands. The seed should be sown in lines about two feet apart, so as to promote branching and ensure abundant pollination, and thorough cultivation and cleaning of seed-beds is necessary. The soil, also, must be properly aerated. A full supply of air to the roots is essential for the production of a good crop of seed, and if grown in this way it is claimed that the so-called disease is avoided and good crops of well-grown seed obtained. The disease which ends in the wilting of the plants is really due to long-continued wetness of the soil, which destroys the young feeding roots. The theory has been put to the test at Pusa and on one of the largest estates in Bihar with good results. The next problem was the

improvement of the crop by selection. In indigo pollination by bees is the rule. There is thus extensive natural crossing in the crop, and any plant selected on account of the high indican content of the leaf is not likely to breed true, but to give rise to all kinds of offspring as regards indican content. It has also been proved that the crop, as ordinarily grown, consists of several distinct types of plant, some of which grow much more rapidly and robustly and carry far more leaves than the bulk of the crop.

The Howards propose, therefore, to take those individual plants in the mixed crop which grow rapidly and strongly, and which by their habit of growth and amount of leaf-surface are likely to give the highest yield of leaf. These will be grown separately, apart from other indigo, so as to avoid cross-fertilisation by bees. It is hoped in a short time to isolate by these means a superior type of plant with a larger yield of leaf, and probably also a large outturn of finished indigo.

From this superior type further selection will be made for wilt-resistance. Experiments on these lines will be conducted both with Java and Sumatra, as the latter will still continue to be grown as a catch-crop after rice.

To pass to the second great method of crop improvement, *i.e.* by cross-breeding or hybridisation. On these lines Mr. Martin Leake has been working for some years on cotton; but results are not yet available, though it is understood that they are full of promise.

It is in wheat, however, that the greatest achievements have been made by this method, as the result of the work of Mr. and Mrs. Howard. As I have said, Forbes Watson had indicated that India could produce wheats of first-class appearance, and that it already possessed wheats of better grade than it put on the market. The first task, therefore, which the Howards set themselves was to find out these better varieties and study their characteristics. They undertook a complete survey of Indian wheats, and separated type specimens of almost every Indian variety.

From the wheats of the Punjab twenty-five types were isolated. These, it was proved, yielded as pure types enormously increased outturns, though great variations in yield were found. They discovered, however, that these wheats were deficient in "strength," that they had weak straw, and that they did not mature early. They noticed also a great liability to rust, and in some varieties a tendency to shed their grain. All these are serious defects, and to eliminate them and obtain those qualities which are essential in a good wheat were the next problems which the Howards set themselves to study.

So far as "strength" of flour was concerned, rapid progress was made by selection from existing varieties and their propagation as pure types. For the other characteristics, such as strength of straw, experiments on Mendelian lines have been conducted and are in progress. Briefly put, this process consists in introducing into a plant by cross-breeding any quality in which it is deficient. The complexity of the problem will be recognised when it is remembered how many characters it is necessary to combine in the one wheat.

Systematic selection and comparison had to be carried out with patience and discrimination from the second to the sixth generation before the now well-known Pusa 12 wheat could be fixed as a type.

From the results already achieved there is good reason to believe that Pusa wheats, obtained either by selection and pure culture or by hybridisation, are the future wheats of India. They have satisfied the tests both of the export and local market, and have proved their capacity to adapt themselves to any environment.

It is impossible to estimate as yet the value or importance of these results to the agricultural prosperity of India, but the work of Mr. Howard and his talented wife in cross-breeding wheat can already be referred to as a great achievement, accomplished in a remarkably short space of time.

It has been calculated that a safe estimate of the gain to Indian wheat-growers, if all seed sown were of varieties like Pusa 12, would be 15 rupees per acre per year. The rate at which substitution of proved seed will take place will depend on the efficiency of provincial organisations for seed distribution. In view of the favour with which these wheats have been received and the cordial co-operation of provincial officers, it is a modest estimate to assume that in the course of a very few years the area under Pusa wheats will reach at least five million acres. This means an increase in the near future in the value of the agricultural produce of India, in one crop only, of 750 lakhs of rupees, or £5,000,000.

Mendelian principles will also play a large part in the important work on sugar-cane being carried out by Dr. Barber. The problem is a

difficult and complex one. Northern India has a predominating interest in the crop; but, on the other hand, while the area in Southern India is comparatively small, we find there much thicker and finer canes than in Northern India. But it is to the improvement of the canes grown in the great sugar tracts of Northern India that attention must specially be directed.

There are several ways in which the improvement of Indian canes may be attempted. An effort may be made to select better strains from the existing varieties at present grown. Again, canes of better quality may be introduced from countries where scientific work has been carried on for years. Lastly, the production of seedling canes, which has worked such a revolution in Java, may be tried in India also. The first two methods have succeeded in Southern India. But, as a general principle, it has been found that imported canes, all of which come from the tropics, are not suited to the sugar tract of Northern India or the prevailing methods of agriculture. The tropical thick canes, which require good cultivation and heavy manuring, are often unsuitable for lack of capital to cultivate them properly. What is wanted is a more hardy type of cane capable of holding its own with the canes grown under field conditions in Northern India. Such types are not usually available among the canes grown in tropical countries, and it is to the production of these that Dr. Barber has devoted himself. Coimbatore has been selected for the work, as it has been noted that canes there flower every year and produce pollen.

The work of the Indian sugar expert is in the main directed to the production for Northern India of superior hybrid seedlings between the local northern canes and the best southern canes. These hybrids will, it is hoped, eventually displace the inferior local varieties. The aim is to obtain such hybrids as will grow under raiyat's conditions and give a greater yield under the same treatment as is at present devoted to the crop. With such canes it is hoped that the cultivator will be enabled to improve his cultivation. At present the margin of profit on jaggery manufacture is very small, and it is improbable that there will be any permanent extension or improvement until the raiyat is provided with better hardy hybrids. The thicker canes are useless because they will not grow under the treatment they receive.

The first duty of the research station, therefore, is to produce hardy hybrids to supplant the present inferior local canes. But there is also another aspect of the work. It has been found that canes under cultivation have only a certain length of useful life, after which they have to be discarded. A batch of good new canes will only last a certain time, after which they will die out on account of deterioration and disease. Improved canes, introduced through the Samalkota farm, have disappeared in eight years. A similar fate will overtake the thick imported canes in other provinces and new hybrids. Cane-breeding must, therefore, never slacken if the wastage is to be made good, and to effect this the number of stations and workers must be increased.

Such is the work on which Dr. Barber is engaged on his own research station at Coimbatore. The seedlings and superior canes, when sufficient have been obtained, will be distributed to provinces. Dr. Barber also advises provincial officers in the survey and selection of the best indigenous varieties and on the method of propagating hybrid seedlings, and since his appointment great advance has been made in the provinces.

As our staff of botanists increases, and the more immediate problems of improvement by selection are solved, work on Mendelian lines will bulk larger and larger in the scientific work of the Agricultural Departments of India. I have merely indicated the crops on which important work on these lines has as yet been done.

It remains to consider very briefly what has been effected by the third method, *i.e.* the introduction of new crops or varieties and improvements in agricultural practice.

As regards the introduction of new crops or varieties, the establishment of ground-nut cultivation in the dry zone of Burma has saved that tract from the recurring danger of scarcity. "Dharwar American" cotton and "Cawnpore American" cotton have been established in Bombay and the United Provinces respectively. Egyptian and Upland American cotton have been introduced in Sind. We have seen that the prospect of a renewal of the indigo crop depends on the successful handling of imported Java seed. Large numbers of new fruits and vegetables have been introduced into the country.

The greatest achievement, however, in the introduction of an exotic crop is the establishment of Cambodia cotton in Madras. Seed was obtained from Pondicherry in 1904. It succeeded at once: the trade co-operated in its

development, the cotton was boomed, and within seven years the outturn had risen to 45,000 bales. The lint was better and the ginning percentage higher than that of any indigenous variety, and it could be cultivated with considerable profit on lands unsuited to Indian cotton. Valued at 180 rupees per acre, it naturally supplanted crops which only yielded some thirty rupees per acre. The large profits were a great temptation to adulteration, and this the cultivator has been unable to resist. Dealers mixed it with local cotton and tried to pass off the mixture as genuine Cambodia. Cultivators grew it on unsuitable land and the staple deteriorated. This inferior cotton was mixed with good Cambodia and palmed off on the bazaar. The crop fell under suspicion, and a premium price was no longer given. The re-establishment of Cambodia on its old footing is one of the biggest problems with which the Madras Department is confronted.

As regards improvement in agricultural practice, it seems hardly necessary to remark that this has been the concern of the Department ever since its establishment. The existing methods have first been carefully studied and improvements tried and recommended when proved. Results can hardly be set forth in detail, but one outstanding success has been the substitution of transplanting for broadcasting of rice in the Chattisgarh division of the Central Provinces. The resulting profit to the cultivators has been some 4½ lakhs of rupees per annum.

Similarly in all provinces the subject of machinery is receiving much attention, and good results have been obtained in the improvement of indigenous implements and in the introduction of European machinery. It must be clear, however, that I cannot enter into particulars as to the improvement of agricultural practice or machinery without an elaboration of details which would be tedious.

Of the purely scientific work of the Department it may be said that provincial chemists have, as a rule, confined themselves at the outset to the routine work of their farms—the analysis of soils and the experimental testing of manures—leaving to the Imperial staff the investigation of more general questions. When the routine work has made some progress they have been able to specialise on questions of importance to their provinces. Thus in the United Provinces, the Punjab, Bihar, and the Central Provinces various aspects of the chemistry of sugar have been taken up. The Burma and Madras chemists have concentrated on rice. Dr. Mann in Bombay has devoted a great amount of attention to the milk question.

At Pusa Dr. Leather has demonstrated the economical use of phosphatic manures on a large range of Indian soils. He has inquired into the water requirements of some Indian crops, and the amount of water and the period of growth during which the crop requires the principal portion of the water has been determined. The rate of evaporation of water from fallow and from cropped land and the formation and movement of nitrates in the soil are also questions which have been investigated. A considerable amount of work has also been done on the chemistry of sugar-cane and sugar-beet.

Mycology and entomology offer great fields for work in India, but the workers are few. There are in fact only three trained European mycologists in the Department, and the same number of entomologists. Even with this small band of mycologists a large amount of investigation has already been done. Potato blight, the rusts of wheat, red-rot of sugar-cane, the wilt of arhar, and the tikka disease of ground-nut are amongst a few of the diseases that have been investigated. An elaborate campaign against bud-rot disease of palms in the Godavari delta of Madras has saved roughly twenty lakhs of rupees annually. A similar campaign against a disease of areca-nuts has saved tens of thousands of rupees.

The investigation of the ufra disease of rice, which is supposed to be caused by an eel-worm, is at present one of the most important problems before the mycological staff.

Progress in mycology must be slow. In each case the disease has to be diagnosed, the cause discovered, and remedies tried and proved. It is to the credit of the handful of mycologists in India that they have already achieved so much, and that their work has led to such practical results.

It is from no lack of appreciation of the work of the entomologists that I refrain from giving details of their achievements. Such an account would be a long list of pests combated by their advice.

The first Imperial Entomologist was Mr. Maxwell-Lefroy. In the short time he was in the country he did an enormous amount of spade-work in the collection and study of the habits and life-histories of Indian insects. His "Indian Insect Pests" and "Indian Insect Life" are monuments to his industry, and he

has also left in India a number of well-trained Indian assistants. The work thus well begun has been continued by his successors; but no great impression can be made till the number of entomological workers, both European and Indian, is largely increased.

Pathological entomology has also been taken up at Pusa, and there is also a branch of agricultural bacteriology.

It will thus be seen that no branch of agricultural investigation is being neglected.

In this rapid summary of the activities of the Agricultural Departments it has, of course, been possible to select only a few of the more striking instances of achievement. But I may say that on a conservative estimate we claim that the annual increase to the value of the agricultural products of India as a result of the labours of the Agricultural Departments is already over £2,250,000. It will therefore be understood why we believe that the policy of agricultural development which established the Pusa College, and secured the scientific study in India of agricultural problems peculiarly Indian, has been fully justified.

A word on veterinary matters. Each province has a wel-equipped Veterinary Department consisting of European superintendents, deputy-superintendents, inspectors, and veterinary assistants. In some provinces the veterinary assistant is a peripatetic officer, going about from one outbreak of disease to another and applying remedies, medical or segregative. In others he has a local dispensary, from which he dispenses medicine or advice, visiting villages as necessity arises. For the training of this staff there are veterinary colleges at Bombay, Lahore, Calcutta, and Madras, and a veterinary school at Rangoon.

The research work of the Department is concentrated at the Imperial Bacteriological Laboratory at Muktesur, where are manufactured the sera and vaccines which are used to combat rinderpest, hæmorrhagic septicæmia, anthrax, and other diseases. The laboratory has a world-wide reputation, and its products are indented for from all parts of the Empire.

On the vexed question of agricultural education I would rather say nothing. First principles are still undecided, and no fixed policy has been laid down. We may struggle in time to a correct solution of the problem, but we are still struggling. I do not think that any interest could attach to an account of the indeterminate discussions of the past. I can certainly say nothing final about the subject. In these circumstances it will probably be best to adopt the policy of the old Scotch minister when confronted with a difficult point in his text: "Stare it boldly in the face and pass it by." We have the equipment; we are endeavouring to discover the best way to get material to train, and the best way to train it when obtained.

I think I have said enough to show that the Agricultural Departments of India are fully alive to their responsibilities, and that they have seriously tackled the manifold problems which face them. Their propagandist labours will be lightened and their sphere of influence extended by the vigorous parallel growth of agricultural co-operation societies—another of the great blessings we have taken to India. It is now possible to take improvements to a group of cultivators bound together by common interests instead of to isolated individuals working only for themselves.

Co-operation, by forming them into groups, gives the small cultivator all the economic advantages of the large landholders. In the harmonious union of these two great movements—scientific agriculture and co-operation—lies the economic future of India.

[In the absence of the author in India, the paper was read by Sir Steyning W. Edgerley, K.C.S.I., K.C.V.O., C.I.E., Chairman of the Indian Section Committee.]

DISCUSSION.

The Chairman (Sir Robert W. Carlyle), in opening the discussion, said the out-turn of rice in India far exceeded that of any country in the world of which we had accurate figures, it being grown over an area which was almost equal to that of Great Britain and Ireland. The production per acre, however, was not at all satisfactory. Compared with countries like Italy and Spain it was very poor, the out-turn in Spain being on the average about five times as great per acre as that in India. In the out-turn of wheat India was second to the United States and Russia, it being grown over an area greater in extent than England. The importation of Indian wheat last year played a great part in preventing an exorbitant rise of prices at a critical period. Here again the production per acre was low, it being barely one-third of the average out-turn in this country. India had the second largest out-turn of cotton in the world, taking second place to the United States. As regards sugar-cane, it headed the world. The out-turn per acre was bad, the average in India being about one ton of raw sugar per acre against four times that amount in Java and Hawaii. Thus there was a large margin for improvement in

quantity and very often in quality of the crops grown over large areas in India. It was impossible to hope that, within any reasonable number of years, the out-turn of rice or wheat per acre would approach that of Spain or England, but it was possible by scientific agriculture to obtain something very much better than the present meagre results. The author had indicated that it was expected in a few years, owing to one improvement in wheat alone, to make £5,000,000 a year more than at present. That improvement affected only one-sixth of the area under wheat, and it would bring the yield up to about one-half of what it was at present in England. The improvement of agriculture in India was, he believed, the greatest problem now before that country. The Indian agriculturist often did admirable work so far as his means allowed, and by many centuries of experience he had evolved excellent methods, but their practice could be improved by scientific application. He did not in the least underrate the importance to India of general industrial development; it was very desirable that the proportion of the population entirely dependent on the vicissitudes of the seasons should be diminished; but the main staple of India must for all time, so far as he could see, be agriculture. The development of agriculture was not only of vital importance to India from the point of view of the economic welfare of the people, but also of very great importance politically. He believed that, under Indian conditions, no political development could be altogether sound which had not at its base a prosperous peasantry capable of understanding and taking its full part in the local administration. It was very fortunate that just at the time when, under Lord Curzon's government, the Agricultural Department was put on its present lines, the great co-operative association movement was also developed. He looked to that movement to produce a profound transformation of Indian social conditions. In the ten years that had elapsed since it was first really started, 750,000 members had joined the associations, and he had seen in all parts of India the great increase in the well-being and well-living of villages where they flourished. As the author had pointed out, the two directions in which agriculture would greatly benefit by the movement were, firstly, that it enabled the Agricultural Department to deal with bodies of agriculturists instead of with single cultivators; and, secondly, it enabled the cultivator to borrow money at a rate of interest so low as to enable him to apply capital to the soil with profit. The cultivator had not, so far, availed himself of that privilege to any great extent, but he was sure that there would be rapid development in this direction, and that, owing to the influence of the associations, much more capital would be applied to the soil. India owed a great debt of gratitude to Lord Curzon for his action in regard to agriculture in India. It was very largely owing to the interest that he had taken in the matter, and to his insight into the best methods of furthering it, that the Agricultural Department owed its organisation on present lines; and it was also largely due to him that legislation was passed which made co-operative associations possible, and which provided the administrative machinery for stimulating the growth of such associations. It was also under Lord Curzon's *régime* that Sir Colin Scott-Moncrieff's committee was appointed which investigated the possibility of developing irrigation in India, and the result of its labours had been that the amount of work done since then on irrigation had enormously increased. All the time he was a Member of Council he never experienced any difficulty in getting money for any irrigation scheme which was ready. The author had shown in his paper a thorough grasp of the problems with which the Indian Agricultural Department had to deal, and he was sure the country would derive great benefit from his knowledge and capacity during his tenure of office as Agricultural Adviser.

Sir H. Evan M. James, K.C.I.E., C.S.I., thought from his experience, going back fifty years, that very great difficulty would be experienced in getting the conservative agriculturists of India to support the Agricultural Department. Fifty years ago there was a great demand for good Indian cotton in consequence of the American War, and a very distinguished Collector, without any assistance from Government, bought up all the seed which he could procure of the best variety then on the market, called Hinginghat, and forced the ryots to sow it. If any ryot sowed any of the old bad indigenous cotton his crop was pulled up. As a result, in the first year the ryots of that district benefited to an incredible extent, owing to the superior value of the new crop. At the conclusion of the American War interest in Indian cotton on the Liverpool cotton market died out, and an Act which had been passed in Bombay to prevent the adulteration and mixing of cotton was, at the instance of the Bombay merchants, repealed. As a result Indian cotton again became a byword in the market; but a fresh attempt was now being made to revive the cultivation of better staples. Unless, however, the Government of India were prepared to go further than merely introducing good staples, by insisting on their being grown and kept pure, all the very benevolent experiments referred to in the paper were, so previous experience proved, likely to prove abortive. The ryot was a very nice fellow, but he was very conservative; and although undoubtedly a good deal might be done in the way of improving Indian cotton, it was a very long and hard climb uphill to do anything really practical and permanent. Nevertheless, he wished every success to the Department.

Sir Andrew H. L. Fraser, K.C.S.I. (formerly Lieutenant-Governor of Bengal), differed entirely from the remarks made by Sir Evan James, his experience making him an optimist in regard to

the future of Indian agriculture. He believed the Indian cultivator was perfectly ready to adopt any method which was actually proved to pay, but it was necessary to show him that something was to be gained by adopting the recommendations of the Department. It was not his experience, especially in later years, that it was difficult to get the ryot to move in the right direction. He was very glad to think that the abominable heresy that an improvement in agriculture could only be obtained through the medium of large capitalist cultivators had now been dispelled. Capital was, of course, necessary; but he would rather give up hope of improvement than see the smaller cultivators swallowed up. The growth year by year of the co-operative system, which had been initiated with so much success, filled him with the greatest belief in the future of Indian agriculture.

LIEUT.-COLONEL S. H. GODFREY, C.I.E., Indian Political Department, said that Central India contained many forest tribes which took very reluctantly to agriculture, but which worked very keenly on the development of forest produce. The importance of lac was brought home to him shortly before the war. The Maharaja of Rewah started a lac factory on up-to-date lines in order to develop that very important industry in Central India, and shortly before the war Germans offered to take the whole of its output, which they mixed with cheap German alcohol and exported as varnish. When war broke out the German trade stopped, and the forest tribes were threatened with the elimination of their means of livelihood. Two small States in Central India, in order to rescue their forest tribes, started a scheme to work the factory themselves, which proved successful: and as the markets in Central India for forest produce were limited, a project was submitted to the Government of India to develop a wider ambit for the Native States which had the various forest tribes depending upon them. It was approved by the Government of India, and the Maharajas of Dattia, Panna and Chattarpur, the Rajas of Nagod and Maihar, and the Chaube-Jagirdars of the Baghelhand Political Agency formed a private limited liability company for the development of the work. Shortly after the beginning of the war, Cawnpore was suffering from the want of tannin; the Chiefs employed a scientific expert to report on their produce, and they discovered they possessed some very valuable tannins which were wanted by the Cawnpore factories for the manufacture of army equipment. The company at present deal with lac, tannin, and hides, and the Maharaja Holkar of Indore had established a factory for the manufacture of vegetable dyes for the replacement of aniline dyes. It was the first co-operative State scheme that had been started in India, and had great possibilities. The Central Indian States covered a very large area, from which it might be possible to obtain acetone by dry distillation, and tannin, the latter of which would go far towards supplying a very sore need at present in India, which had to be met by the importation of wattle bark from countries as distant as South Africa. If encouragement were given to the far-sighted and patriotic Indian Chiefs who had risked their money in the concern, it would not only benefit them and their people, but it would go a long way in the scientific development of other States. The Chief Commissioner of the Central Provinces had signified his approval of the scheme by giving to the company large tracts of forest in the northern portions of the Central Provinces on what was practically a profit-sharing basis, which seemed to show that a responsible official had some belief in the development of Central Indian forest produce on scientific lines. His Majesty's Secretary of State for India had sent a tannin expert to India and Burma with instructions to visit the Native State factory at Maihar, in Central India.

MR. A. YUSUF-ALI, I.C.S. (retired), pointed out that the apparent slowness with which agricultural improvements were introduced into India was not due so much to the unreasonable attitude of the ryots or of the people as to certain conditions which made it difficult for them to utilise those processes from which they were convinced they could make money. He was an optimist in regard to the improvement of Indian agriculture in the future, but there were four main difficulties in the way of a greater scientific application of improved methods. Firstly, the ryots had very little capital. Although agricultural co-operation had placed within their means the power of combining together and raising capital, it must be recognised that the co-operative credit movement was in its infancy, and as long as rates of interest of 9 and 12 per cent. prevailed it was impossible to speak of the salvation of agriculture in the matter of borrowing capital. The second need of the Indian agriculturist was a better organisation, not only in regard to the selection and issue of good seed, but in the selling of the produce. The ryot often received far less than his due for his produce, a larger proportion than was equitable going to the middleman. Thirdly, a more favourable fiscal arrangement was required. Many of the by-products of agriculture were not utilised because the ryot sometimes felt that he was handicapped by the Revenue Law. A great deal had been done in recent years in the Northern Provinces in the way of ensuring to the ryot the benefit of any improvements he made, but he did not have as much protection as he should do. The Zemindars were also chary in many cases of investing capital in the land, because they found that, in the periodical settlement, they did not always obtain the results which were contemplated under the Revenue Law. An improved Revenue Law in regard to the partition of land was required. Small holdings were sub-divided to such an extent that holdings of less than one acre existed. Such minute sub-division was not necessary, and it would be found in many cases that they were merely paper sub-divisions. It was necessary to insist that in Revenue partitions the holdings should be compact

NOTICE.

ANNUAL GENERAL MEETING.

The Council hereby give notice that the One Hundred and Sixty-second Annual General Meeting, for the purpose of receiving the Council's report and the Treasurers' Statement of receipts, payments, and expenditure during the past year, and also for the election of officers and new Fellows, will be held, in accordance with the By-Laws, on Wednesday, June 28th, at 4 p.m.

(By order of the Council),

HENRY TRUEMAN WOOD, *Secretary.*

PROCEEDINGS OF THE SOCIETY.

COLONIAL SECTION.

A meeting of the Colonial Section was held on Tuesday, May 2nd, 1916; THE RIGHT HON. VISCOUNT BRYCE, O.M., D.C.L., LL.D., F.R.S., in the chair.

THE CHAIRMAN, in introducing the reader of the paper, said it was to him a great pleasure as well as a great honour to be asked to take the chair and to introduce to the meeting his very old and valued friend, Sir William MacGregor. Sir William was one of those who had sustained the credit and shown the capacity of our countrymen far beyond the seas, and had held many of the highest and most difficult positions in the service of the Crown. The most difficult positions were not always the highest, but in Sir William's case they had often coincided. He had been in high office in Fiji, New Guinea, West Coast of Africa, Newfoundland, and finally in Queensland, having thus had experience both in the government of Crown colonies and in self-governing dominions; but wherever he had been he had acquitted himself to the immense benefit of the country and to his own high reputation. He had long thought of him as being in many respects a model Governor, because he possessed not only gifts which enabled him to represent the Crown for political purposes and to hold the balance where it was necessary to do so between rival claims and different parties in the self-governing dominions, but he also possessed a very wide and accurate scientific knowledge which had enabled him to render the greatest services to the governments of the various colonial possessions and dominions where he had been called upon to hold office. The value of the work done by Sir William MacGregor in the various colonies and dominions could not be over-estimated. The possession of scientific knowledge on the part of a Crown representative in these circumstances was rather a rare thing among our governors, excellent in other respects as they were, and anyone possessing them was able to do for these colonies or dominions many things that nobody else could do, in calling the attention of Ministers to work that could be done and giving them a line of direction which was seldom within the knowledge of a politician or even of a statesman. Sir William had been able to do that with admirable success in the many positions he had occupied with such distinction, for he combined in an eminent degree those two things, namely, a mastery of scientific knowledge and great practical tact and shrewdness.

The Secretary of the Section read the following letter received by Lord Blyth, Chairman of the Colonial Committee, from Lord Lamington, formerly Governor of Queensland:—

"I am really disappointed at being unable to be present at Sir William MacGregor's paper to-morrow. I have been with him in New Guinea, and I know happily by experience his remarkable powers and capacity not only as an administrator in dealing equitably between the influx of whites amid a native race, but also, by his knowledge of botany, astronomy and other sciences, of being able to turn to the best advantage the resources of an undeveloped country. His address should be full of interest."

The paper read was—

SOME NATIVE POTENTATES AND COLLEAGUES.

By THE RIGHT HON. SIR WILLIAM MACGREGOR, G.C.M.G., C.B., LL.D., D.Sc.

When invited to read a paper before this venerable Society my thoughts not unnaturally turned to the many men of different races with whom I have been associated, and to whom the Empire, and I as a humble individual, owe so much. It is to be feared that we are too apt, in the rush of modern life, to forget the important position such men occupy in the constitution and life of an Empire that in complexity greatly exceeds any that has hitherto existed. We overlook the fact that we are a coloured Empire; and we have been governing great areas and vast numbers of people by sending out from this country officers that, in a majority of cases, have had absolutely no training for such work. And yet we have not failed, because these officers in so many instances have had genuine sympathy with native races, and have had an innate sense of justice. One often hears it said of a native race, "Oh, they are just like children." In some ways they are, but I hope to show you that many of them are our equals, and not a few of them superior to most of us.

THAKOMBAU.

The first person of whom I have to speak is Thakombau, the greatest and best known man of the Fijian race, in many respects a very remarkable man. It may safely be said of him that no ruler, not even the first Christian emperor—whose career that of Thakombau in many points resembles—ever saw his country transformed by such enormous changes as this Fijian chief both saw and assisted in.

His grandfather, Banuvi, was the first ruling chief of Mbau of whom we really know anything. His father, Tanoa, succeeded a brother, and was constantly occupied with plunder, murder, and war, and died as he had lived, a heathen. When advised to allow the introduction of Christianity to Mbau, he replied, "You will see Christians on the island of Mbau when you see vegetables growing on my back." He little thought how his prophecy was to be realised.

Unfortunately the history of Thakombau cannot now be written, as so many of the stirring events of his picturesque life are already lost in oblivion. Here one can only have a look, in passing, at a few incidents in his career. It seems that he was born in the year of Waterloo. Soon after his birth he lost his mother, which led to his spending the first years of his life at Rewa. The first glimpse we get of him is when, as a child of six or seven, he kills a little playmate that, however, belonged to a different tribe. Then he is presented to us as the stripling Seru, living at Mbau, from which his father, Tanoa, had been driven by a rebellion. The youth was not killed nor banished, because it was thought he was too young and inexperienced to be dangerous. He was, however, clever enough to form a party that expelled the rebels, on which he brought back his father to Mbau and to power. It was from this achievement that he got the name of Thakombau, which, according to Mr. Calvert, means "Evil to Mbau"; while Mr. Royce interprets it as "Mbau is bad." He also got the name of Thikinovo, the centipede, both names having reference to his *coup d'état*. But he is best known to history as Thakombau.

In 1835 the first Methodist missionaries came from Tonga to Fiji, and two years later the Rev. Mr. Cross went to Mbau, then the centre of greatest influence in the country, but found matters so unsettled after the civil war that he did not try to remain there, but went on to Rewa.

They had just finished eating two of those chiefs that had been concerned in the expulsion of Tanoa, and two more were in the oven when Mr. Cross called at Mbau. Thakombau, however, received Mr. Cross and showed him where he could build a house; but he was not prepared to offer him protection. His pride was certainly wounded by Mr. Cross leaving Mbau and settling down in Rewa.

The white man was already well known in Fiji, but not favourably. The Rewa chief said of his own wicked brother that he had no soul, that he was like a beast, or like one of the Englishmen that came to Fiji because they would not be Christians in their own country.

In Suva, the present capital of the colony, Christianity was introduced in 1840, though that place was subject to Mbau. It was attacked by Rewa three years later, and about a hundred persons were killed, and most of them were eaten. Thakombau could not overlook this, and he went to war with Rewa. Some white men assisted Rewa—a fact that made Thakombau still more indisposed towards Europeans and missionaries. One of his brothers sided with Rewa, and in 1846 we find Thakombau obtaining permission from his father to kill this brother.

There is recorded the chagrin of Thakombau when his father accepted peace offerings from, and pardoned the people of, the village of Mathuate, which had neglected to pay the usual tribute to Mbau. In his wrath he said, "Christianity is powerful; because of it we cannot get men to eat."

His appreciation of human flesh was also shown in his reply to Captain Erskine, who had urged him to give up cannibalism: "You whites when you sail about have salt beef to eat; we have no beef, and therefore eat men."

He induced Verani of Viwa to assist him to carry out a most treacherous and cunning onslaught on Namena, when they together killed upwards of a hundred people, took their bodies to Mbau, cooked and ate them. Eighty women of Namena, wives and relatives of the dead men, were strangled. The brother of Thakombau offered the latter a present of a fine canoe to save the lives of these people; but Thakombau replied, "Keep your canoe; I want to eat men." These men had to prepare the stone ovens and to get ready the firewood to cook their own bodies. Their blood was first drawn and drunk; then their arms and legs were cut off, and their tongues cut out; then they were killed outright, cooked, and eaten. The Rev. Mr. Watsford reported in 1845 that more human beings were eaten at Mbau than perhaps anywhere else. He relates, as an example, how the Mbau people caught twenty women fishing, brought them alive to Mbau, put some of them into the ovens before they were dead, and ate the lot in one day. Sir William Des Vœux, who, as Governor, had excellent opportunities of acquiring information, was of opinion that Thakombau between the ages of six and of fifty—when he became a Christian—had eaten part of about one thousand persons.

Whilst Thakombau was continually participating in such horrors as these he saw clearly enough the merits of Christianity. He reproved those that spoke evil of the missionaries and of the Gospel they preached. When urged by the missionaries to become Christian, he asked them to be patient, to wait till he had finished his wars, then he would become Christian, and all would follow.

As a matter of fact, the Fijian, taking him all round, is the most amiable of men, and in him the religious instinct is highly developed. This characteristic, and the splendid devotion to duty of the Methodist Mission, have together produced results that are second to none in the history of evangelisation. Thakombau was no exception to the general character of his race. Even old Tanoa was at times inclined to favour the Mission. When, in 1849, fourteen women had been captured and brought to Mbau to be eaten by some visitors of distinction, Mrs. Calvert and Mrs. Lyth hurried to Mbau and rushed into Tanoa's house, which was absolutely forbidden to women, and begged that the lives of the victims should be spared. Nine had already been killed, but Tanoa spared the five still alive, and pardoned the intrusion of the heroic wives of the two devoted missionaries.

When Thakombau's father had become old, great pressure was brought to bear on the former to prevent the strangulation of a number of Tanoa's wives in accordance with custom. The missionaries offered Thakombau anything, everything they had, if he would spare the lives of the women; captains of ships of war threatened him. Thakombau, however, made no promise to bribes or menaces, but said that so great a chief as Tanoa must not die unattended, as that would be a disgrace throughout Fiji.

The Rev. Mr. Watsford as soon as he heard of Tanoa's death, in 1852, hurried to Mbau. When he arrived there one woman had already been strangled. The second, who had at one time professed Christianity, rose when called, and as she passed Tanoa's body spat on it and said: "Ah, you old wretch, I shall be in hell with you directly!" The third woman was a lady that had volunteered to be strangled in lieu of her sister. She was a proud woman, and demanded to be strangled with a new cord. Her demeanour was warmly applauded. Thakombau, who presided, was acutely distressed in the presence of the missionary, and ordered that one of the victims should live. She refused, and her own son helped Thakombau and others to strangle her. All this time Thakombau was in mental agony between pious reverence to his father and the Gospel.

The mental attitude of women with regard to strangulation under the rule of Thakombau it is not easy to understand. We constantly find a sister, the mother, or a friend volunteering as a substitute; and the proper parties frequently insist on being strangled; but that was before they had become Christian.

Shortly after the death of his father, Thakombau was formally invested with the supreme dignity of Vunivalu, "War Lord." This was his proper official title after Fiji became a British colony, but neither that designation nor his

baptismal name of Ebenezer displaced the better-known name of Thakombau.

Eighteen persons were to be eaten on the assumption by Thakombau of the title of Vunivalu, and they were brought to Mbau, some dead, some alive, for that purpose. But the Rev. Mr. Calvert prevented the eating of the bodies.

The time came, however, when things went all wrong with Thakombau. The rival Rewa became too strong for him; the whites were opposed to him, helped his enemies and cut off his supplies; he got into serious trouble with the Americans; in the eastern horizon he saw a dark danger-cloud loom up in the form of his Tongan vassals, and King George Tubou wrote to him urgently to become a Christian. Thakombau was humbled, and felt himself powerless against his enemies, but befriended by the missionaries. He sought refuge in the Christianity he had put off so long, but which he had now fully recognised to be a great power in the land.

On April 30th, 1854, he caused the death-drum—"rongorongo valu"—to be beaten to assemble the people; and in the presence of some hundreds of them avowed himself a Christian. He was baptised January 11th, 1857.

Next year Thakombau offered to cede Fiji to Queen Victoria. The offer was not then accepted.

The protection of the Crown was, however, extended to Fiji in 1874, and I was present at the Declaration of Sovereignty over that colony in June, 1875.

When I first became acquainted with Thakombau he was about sixty years of age. One could see at the first glance that there was something imposing and impressive in his face. An examination of his features revealed the fact that in him the upper eyelid just touched the circumference of the iris of remarkably expressive, bright and yet soft, eyes, which gave a look of quiet dignified command to his countenance, with an air of serene intelligence.

Captain Erskine described him as a man of magnificent physique, every inch a king.

Sir Arthur Gordon said of him the first time he saw him: "He is far more striking than the photographs represent him, very kingly in bearing, and with a most intelligent head." Lady Gordon and Lady Des Vœux described him as having the manners of a perfect gentleman.

In the unique career of this wonderful man nothing is more striking than his sterling loyalty to the British *régime*. Like the Roman Emperors up to the time of Constantine, his personality in his own estimation and in the attitude of others towards him was a sort of quasi-divinity. Yet almost as soon as the first Governor arrived Thakombau came to Levuka with some hundreds of attendants to make, without reserve and in public, his feudal submission according to the form proper for an inferior chief towards his superior. He presented to the Governor a great root of yaqona, broke off a piece, put it in the hand of the Governor, and led off the "Woh," the salutation proper to a supreme chief. The effect was electrical, and the example was followed by all Fijians ever after. When Sir William Des Vœux arrived in Fiji and drank the yaqona, Thakombau again led off the "Woh" in the same manner. Sir William put on record that Thakombau "on this, as on all other occasions up to the time of his death, seized every opportunity of showing his loyalty to the new *régime*."

Mr. Victor Williamson wrote of him that he was one of the great men of whom the world knows little; that the British Empire is indebted to him for unswerving loyalty.

Thakombau and Fiji were fortunate in their two first Governors, Sir Arthur Gordon and Sir William Des Vœux, men not only of extraordinary capacity, but also of genuine sympathy with native races. Thakombau was quick to see that, and there was very real and sincere friendship and genuine esteem between Thakombau and those representatives of the Crown. Thakombau, recognising that these men had at heart the welfare of his race, was always ready to assist them in any thing, however great, however small. I never heard the smallest approach to intrigue imputed to him, but have very many times heard the two first Governors of Fiji express their great indebtedness to Thakombau.

Personally I enjoyed, in an unusual degree, the friendship of Thakombau, who always called me "Matai ni mate," though by others I was known as "Vu ni wai." Thakombau thought the title he used to be the more applicable for surgery, in which there was a great field, and in which he took a very deep interest. One particular case made a very great impression on him, and after he had satisfied himself of the successful result, he said of it: "These whites are gods, this is making men." Like all native chiefs he was an eloquent speaker, using metaphors and similes that would rival the Iliad.

Thakombau died in 1883. The Commissioner for Native Affairs informed me that in his will Thakombau expressed the desire that I should examine his brain and write a report on it. Unfortunately, I was studying in Berlin when he died, and consequently could not comply with the wish of my old friend, and no examination of his brain was made—a distinct loss to science.

To understand the character of Thakombau, one must look at his extraordinary political sagacity in procuring allies and friends, and in isolating and destroying his enemies so as to extend his power; his firmness of purpose in carrying out his designs, in spite of bribes and threats, so long as he felt he had the power and strength to complete them; his clearness of vision and soundness of judgment in estimating his own power and the overwhelming forces arrayed against him when fortune went from him to the side of his enemies; his self-control in avowing himself a Christian in the presence of his own people, becoming before them a humble, impotent mortal, instead of being a sacred entity; and finally his unfaltering, whole-hearted loyalty to the British Crown.

Roko Tui Dreketi.

This chief was the head of a great family, which formerly ruled Rewa when it was at times as strong as Mbau. The families of Thakombau and of Roko Tui Dreketi were connected by intermarriage in the days of Tanoa and Thakombau. Roko Tui Dreketi was, as regards kingly bearing, personal appearance, and propriety, the antithesis of Thakombau or Maafu.

At the first meeting between Sir Arthur Gordon and the great chiefs at Mbau, Thakombau publicly denounced Roko Tui Dreketi as a drunkard. Yet, in spite of all his defects, this mean-looking, dissipated little man convinced me that he possessed genuine aristocratic spirit and an abundance of latent courage and fortitude.

He had a tumour about the size of a small walnut on the middle of his forehead, and this he thought disfigured him. He had asked me two or three times if I would remove it for him, and I had said I would do so whenever he was ready. I happened to be at lunch one day at Government House when the chief was there. When lunch was over we adjourned to the room of Captain Knollys, A.D.C. The *Rokotui*, when sitting in a half-reclining cane chair, turned to me and said, "Vu ni wai, when are you to remove this tumour?" I said, "Now, if you so desire." He replied, "Good, do it now." I got from my pocket-case the necessary instruments, took my place behind his seat; and laid his head back on the top of the chair, thus putting his head at a convenient height and in good light. When he saw the knife in my hand he said to me, "What about the 'sleep-water'?"—meaning chloroform. I replied, "Oh, sleep-water is for the meaner sort (Kai-si); chiefs do not require it for an operation." He replied, "That is good," and laid his head back, when I deliberately dissected out the tumour by a transverse incision so as not to mark his forehead, and sewed up the wound. He never uttered a word or a groan—never moved a muscle.

Nearly about the same time I had to open a whitlow on the toe of a powerful, fine-looking man of the common people in the hospital at Levuka. It took some half-dozen assistants to hold that man's leg for the small operation. Never before or since have I seen such a contrast, nor such a fine example of *noblesse oblige* as that furnished by Roko Tui Dreketi.

Maafu.

The Tongans as a race are not nearly so numerous as the Fijians. They were great sailors and very skilful at building canoes. Fiji contained a great deal of the finest timber for shipbuilding, and it was in connection with this industry that the Tongans frequented Fiji. They were, moreover, recklessly brave, so much so that Mara, a brother of Thakombau, declared them to be invincible, gods in fight, not human. They were of great use to the chiefs of Fiji in building war canoes, and as the sea was the special element of Mbau, the Tongans were in great repute there. It was to take delivery of a new great war canoe that King George Tubou came to Mbau in 1855, when he became involved in war and rendered important aid to Thakombau. The Tongans, though valiant and good shipbuilders, were, however, idle, in spite of the example of Thakombau and of King George, who were industrious workers in their gardens, and upheld the principle of no work no food. But what the Jutes, Saxons and Angles became to their hosts the Britons, or the Visigoths to Valens and the sons of Theodosius, that the Tongans were becoming to Thakombau and the Fijians, and this undoubtedly was one of the causes that prompted Thakombau to put himself and his country under the protection of the British Crown.

When King George returned home from Fiji

he left his relative Maafu in charge of the large number of Tongans in the eastern islands of the Fijian group. Maafu was a man of magnificent physique and of high mental endowments. Lady Gordon wrote of him that he was the handsomest man of all the chiefs. He had been a Christian from an early age, and was in all respects a man of high character, but of few words. He had a peculiar way of expressing assent to anything. I am not sure that I ever heard him say "Yes." He indicated an affirmative always by raising his eyebrows in quite a convincing manner. He ruled the eastern islands well and firmly. On my first visit to Maafu I found Ratu Timoci, the most amiable of Thakombau's sons, as his guest. He had been completely captivated by a niece of Maafu, a young lady of a figure and carriage that might have been envied by the spouse of Jove. They were married the day of my arrival. I never could learn whether this was done with the approval of Thakombau, but in any case this marriage united together the two royal families of Tonga and Fiji.

Sedu.

Sedu, a Papuan, was certainly one of the finest characters I have ever known, and his untimely fate I have never ceased to deplore.

He was the youngest brother of the chief of the Turituri tribe, who lived on the coast some thirty miles west of the Fly estuary.

He was given to me by the chief of his tribe, to wait at table, when he was about thirteen or fourteen years old. He was a gentle lad, of good manners and good temper; clever, and attentive to his duties. When he was about fifteen I had a fine example of his splendid courage and devotion to duty. I was making a traverse of a bay on the north-east coast in a boat towed by a steam launch. I had with me only Sedu and an old man from a town in the south end of the long bay, a little of whose language I understood. He was taken as interpreter. On account of bad weather my boat could not live in the sea, and about sunset we had to let the steam launch go off for shelter, while I steered our boat through the breakers and to land, going before the wind. We were surrounded by a crowd of wild and excited natives, who took possession of our heavy six-oared river boat and carried it away a considerable distance inland, so that we should not escape. Large numbers of men arrived during the night with the intention, as we were informed, of killing us next morning. With great difficulty we put up our little tent, and I went to bed in my hammock, the only time in my life that I ever lay with a revolver in my hand. About midnight a man came to me and said he wished to befriend us, and stated that if we would get up and fly with him to his town they would receive us and help us. I thought we could make a better defence where we were, and refused to start, knowing that we could so easily be clubbed or speared from behind in the dark. We got away safely in the morning, after a most interesting experience.

When we were out of danger, I said to Sedu, "Were you afraid?" His answer was, "No, sir, I was not afraid; but when that very big man shook his club over my head, I thought he would certainly kill me; but I did not care, because I knew that if he killed me you would immediately shoot him dead." According to Sedu's belief, that man, if shot as he expected, would have accompanied him to the "beyond" and been subject to him. If Sedu had shown fear, I should probably not be before you now.

When grown up he entered the armed constabulary, and was, as corporal, in charge of the six men employed as guard for Mr. Green, who was at the Mambare station, forty miles up that river, not far from the German boundary. Mr. Green was forming a new station a mile or two up an affluent of the Mamba, on a good site. One day they were all starting to work at the new place, and Sedu had the rifles of the guard put into the boat by which they were to travel. Mr. Green told Sedu that it was not necessary to take their arms. Sedu said that he had put them in the boat because the Governor's orders were very strict that they should never go out without their rifles. Mr. Green repeated his order, pointing out that they were only going to the other place, and it would be wetting the rifles unnecessarily. Sedu repeated what he said about the Governor's orders, and added that he did not like the look of the natives lately. Mr. Green said, "Sedu, are you afraid?" He replied, "No, sir, but these are my reasons." Then he received a positive order, and took the rifles back to the house, and they went without them.

When they reached the new station the men were sent out in different directions to look for building material. Mr. Green divested himself of his belt and revolver and went up to nail some rafters on the roof of the new building. A fine plantation of several acres had been made near the new quarters, and Sedu had crossed that space and was about

300 yards away when he heard the yells of two or three hundred savages who had been lying in wait for them near the new house. They all rushed for Mr. Green, and when Sedu saw him struck by a spear and fall to the ground, he turned and went straight back to die with his superior officer. Sedu was in perfect safety had he chosen to run in the opposite direction. Two or three of the other men were also killed in the bush. The bodies of Mr. Green and Sedu were cut up and thrown into the river. This took place in January 1897.

The ambuscade had been planned by the only man that had ever deserted from the armed constabulary, a Mambare man named Dumai.

We had, as soon as possible, to attack and defeat the league of tribes concerned. This was a very troublesome business, on account of the nature of the country and our exposure to fever. Several attempts were made to capture Dumai, by myself and others, but all failed till in July, 1898, I took back to the Mambare five men that had been made prisoners, and had gradually been drafted into the constabulary and been trained for about a year. One of the five had been an excellent prison warder at Samaria; another had accompanied me on many difficult journeys, and had always done good service. I appointed these men village constables on July 2nd, and told them their first duty was to capture Dumai. On the fourth one of them came to the station with some friends to deliver to me a message from the tribes of the upper Gira, that if I wished to take Dumai I had better come for him. We had already fought those people, and it was seen that they wanted to get rid of Dumai. The new village police went after him, and on July 8th brought him in irons on board the "Merrie England" steamer, at the mouth of the Mamba River. I had determined that I should not leave British New Guinea before Dumai was captured, and I had gone to the Mambare on purpose to have that completed, and it was a great satisfaction to me to leave Dumai in prison when I finished my term of ten years in that country.

I put a brass plate in the church at Port Moresby to the memory of Mr. Green and Sedu. But there remained for me an unpleasant task—to face his tribe, which it manifestly was my duty to do under such circumstances. As soon as I landed at Turituri all the men of the tribe assembled, and when we were seated in the great "man-house" a spokesman demanded to know whether it was true that Sedu, whom they had entrusted to me, had been killed.

It was evident that the position required some tact and patience. I replied that it was true that, to my great grief, Sedu had been killed, but that Sedu was still with us at Port Moresby in the spirit; and I showed them a photograph of the memorial brass tablet I had put in the church there, and told them that Sedu lives and speaks through the inscription on that brass plate to all that enter the church, and tells them to be good men and true, and to follow his example and be faithful in duty even until the death of the body. There was not another angry look in the assembly.

The Garter King of Arms was so kind as to let me have Sedu in my arms as my dexter supporter; and three years ago I sent a photograph of my arms to Sedu's tribe that they might have another proof that as long as I live I shall never forget Sedu.

Komodoa and Yakoba.

Komodoa, chief of the Polatona tribe, in Bentley Bay, and Yakoba, chief of Mita, in Milne Bay, were the two first men of note to accept and assist Government in New Guinea.

In November, 1888, on the first official visit to the north-east coast, we came on the wreck of a stranded vessel that had been recently burned. Inquiry showed that this was the remains of the "Star of Peace"; that a combination of neighbouring tribes had murdered the master, looted and burned the vessel. They had obtained a rifle, two shot-guns, and two revolvers, with a quantity of ammunition for these. This matter occupied the whole available strength of the Government for two and a half months, for it had been decided to adopt from the beginning the principle of individual, and not tribal, punishment. It was the first assertion of rule by the new administration.

That part of the country was thickly populated by tribes or communities, most of which could muster four or five score of spearmen. The two men, Komodoa and Yakoba, probably had more influence over their tribes than had any other chief in the district. Each of the two had some crude knowledge of Christianity, and were favourable to the missionary idea.

When search was made for the murderers and ringleaders the Government party came to a village called Huhuna, the chief of which was one of the principals in the attack on the ketch, and it was known that a man was there who had in his possession one of the guns and a case

of tobacco from the vessel, allotted to him for the part he took in the attack. This man was found, and the first I knew of his arrest was when Mr. Basil Thomson appeared near the beach dragging the man towards our boat by the handcuffs already on the man's wrists. How Mr. Thomson managed to get the man in irons I cannot say. The prisoner called for help, and the result was a spirited attack on us by heavy spears thrown javelin fashion. In the *mêlée* the prisoner got away, but was shot down. When we got on board our vessel in the bay, Komodoa, who was the nearest neighbour to our assailants, came on board at once to offer friendship and co-operation. But as Komodoa had kept aloof hitherto he was regarded with some suspicion. He denied all part in the attack on the vessel and her crew, and when asked why he did not join the others, his reply was, "Too much fear God." He was informed that he could prove his sincerity by capturing the principal leader in the outrage. He undertook to do so. He recovered the firearms taken from the vessel and sent them to us; and, after a delay that was beginning to look unpromising, Komodoa at last appeared at the head of a file of seventy or eighty spearmen with the man we most wanted in irons in the middle of his followers.

When the murderers were all finally dealt with, and the time came to resettle the people in their villages, the magistrate, assisted by Komodoa, could not induce them to return, and they sent messages that only if the Governor came without an armed force would they return and be at peace. Komodoa, without any hesitation, accompanied the administrator with one other man to meet and resettle several hundred men, the principal leader of whom he had captured only a few weeks previously. Although the Papuan is generally timorous, instances like this of absolute fearlessness are common enough. Komodoa remained a most faithful and devoted servant of the Government, and I deeply regretted his death when I heard of it several years afterwards. Yakoba, of Mita, was as ready as Komodoa to help us, but operations were confined to the district of Komodoa. But Yakoba had an opportunity of using the execution of one of the murderers for the propagation of his knowledge of the Gospel. He and some of his people sang hymns and spoke in favour of mission work at the execution.

The point of greatest interest in connection with those two men is that even a very rudimentary knowledge of Christianity may be of very great use in dealing with savage and hostile heathens. When the resettlement was fully discussed and the functions of the Government explained, the last request of the Chad's Bay people was that the next tribe to the north should be informed, because they said, "They kill and eat us, and we kill and eat them."

Not long after the resettlement of the natives of Chad's Bay I went there with the special object of acquiring some knowledge of their language. In this work the first necessity always is to find how to say in their tongue, "What is that?" I spent a day and a half trying to discover that phrase, and when I had failed utterly and had ordered my men to take down my tent to depart, the chief pointed to something on the ground, and I felt sure said, "What is that?" Two days after that I left with a vocabulary of some seven hundred words, quite enough for ordinary use, as you will readily believe when you remember that Paul, for example, wrote his letters to the Corinthians with 963 Greek words, and those Epistles are considered to have an unusually rich vocabulary.

Maa and Chief of Suku.

About the middle of September, 1898, when I was packing my baggage to proceed to Brisbane, an urgent message arrived from some prospectors that they had been robbed and hemmed in by a warlike tribe called Goromani, at an altitude of 9,000 or 10,000 ft. on the west end of the Owen Stanley Range. Mr. Wriford, who was known to be a courageous man, had written, September 6th, "For God's sake send me help at once . . . We were attacked yesterday, and Martin, I am afraid, mortally wounded; it is not safe to go for water... they are all about..." It was manifestly a matter of life and death. Within three days we had fitted out a party of 110 persons, of whom fifteen were armed constabulary and twenty were good conduct prisoners who were taken as carriers.

On September 22nd the party reached the village of Suku, the chief and people of which were friendly and desirous of assisting the Government. The chief and three or four of his followers joined the party without hesitation, though we were to stop at places that had been at enmity with Suku. The hardships of the carriers from Suku onwards was terrible. The track was continuously over precipitous ridges that were wet and slippery, and very dangerous to naked feet. The carriers did not grumble, for they all knew that it was a race against time to relieve the besieged party; but their trials

were so severe that many cried like children. Not a man was punished nor even reprimanded. What was needed was encouragement.

It had been intended to proceed from a village called Iritumuni direct to Goromani, to attack the tribe at home; but a native of Iritumuni gave the information that one miner had been killed at Goromani, and that he had seen Mr. Wriford's man speared and clubbed. This informant was prepared to guide us to the besieged by a direct path, that would take us to the camp two days sooner than by way of Goromani. By this track, on the thirteenth day from Port Moresby, we reached Mr. Wriford's camp with the Chief of Suku and the strongest of the armed constabulary.

I had noticed that the chief carried a new American axe, that he guarded most carefully and never used for any purpose. When asked for the reason of this he replied, "This axe is kept to be dyed in the blood of Goromani." He explained that this warlike tribe had at one time killed a number of Suku people for whom "payment" had never been taken.

On the way to the camp, from altitudes of 5,000 to 10,000 ft., and during intervals clear from fog, the village of Goromani was several times plainly visible below us, distant only a few miles. It was quite clear how it could be approached and rushed. It was found that the Goromani were holding a great feast prior to killing off the party they had plundered, and of which they had already murdered one man and severely wounded another.

Early next morning, on the way to Goromani, we passed the spot where the baggage of the miners had been pillaged, as was shown by the torn wrappings, etc.

The attacking party was able to get unseen to within 300 or 400 yards of the village, where the constabulary divested themselves of every thing save their knickerbockers, rifles and cartridge pouches. When the word was given, they, led on by Corporal Sefa, went like the wind on the village. The miners who were following on behind—they could not keep up with the constabulary—were signalled to in order that they should guard the baggage. In three or four minutes the constabulary had taken the village and the Goromani fighting men were routed and fled.

The Chief of Suku had appointed himself my bodyguard, along with my cook and some carriers, who were armed with bush knives. It was noticed that a quite new track led off the path into a place covered by tall reeds, and it was suspected that there was probably an ambuscade there. The cook, with his rifle ready, led the party into the reeds, and was confronted by the great war chief of Goromani and a few of his followers. Maa, the cook, was cleverer than the great warrior, and shot the latter before he could throw his spear, on which the Chief of Suku sprang on the Goromani man like a wild cat, and buried his fine new American axe in his skull. The others fled. The cook thus became the hero of the expedition. When the news of his exploit reached his tribe, great was their joy over the renown he had brought them. It happened that he was very much in love with a young lady of his tribe, and that the young lady reciprocated; but they were cousins, and consequently within the prohibited degrees of relationship in that tribe. They held a public meeting and decided that in this case the two young people should be made an exception, and be allowed to marry.

Koapena.

The most numerous and most powerful tribe in British New Guinea was that of Aroma, on the south coast. The best-known man in the tribe was Koapena, a tall muscular man of distinguished appearance, who maintained a great reputation by conveying to Europeans the impression that he had unbounded influence over the tribe, and to the tribe that he could obtain any favour from Europeans. He was, however, for a Papuan, hospitable, always courteous, and invariably good-humoured. The tribe, which numbered between 4,000 and 5,000, was well aware of its strength; and it was comparatively rich in coconut groves and good planting land. This people at first neither knew nor cared anything about the newly-established Government, but when they heard of its doings from time to time they did not scruple to say that the Government dare not interfere in any way with them. Many messages were sent to the Administrator warning him that he could never fight Aroma, that he would be killed before he could cross the loose sand of the dunes. They, however, ceased to make war on, or to molest, their neighbours. In June, 1893, the poet-musician of one section of the tribe had brought out a new choral dance, and another section of the tribe used it without permission. The result was civil war, and that some thirty men were wounded, one killed, and others apparently mortally wounded. The Government was obliged to take action in such a case, especially as the Administrator was in the neighbourhood at the time. A landing was made at one of

the outlying villages, and Koapena appeared as usual and admitted the trouble that had arisen, and gave the assurance that the belligerents had united against and would fight the Government were any arrest attempted. The position was serious, as only a score of the armed constabulary was available at the time, and these were all recent recruits speaking different dialects and not half trained.

A visit was made to the principal village, though this was not without risk, and the people solemnly warned that they must surrender the ringleaders or the Government would attack the village and take them by force. The small detachment was made as safe from attack as possible, and left where landed.

A river ran up-country between Aroma and the spurs of the mountains at some distance behind, the mouth of the river being some miles from Aroma. It was cleared and ascended by using dynamite and American axes, and the clearing party were welcomed by the hereditary enemies of Aroma. On the return of the Administrator, Koapena admitted that this isolation and the attitude of their former foes had caused a division in the tribe, as many had become seriously alarmed. The final result was that the tribe yielded to continuous pressure, that they surrendered three of the four ringleaders, that six village constables were appointed and duly installed. One of the three surrendered men escaped, but the new constables remained loyal, arrested him promptly, and handed him over; and the fourth one who had fled was arrested by them later on and brought to Port Moresby. After the appointment of their police the only man that showed a tendency to disloyalty was Koapena himself, who, like the Hereditary Boiler of Human Heads in the tribe, saw that his own position was lessened in importance. Koapena was too clever a man not to see that he must adapt himself to the new order of things, which had brought the whole tribe completely under Government control, to which Koapena had, indeed, though unconsciously, contributed.

This was the greatest achievement of the Government during the first ten years of its existence. On several prior occasions, where hostile tribes had been brought under control by the exercise of violence, the Administrator had received congratulations from his superiors, but of this case no notice was taken by the Secretary of State or by the Colonial Governments concerned. It would have been different had there been bloodshed.

Some time later on an amusing incident occurred with Koapena. I called at Aroma when Sir Samuel Griffith was my guest. Koapena was in mourning for some relation he had lost, as shown by his face being covered by a thick layer of lamp-black. The method of polite salutation there then was to rub noses. I learned afterwards that there was much discussion as to whether Sir Samuel would rub noses with Koapena under such circumstances. To the surprise of the onlookers Sir Samuel never hesitated a moment, but rubbed noses with Koapena as heartily as if he had been the chief's brother, or as if the salute were to leave no trace behind. It certainly was a remarkable sight, and it contained a great lesson, to see this distinguished scholar, jurist, and statesman, who had indeed been the principal in establishing a government there, rub noses with such a barbarian as Koapena. Naturally, Koapena and his people were greatly pleased.

The succession to the chieftainship in that tribe is from chief to nephew, so that probably Koapena's brother's son is now chief of Aroma.

John Allan, an Australian Aboriginal.

John Allan, of Mundoolan, a man of nearly sixty years of age, is the last of the Wangerriburra tribe. He lives on the estate of Mundoolan near the south coast of Queensland. He has been educated to read and write. He speaks English well, and is in every respect, save in colour and feature, a white man. He is employed about the homestead, and is treated just as if he were a European. He is the only living aboriginal of the Beaudesert district. I became interested in this man, and in the language and customs of his tribe. A competent officer was provided with the standard directions for writing aboriginal dialects, and was sent to secure a large vocabulary of the Wangerriburra tribe, which, but for this man, would have been lost for ever. It was published in the Report for 1914 of the Chief Protector of Aboriginals of Queensland.

It appears that in this country the intelligence of the Australian aboriginal is greatly underrated. As a matter of fact, they are very brave, ingenious, dexterous, and capable of enduring great fatigue. They probably represent the oldest race of men of which we have any knowledge. What seems perplexing is the fact that they were unable spontaneously to make any advance along our lines of civilisation. I have met a considerable number of them that, up country, earn good wages as stockmen. It is greatly to be deplored

that they are fast hastening towards extinction, for they would have been of the greatest use as station hands. One example of their inventiveness will suffice. Away in the north-west of Queensland a tribe prepared a corroborree for my benefit. I found the young men covered over by the feathers of the white cockatoo. It was ascertained that they had bled several men by opening a vein of the arm to obtain blood with which to glue the feathers to their bodies. A month or two later I read in a German paper an article on the new use of bullocks' blood in glueing on veneer in cabinet-making in Germany. I am sure the aboriginal did not learn this use of blood from the German.

The Alake of Abeokuta.

The most distinguished and most enlightened chief in the Protectorate of Lagos in my day was the Alake of Abeokuta. Ake is the name of the dominant quarter of the town of Abeokuta, the capital of the Alake's province, and his title may be paraphrased as "Lord of Ake." He estimated his total population at 350,000; that of his capital is over 50,000.

The Alake is of a hereditary ruling family, one of the chiefs that have the right to wear a crown and other regalia. The divinity that doth hedge a king is still in full vigour among those very conservative peoples. Even the Oni of Ife, whose ancestors were the heads of the Yoruba race, could not add to the number of crowned heads, from fear of the fetish. Indeed, when the Oni visited me in Lagos, where a great Council was held to determine the question whether a certain chief who had assumed royal ensigns could do so legitimately, he had to sacrifice five sheep to his own crown between Ife and Ibadan, a two days' journey on foot.

The Alake's province enjoyed many attributes of self-government under treaties with Great Britain, and the Alake and his people had made greater advances in the development and settlement of their country than any other native administration on the west coast. He ruled his province with vigour, and was conscientious in dealing with the public money of his people, some £12,000 to £15,000 a year. When I complained to the Alake that his people were stealing the fine wedges of soft steel used in fixing the rails in the metal sleepers of the railway, and explained that this might cause disastrous accidents, he promptly passed a law to make this a capital offence. Not another wedge was stolen.

He and his people were given to agriculture, road-making, house-building, and trading. He took up cotton-growing and sanitation, regulated police and prisons, and had a high regard for education. The Alake and his council possessed judicial as well as legislative and executive functions. But my last official act there was to put through an arrangement to bring indictable offences committed in the Abeokuta province under the cognisance of the Supreme Court of Lagos.

The Alake came to this country in 1904, to give effect to two wishes he had for some years entertained: to be presented to the Sovereign, and to learn here what he could that might be useful to his own people. He insisted on coming to England while I was here, in the hope that I might help him. He was most industrious while here. At one agricultural show he ploughed land, but he had difficulty in believing that he was not required to push the plough. At the same place he fearlessly entered a gauze-wire net enclosure where there were several swarms of bees, and handled them like the immune keeper. He hauled a net at salmon fishings; and he made some blocks for street pavement from granite similar in colour and texture to the rocks on which his own capital stands.

But the delight of the Alake's life was in his being presented to King Edward at Buckingham Palace.

His Majesty, seated on the throne and with the Secretary of State and other great officers on the steps, received the Alake in state. The Chief wore his native regal robes. When he advanced to about three yards from the throne he knelt on the floor and touched the carpet three times with his forehead.

His Majesty, in a brief but admirable speech of encouragement and approval, addressed the Alake; and the chief made an excellent loyal and dutiful reply, expressed in picturesque language.

You have all heard of, and many of you must have seen, the fine engraving of Queen Victoria presenting a Bible to an African chief, as "the secret of England's greatness." The African chief in question was the father of the Alake. Through the kindness of Henry Graves & Co., Pall Mall, we have been able to put on the wall a copy of that engraving.

The Alake mentioned in his brief speech how Queen Victoria, His Majesty's Royal Mother, had presented a Bible to his (the chief's) father, and how that gift had been treasured by the recipient and his people. When the ceremony

was over, I asked the Alake how it was that during my many visits to Abeokuta they had never mentioned, nor shown me, that Bible. Then it came out that when the King of Dahomey with his women regiments invaded Abeokuta and burned part of the town, the Bible perished in the flames.

When, a few days later, I was relating this to the late Hon. Maude Stanley, that lady said, "Why do you not ask the King to give a Bible now to the Alake?" I replied to the effect that I had reserved that for Miss Maude Stanley, to which the answer was, "All right, get me the particulars."

I had already got into a railway carriage which the Midland Railway had put at the service of the Alake to convey him to Liverpool on his return to Africa, when a Royal messenger handed me a parcel with a letter, which ran as follows:—

"General Sir Dighton Probyn, Keeper of the Privy Purse, presents his compliments to Sir William MacGregor, and sends him, by command of the King, the accompanying Bible, which His Majesty requests Sir William will be good enough to give to the Alake of Abeokuta as a present from His Majesty, to replace the Bible given to the Alake's father by Queen Victoria, and which was destroyed in a fire some twenty years ago.—July 7th, 1904."

The Bible was duly presented to the Alake at Liverpool as commanded by the King. The Alake himself was very broad-minded in matters of religion, and would go in one forenoon to several religious services, of different Christian sects, and would look in on Mohammedan or Shango meetings on the way home. When I last saw him he had not made up his mind as to which Church he would join.

It was thought by some people that the notice taken of the Alake in this country would spoil him; but I never heard that he had lost his equilibrium by it.

DISCUSSION.

The CHAIRMAN (Viscount Bryce) said it was entirely superfluous for Sir William MacGregor to apologise for the length of his paper, because he was sure they would all have been pleased to listen to him if he had gone on for an hour or two longer. They had been told many interesting and instructive things that enlarged their ideas about those whom they were in the habit of calling barbarous or savage peoples. What Sir William had said was quite true, as anyone who had studied a little of the history of these semi-civilised and barbarous people knew. There were many very remarkable and striking characters who from time to time appeared among these peoples, who achieved great things and left fame behind them for generations. He would like to be permitted to give two or three examples. There was a great chief in Hawaii who was seen as a very young man by Captain Cook, and who lived to be, first of all, conqueror of his own island, and subsequently, by his many successful expeditions, the conqueror of the rest of the Hawaiian Archipelago. His name was Kamehameha, and he was the founder of a dynasty which ruled over the Hawaiian Islands until they fell into the hands of the United States thirty years ago. Another such was Moshesh, a famous chief of the Basutos, in South Africa, who ultimately, like Thakombau, gave his country over to our direction, since which the Basutos had lived happily and thrived wonderfully under our government. Another such man (unless he was mistaken) was Khama, who still holds dominion over a large territory in Bechuanaland. These were a few cases similar to those mentioned by Sir William MacGregor, and it was very interesting to have such studies of their character as had been given in the paper. There was a great deal in the paper which they would all remember with pleasure, and when they had all of it, with the parts which had been omitted for want of time, before them they would all undoubtedly return to it in order to read what Sir William had been obliged that afternoon to omit. In conclusion, Lord Bryce read a letter from the Prime Minister of Queensland, the Hon. T. J. Ryan, regretting his inability to accept the Society's invitation to attend the meeting. Mr. Ryan added: "No one is better qualified to speak upon the subject he (Sir W. MacGregor) has chosen. His fame as a pro-consul is universal, but we in Australia have had a special opportunity for appreciating his great work. Amongst the natives of New Guinea, although many years have passed since his Governorship of that dependency, his name is still held in almost supernatural regard."

MAJOR SIR THOMAS B. ROBINSON, K.C.M.G., Agent-General for Queensland, in proposing a vote of thanks to Sir William MacGregor, said they had all enjoyed listening to the many interesting things he had told them. In Queensland they had had long experience of Sir William, they knew the great work he had accomplished for the Empire, and they were all exceedingly sorry when it became necessary for him to leave the colony.

SIR ARUNDEL T. ARUNDEL, K.C.S.I., in seconding the resolution, said Sir William MacGregor had given them a most interesting account, with wonderful descriptive sketches, of what to him (the speaker) was an entirely

new world. He had been very much struck by the extraordinary tact Sir William had shown in all kinds of difficult situations—situations from which he had emerged in a manner that was not only creditable to himself, but of great advantage to the Government he served. Lord Bryce had referred to Sir William's scientific knowledge, and to the few cases in which such knowledge was possessed by our administrators in distant parts of the Empire. He had been making a mental calculation of how many Governors he had known in India, and thought he could number fourteen; but he did not think one of them had any acquaintance with science in the way that Sir William MacGregor had. In those days probably the difficulty of acquiring such knowledge was very great, but in future it would be less so.

The Hon. J. G. Jenkins, in supporting the motion, said it was now twenty years since Sir William met several of them who were Ministers of the Crown in South Australia, and gave them a most graphic description of British New Guinea. He had met him since on several occasions and had visited both Fiji and New Guinea. It was difficult to measure the value of the work done by Sir William in New Guinea. For ten years he was there in the midst of a population of many hundreds of thousands of blacks, and the great majority of them, especially on the western side of the island, were cannibals. Yet he brought these islanders practically into a state of civilisation, so that, with the exception of the extreme west, it was now possible to travel in every part of New Guinea in perfect safety. One of the causes of this great change was his treatment of prisoners, who had committed crimes without knowing they were crimes, and which had been the ordinary practices for centuries. When in New Guinea he (the speaker) visited places miles and miles away from any white settlers, where the only persons in charge were the jailor or prison superintendent and some prisoners. He found the prisoners perfectly safe—indeed, to such a state had discipline been brought that they were told that if they did not come in from their work at night they would be locked out! The immediate successors of Sir William had followed the lines laid down by him, and it was doubtful whether anywhere else in the world had such a large number of natives been brought, in so short a space of time, to the realisation of civilisation, especially remembering that the inhabitants of New Guinea were not possessed of the intelligence which characterised, for example, the Maoris of New Zealand.

The resolution was put to the meeting and carried unanimously.

Sir William MacGregor, in replying, expressed his appreciation of the references that had been made to himself, and regretted that his services did not deserve the encomiums they had received. He considered it a great honour to have Lord Bryce in the chair, and mentioned that as Chancellor of the University of Queensland he had enjoyed the signal pleasure of conferring on his lordship what he believed was his twenty-fourth or twenty-fifth university degree. He added that such distinctions were not granted by universities without due cause. He himself had been surprised and delighted by the extraordinary range of knowledge possessed by Lord Bryce, which covered botany, astronomy, geology, literature, etc.; but this was only telling them less than half, as they would gather from the fact that he (Sir William) was informed by the Attorney-General of a former Government that there is nothing worth knowing in international law with which Viscountess Bryce is not acquainted. He expressed his sincere thanks to the audience for their attendance and attention, and apologised for the fact that in the paper there was too much of the first personal pronoun.

THE SOCIETY'S PREMISES IN 1760.

An interesting confirmation of the information about the premises "Opposite Beaufort Buildings," given in the History of the Society, is provided by an old plan, lately discovered in the office of the Bedford Estate. The property east of Southampton Street, between the Strand and Tavistock Street, at one time belonged to the Dukes of Bedford, but was sold by them, and the plans and documents relating to it have therefore not for the most part been preserved. There are, however, still certain plans in existence, and it was from one of these that the plan given on page 56 of the History was compiled. Some of the details, however, were rather conjectural, but these are now confirmed by the newly found plan, which shows the precise area occupied by the Society's premises. It is marked as "On lease to John Price, in the Occupation of the Society of Arts and Sciences and others." Price was the original lessee, and he demised the property to Williams and Woodin, by whom it was let to the Society of Arts. The dimensions of the "Great Room" and the other buildings are set out, and correspond with those given in the History. There is indeed no fresh information provided, but it is very satisfactory to find the previous researches so fully confirmed. The Society is again indebted to Mr. Stutfield, the steward of the Bedford Estate, and to his colleague Mr. Marchant, for the kind thought which led them, on the finding of the old plan, at once to show it to the Secretary of the Society, and to permit him to have a copy made of it. The date of the plan is not known, but it must have been some time between 1760 and 1774.

OBITUARY.

Elmer Lawrence Corthell, D.Sc. — Mr. Corthell, the well-known American civil engineer, died on May 16th. At the time of his death he was actually President of the American Society of Civil Engineers. He was born in 1840, and commenced his professional career in 1867. He carried out a large number of important engineering constructions in the United States, including many large bridges, and carried out much important railway and canal work. He was associated with Captain James B. Eads in the improvement of the Mississippi navigation. He also took part with the same distinguished engineer in the project for the Tehuantepec Ship Railway. This scheme, jointly devised by Captain Eads and Mr. Corthell, was never carried out. He also carried out important works in Mexico, amongst others the improvement of the harbour of Tampico. He was a prominent figure in engineering circles in this country, and on the European continent, as well as in the States, for he acted as American representative on various Congresses and Conferences.

Mr. Corthell joined the Royal Society of Arts in 1891, and took much interest in its concerns—indeed, until a very recent time he was in constant correspondence with the Secretary. It may be mentioned that he took a good deal of trouble in obtaining a complete set of the Society's *Journal* for presentation to his old university—the Brown University of Providence, Rhode Island—of which he was a D.Sc.

GENERAL NOTES.

School of Oriental Studies.—It is announced that a Charter of Incorporation has been granted to the School of Oriental Studies, into which the London Institution has been converted, and that the Governing Body has been constituted. The charter states that the purpose of the school, which is to be an institution of the University of London, is to give instruction "in the languages of Eastern and African peoples, ancient and modern, and in the literature, history, religion, and customs of these peoples, especially with a view to the needs of persons about to proceed to the East or to Africa for the pursuit of study and research, commerce, or a profession." It is understood that the first meeting of the Governing Body will be held before the close of this month, and it is hoped that the school will be started in the autumn.

The Truffles of Perigord and Sarladais.—The districts of Perigord (Department of Dordogne) and Sarladais are famous for their truffles. These highly-prized fungi make their appearance during the first days of August, and are gathered from then to the end of March. They are found under a variety of oak called the truffle oak (*chêne truffier*), also near the evergreen oak (*chêne vert*), and the hazelnut tree (*noisetier*). Those who make a speciality of gathering truffles are called "caveurs de truffes." They search for them with trained dogs or pigs, the animal locating the hidden truffle by scent. The truffles are gathered every day or two and carried by the "caveur" to the nearest market town, where he sells them to commission merchants, who buy for the large dealers. The normal price for truffles is 5 francs per kilogramme (about 4*s*. per lb.), but sometimes the "caveur" receives as much as 12 and 15 francs (9*s*. 6*d*. and 12*s*. per lb.). The first-of-the-season truffles are called "truffes à la marque," and are inferior in quality to those gathered later. "Truffes à la marque" are black outside and white inside, and have little or no fragrance. With the appearance of cold weather, says the United States Vice-Consul at Limoges, the truffles improve in quality and acquire a greater fragrance. The fine-quality truffle is black outside, black and grey grained inside (*noire marbrée*). The truffles grown in Perigord and Sarladais possess the most fragrance, and are generally superior to those grown in other sections of France. In 1913—the latest year for which detailed statistics are available—France exported 451,500 lb. of fresh, dried, and pickled truffles, 21,600 lb. of which went to the United States. These shipments had an average value of about 5*s*. 6*d*. per lb.

MEETING OF THE SOCIETY.

Indian Section.

June 29, 4.30 p.m.—Sirdar Daljit Singh, C.S.I., Member of the Council of the Secretary of State for India, "The Sikhs." The Right Hon. Austen Chamberlain, M.P., Secretary of State for India, will preside.

MEETINGS FOR THE ENSUING WEEK.

Monday, June 19...London Society, at the Royal Society of Arts, John-street, Adelphi, W.C., 5 p.m. Mr. A. Crow, "The Port of London."

East India Association, at the Institution of Civil Engineers, Great George-street, S.W., 4 p.m. Mr. H. Kelway-Bamber, "Thirty-five Years' Advance in Indian Railway Development."

Geographical Society, Burlington-gardens, W., 8.30 p.m. Mr. A. E. Kitson, "The Gold Coast: Some Considerations of its Structure, Peoples, and Natural History."

Tuesday, June 20...Statistical Society, 9, Adelphi-terrace, W.C., 5.15 p.m.

Colonial Institute, Hotel Cecil, Strand, W.C., 8.30 p.m. Sir Lionel Phillips, Bt., "South Africa and the Empire Problem."

Wednesday, June 21...Meteorological Society, 70, Victoria-street, S.W., 4.30 p.m. 1. Messrs. J. E. Clark and H. B. Adames, "Report on the Phenological Observations for 1915." 2. Messrs. M. Christy and W. Marriott, "Audibility of the Gun-Firing in Flanders over the South-East of England, September 1914—April 1916." 3. Lieut. E. H. Chapman, "The Relation between Atmospheric Pressure and Rainfall at a Single Station."

African Society, Hotel Cecil, Strand, W.C., 7.30 p.m. Mr. P. A. Talbot, "Ibo Customs and Beliefs of Yesterday."

Microscopical Society, 20, Hanover-square, W., 8 p.m. Miss G. Lister, "A Sketch of the Life History of the Mycetozoa, with special reference to Ceratiomyxa."

London: Printed by William Clowes & Sons, Ltd., Duke Street, Stamford Street, S.E., and published for the Royal Society of Arts by G. Bell & Sons, Ltd., York House, Portugal Street, W.C., in the Parish of St. Clement Danes, in the City of Westminster.—June 16, 1916.

Journal of the Royal Society of Arts.

No. 3,318. VOL. LXIV.

FRIDAY, JUNE 23, 1916.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

FINANCIAL STATEMENT FOR 1915-16.

The following statement is published in this week's *Journal* in accordance with Sec. 40 of the Society's By-laws :—

TREASURERS' STATEMENT OF RECEIPTS AND PAYMENTS FOR THE YEAR ENDING MAY 31st, 1916.

SANDERSON,
WILLIAM H. DAVISON, } *Treasurers.*

H. T. WOOD, *Secretary.*
KNOX, CROPPER & Co., *Auditors.*

Society's House, Adelphi, 21st June, 1916.

NOTICES.

ANNUAL GENERAL MEETING.

The Council hereby give notice that the One Hundred and Sixty-second Annual General Meeting, for the purpose of receiving the Council's report and the Treasurers' Statement of receipts, payments, and expenditure during the past year, and also for the election of officers and new Fellows, will be held, in accordance with the By-Laws, on Wednesday, June 28th, at 4 p.m.

(By order of the Council),
HENRY TRUEMAN WOOD, *Secretary.*

INDIAN SECTION.

Thursday, June 29th, 4.30 p.m.; SIRDAR DALJIT SINGH, C.S.I., Member of the Council of the Secretary of State for India, "The Sikhs." THE RIGHT HON. AUSTEN CHAMBERLAIN, M.P., Secretary of State for India, will preside.

EXAMINATIONS.

The results of the Advanced (Stage III.) Examinations, held from April 10th–19th, were posted to the Centres concerned on the 21st inst. It is hoped to publish the results of the Intermediate Stage early next month, and of the Elementary Stage a few weeks later. The publication of the results is this year considerably delayed owing to the war, as not only is the Society's staff considerably depleted, but the Examiners have also lost the services of many assistants, who have joined H.M. Forces.

THE PLACE OF SCIENCE IN EDUCATION.

By DR. J. A. FLEMING, M.A., F.R.S.,
University Professor of Electrical Engineering in University College, London.

On all sides we see evidence of a widespread feeling that we shall not be able to secure our national position after the sacrifices of the war unless attention is at once given to the more systematic development and application of scientific knowledge, and a radical improvement effected in its position in our educational schemes.

This opinion is showing itself in the establishment of numerous Committees, Boards, and Conferences of various kinds. These discussions may be necessary to clear the ground and awaken interest, but they will be futile if they have no other result than mere assertions of national inefficiency or neglect.

The need of the moment is a careful and searching analysis of the causes of this failure

to cultivate sufficiently scientific knowledge, and of the small popular appreciation of it, and we shall then perhaps be able to agree on the practicable remedies. Above all, we must estimate and define its proper place and function in popular education, so that we may not err in undervaluing or in overstating its importance.

In the last half century there has been an enormous progress in our knowledge of the physical universe and in the degree to which we are able to control its inexhaustible energies, powers, and materials for human purposes. It has been found that this knowledge not only brings great benefits in its train, but also that it is unfortunately applicable also in the most effective service of the powers of evil.

Hence we are compelled to pursue it not only for its intrinsic advantages, but also that we may meet and control misapplications of this knowledge, and prevent ourselves from being brought into subjection to those whose ethical development has not kept pace with their progress in using scientific knowledge.

A careful study of the subject shows us also that a too exclusive attention to the material side of Nature, and to its purely physical phenomena, has its special dangers and disadvantages.

The important questions which therefore arise for consideration are the place and character of the instruction in science which should be given in primary and secondary education; in the next place, the mode and means by which an intelligent public interest in, and appreciation of, scientific knowledge may be stimulated; and, thirdly, the steps which should be taken to encourage and assist scientific investigation.

As regards elementary education, our first duty to the child is to teach him or her something of the laws and phenomena of the physical universe into which it has been born, something concerning its own bodily structure and powers, so that it may learn to live well and in right relations to its fellows, and also to other forms of life around it.

The young child is naturally vastly curious and interested in its new surroundings and asks to be instructed, but the majority of children are deliberately educated into stupidity by the greater stupidity of adults around them, who cannot answer the child's questions and will not take the trouble to learn how to do it.

The child is by nature a philosopher eager to know the reasons for things; an experimentalist ready for all risks; and an artist who lives in a world in which imagination clothes ugly facts in picturesque raiment.

Right methods of education take advantage of all this to enable the child to educate himself. The success of the Montessori system of training young children is based on the fact that the child is naturally an experimental philosopher. The instant and permanent triumph of the Baden Powell Boy Scout movement was due to the right utilisation of the boy's imagination and love of adventure. The cardinal and disastrous error made in elementary education, as administered by the State at present, is that it begins with language, words and books, instead of with things and natural phenomena. The first thing we do is to teach the child to read and "learn by heart." It learns to repeat strings of words, and at a later stage commits to memory an ill-assorted collection of information on grammar, history, geography and literature, all of which has small bearing at all on its immediate requirements. There is very little training of the hand and eye, and little or no pains taken to bring the town-born child in contact with Nature and Nature-study.

Meanwhile the picture palace has become the chief source of recreation to city-bred children, and its inanities, representations of disasters, to say nothing of the ineffable foolishnesses of much of its displays, have occupied the field to the great damage of the child's eyesight and the still greater damage to its mind.

Consider for one moment the great service the "moving picture" could render to education. It can in the first place represent to the eye moving animal life, the habits of animals and their ways of life. By taking photographs of growing plants at intervals of a few hours and then uniting them sequently on the film, it can represent the growth and development of a chestnut blossom or a blade of wheat in a few seconds, which in Nature takes days or months. It can thus bring to the eye the facts of botany and the perpetually repeated miracle of the spring or summer, and this appeal to the eye can be interspersed with short instructional remarks or explanations. It can give ocular demonstrations of facts in physics, mechanics or astronomy, which no stationary pictures can do. The progress of a solar eclipse, with all its impressive phenomena, can be shown to a class, and the action of a steam-hammer or petrol-engine explained in detail by motion pictures, which are under complete control. Instead of this we allow the whole of this

invaluable means of scientific education to be enlisted in the service of frivolity and the demoralisation of children by cheap exhibitions, which more than one police-court magistrate has described as an unmitigated evil.

If free access to these places is to be permitted to young children under fourteen years of age, the least that can be done is to establish a strict censorship over the character of the pictures shown, and to insist that a certain amount of educational work and Nature instruction shall be given by carefully selected films as well.

Then as regards school instruction in scientific knowledge, this should begin with elementary facts of astronomy and natural phenomena, such as the properties of air, water, and common substances, the effects of heat and cold, the simplest facts, light and sound, and the growth and structure of familiar plants and trees. All this should be taught by appeal to the eye and by motion pictures or models, the principal aim being to train the child's powers of observation, description and logical inference.

It will require a greater national expenditure than at present, but the nation has to learn the truth that there is no economy so false as economy in national primary education.

Coincidently with this Nature-study the child should be taught reading, writing, elementary arithmetic, and drawing; but beyond this the training of eye and hand, the practical arts of life, co-operative action in drill and dancing with the aid of music should take precedence of books and words.

The main thing is that the child shall be taught to *do* things, or effect practical achievements, and not simply to store memory with words, or the analysis of them. The right use of language, and its employment to describe experience, should be conveyed by example and imitation from the living teacher and not the dead book.

Turning then to a more advanced stage of education, we find at present a strong consensus of opinion that radical changes are necessary in the curricula of public schools. The large amount of time spent at present over the grammar and literature of Latin and Greek brings no return at all proportional to the effort and expense spent over it. The mental discipline can be obtained more usefully in other ways.

There are four great groups of educational subjects which should be put on an exactly equal footing, and claim each a quarter of the whole working time of the schoolboy. These are: (1) Language and literature, considered chiefly as a means of expressing thought and experience; (2) Science or a knowledge of the facts and laws of the physical universe; (3) Mathematics and graphics, or the study of number and form, including arithmetic, geometry and algebra, and drawing in various forms geometrical and freehand; (4) Civics, or the preparation for citizenship, which includes history, both of the world and of the native country, elementary political economy, religious or ethical instruction, elocution and military drill or exercises.

Assuming a total of working hours of about forty per week, this would give ten hours a week, or, say, 360 a year for the study of scientific subjects. In the next place we have to consider what these subjects should be. When science teaching was first introduced into schools, chemistry seems generally to have been selected, and under its schoolboy designation of "stinks" has been the principal subject always taught.

Chemistry is, however, by no means the best subject for initial instruction in science. It provides, of course, attractive experiments and requires no very expensive appliances, but it lends itself almost too readily as a subject for cram knowledge, whilst its necessary theoretical basis is difficult to expound. The chief object of school instruction in science should not be the mere acquirement of cut-and-dried information as to facts, but the cultivation of the student's powers of observation and experiment and drawing correct logical deductions therefrom. Hence it is far better to begin with mechanics, elementary physics and botany. A skilful teacher, provided with the proper apparatus such as that described in the late Sir Robert Ball's "Experimental Mechanics," can make mechanics an excellent introductory subject for school instruction. A properly equipped physical laboratory should form part of every school, and the work therein should consist in taking the boys, arranged in pairs or couples, through a carefully selected series of practical exercises in magnetism, heat, light, electricity and acoustics.

It is a great mistake to lecture too much to boys as if they were adults. This type of oral teaching is easy to give, but most ineffective in results. The students should perform the experiments and not the teacher, and the work should consist in making careful observations or measurements, which are then as carefully described by the boy in his own language in

writing. The proper description of experiments or observations in good, simple, lucid English should be strongly insisted upon, and marks given for this as well as for accuracy in results. The effort should be to make the boy rediscover for himself, under guidance, the elementary facts and laws of the subject under study.

It is advisable to postpone the study of chemistry until after the elementary physics and mechanics, and until a little training in experimental work has been acquired. In some schools a great show is made with carpenters' or engineering workshops. This impresses parents and attracts boys with a mechanical turn of mind. But there is little or no real scientific training in it. The making of a model steam-engine is an amusement for leisure hours or wet half-holidays, but is perfectly useless as a means of scientific education for boys. The school work should be confined to imparting a really practical and thorough knowledge of elementary principles of science. Of course, in all this the quality and kind of teaching given is the important factor. The mode in which a subject is taught is even of more importance than the subject itself. Chemistry can be so imperfectly taught as to be of little use as a mind-training. It is possible to give a very scientific lesson on a Greek verb, and also to give a lesson on an electrical machine which is not scientific teaching at all.

Hence here as elsewhere the man counts for more than the machine or apparatus. Nevertheless, the good teacher is wasted unless he has the necessary appliances. For this reason every public school should be adequately provided with museums containing geological, mineralogical, botanical and zoological specimens, and these should be continually increased and well arranged. The physical and chemical laboratory accommodation should be ample and well equipped. Every school should also have a small astronomical observatory with an equatorial telescope, clock, and transit instrument, and an outfit of surveying instruments, such as a theodolite, chain, level, and surveying staffs. Trigonometry as a mathematical subject should be taught in a practical manner by the aid of these last-named appliances, and not merely made to consist in the memorizing of formulæ.

Instruction in elementary astronomy, comprising a practical knowledge of the constellations and movements of the sun and moon, should form part of all school education. It is lamentable to notice how few adults even in the educated classes have the smallest knowledge of these things, or the faintest conception of the reasons for the tidal movements of the sea, the changes in the seasonal appearances of the starry heavens, the phases of the moon, or the phenomena of eclipses.

A classical scholar, on being told that on a certain night an eclipse of the moon would be visible, observed to the writer of this article that it was "fortunate" that the moon would be full on that night as the eclipse would be better seen. It is a most elementary fact of astronomy that it cannot occur at any other time except at full moon.

One of the essential things is to give proper dignity and importance to scientific knowledge and teaching. It has been far too long considered as the Cinderella of school subjects. The division of schools into classical and modern sides, accompanied as it has been by an air of unquestionable superiority on the part of the classical department, should cease.

One great reason, of course, has been the vastly greater inducements to classical studies by university scholarships and exhibitions, and the predominance awarded to them by the marks allotted in public and Civil Service examinations.

An influential meeting was, however, held lately, under the chairmanship of Lord Rayleigh, at which important resolutions were passed urging: (1) that the study of nature sciences should form an integral part of the educational course at all the great schools of the country and of the entrance examinations of the universities old and new; (2) that the Government should encourage this study by assigning capital importance to scientific knowledge in the competitive examinations for the Home and Indian Civil Service, and for admission to Sandhurst.

If these resolutions are acted upon by the authorities, pressure would at once be put upon the public schools to reform and augment their scientific teaching. We should not then in the future run the risk of our legislators in Parliament exhibiting, as they have done recently, the most astonishing ignorance of simple facts of chemistry.

Another and equally important reform would be the revision of the relative value of the scholarships and exhibitions offered at the universities for classical, mathematical, and scientific knowledge. At present there is evidence that the lion's share of these encourage-

ments falls to classics. Hence the public schools devote most attention to the subject which "pays" best. The right arrangement would be to put the subjects on an equal footing. If these recommendations were followed, the study of science would shortly cease to be regarded as of inferior importance, and would take its rightful and dignified position. It would no longer be regarded as a curious and unimportant hobby by those who know nothing about it, and an ignorance of the broad general facts of chemistry, physics, biology, or astronomy would be regarded as a mark of ill-education. What is required is, not merely to produce scientific specialists, but even more to create appreciation of, and sympathy with, scientific work and aims in the mind of the general public.

Assuming, however, that a reform in the public school methods will lay the foundations for this increased sympathy, it is then essential that scientific men should continually endeavour to place the results and methods of their work in such form as to encourage and justify public interest. The chief method by which this can be done is by public lecturing and also by written communications to the public press, chiefly the great daily newspapers and the more widely circulated general magazines. The public lecturing is by far the most important, because this can be illustrated by actual experiments, diagrams, lantern-slides, projections, or specimens.

The art of public lecturing does not, however, come by nature, and an intimate special knowledge of a subject may yet be coupled with a great inability to expound it so as to fasten and stimulate general attention. Some of the great scientific workers of the past age and also of the present have, however, made this art of public exposition of difficult scientific matters a great study. Faraday, Tyndall, and Huxley were past masters in it. It demands not only trained elocution, but the power of marshalling ideas and uttering them in apt and forceful phrases with attention to time limits and public capacity to assimilate new ideas. Lecture experiments and demonstration need also special abilities and ingenuity.

The Friday evening discourses at the Royal Institution, or the afternoon lectures in the same place, may be taken to represent generally the highest achievements in this form of public teaching, as also do the similar lectures at the Royal Society of Arts. Most large cities have institutions at which similar public scientific discourses are given at frequent intervals. The Gilchrist Educational Trust has also done a great and useful work in the last thirty years in enabling large popular audiences all over the country to receive such instruction in scientific matters from the most eminent exponents and lecturers. The discussions and popular lectures at the British Association meetings are also of service in the same sense. The work has of course been interrupted to a large extent by the war, but when peace returns it must be revivified and extended. This primary and popular scientific teaching is, however, merely a preparation of the ground for more serious work.

We reach the core of the matter when we come to consider the place of science in university and technical teaching. Here the principal object in view is not merely the dissemination of information, but the instruction and training of men who can create new knowledge. Of late years the ancient as well as the modern universities have added greatly to their equipment in laboratories and museums, with all the appliances of scientific study. Nevertheless, too much of it has been devoted to the purpose of making graduates rather than investigators.

The chief function of a university is to increase our knowledge, and not merely to put the hall-mark of a degree on young men who have acquired a certain store of learning concerning the achievements of others. The obsession of the written examination paper and degree still holds us in its grip. Whilst it is essential to insist on a certain breadth of acquaintance with known things to prevent the creation of narrow specialists, the university does not accomplish its final purpose if it fails to animate its students with an intense zeal and some ability to push forward the confines of knowledge. Hence the main duty of a university is research. The duty of advancing pure scientific research is the particular responsibility of the science teachers and advanced students and graduates in it. No one is fit to fill the post of a university teacher who is not actively engaged in research in his own special department of knowledge. His success ought largely to be gauged by the degree to which he gathers round him students who can take part in and assist in new investigations.

The value of this work has to be measured by its quality as well as its quantity. There is at the present time an enormous output of published researches, but a great deal of this is work which is concerned with minor questions, quantitative measurements, and with the gleaning

of corners of the scientific field. The really great investigations are those which open for the first time some novel and rich mine of scientific truth. Such, for instance, were the epoch-making investigations of Sir J. J. Thomson on masses smaller than atoms; those of Hertz on the creation of electromagnetic waves; of M. and Madame Curie and Sir E. Rutherford on radioactivity; of Sir William Huggins on stellar spectroscopy, and of Röntgen on the X-rays.

A most important matter is the consideration of the conditions under which this stimulative originality can be fostered and increased. One thing is certain, that too much devotion to the study of what others have done is apt to diminish original powers. The great inventors and discoverers instinctively turn to new fields of research. When a man has this notable originative power, everything should be done to facilitate his possession of every material means necessary. It is the most wanton waste of rare gifts if an experimental genius is allowed to spend much of his life in a heartbreaking struggle to acquire merely the implements of research. The British nation has yet to learn the immense resources which in Germany, and also in the United States, are being put at the disposal of those who have proved powers of scientific investigation.

The German Emperor founded and obtained large funds by subscription not many years since for a special institution called the Kaiser Wilhelm Institute, devoted entirely to the highest class of scientific research, which is quite apart from and independent of all university work or control, or even of the Reichsanstalt, which is the German equivalent of our National Physical Laboratory. In the United States there are large endowments available for similar work, and anything which we possess is small by comparison. The better equipment of all our university laboratories is therefore an urgent matter.

It is not a day too soon, therefore, that the Government has created a Committee of the Privy Council to deal with scientific and industrial research, and an Organizing Council to direct the disposal of the funds which will be administered.

There are indications that this will be done by grants to learned scientific societies for special researches, by grants to universities and colleges, and to individuals and committees for definite research work. By the assistance of research scholarships and fellowships it will be possible to give the necessary financial assistance to trained men who have exhibited the necessary qualities of mind. We have to search diligently for this capacity and cultivate it, not simply to wait for it to turn up, and we may then hope to increase greatly the systematic pursuit of advances in scientific knowledge.

The direction in which all the above effort must tend is, however, in the application of this knowledge in commerce and the arts. If we are not to suffer hopeless defeat in the coming commercial contest of brains we have continually to bring this scientific knowledge to bear upon all the problems of industry.

One great difficulty which presents itself is the small faith which so many British manufacturers have at present in the utility of scientific research. This shows itself in the unwillingness to make the necessary investment of money in it.

The technical problems are often insoluble unless very considerable expenditure is made on the preliminary research. To make a large effective improvement in a dynamo, an optical glass, or a dye, an expenditure of anything from £20,000 to £100,000 may be necessary. It is, therefore, necessary to have a strong confidence in the ability of research to justify the expenditure. This can only be attained if the manufacturer himself has had sufficient scientific training and education to know the history of industrial developments and of the achievements of research power in aiding them. It all, therefore, comes back to the question of education. Give your manufacturer sufficient knowledge of what science has done and you will induce in him a stronger faith in what it can still do.

Again, if our educational methods are directed sufficiently to the production of men who can do new things, and not merely know about old ones, we shall provide the manufacturer with the men who can give him the efficient assistance. We have, therefore, to make science an integral part of our national education. We have to create conviction in the public mind that only in this manner can we forge the weapon which shall give us the ability to retain our place as a world power. We have, therefore, to reconstruct the basis on which our educational systems rest and make a study of the laws, phenomena and processes of Nature of primary importance in them.

It has to be clearly realised that, great as are the victories of science in the past, there are revolutionising discoveries and inventions yet

to be made which will affect human life in every way. We cannot afford to be and remain content to have no part in them, but they will only come as the reward for strenuous labour on our part. We may not be able to effect all the reforms in education which are an essential precursor, but we can do something, and we can do it at once.

DECLINE OF PINE-APPLE INDUSTRY IN THE AZORES.

St. Michael pine-apples—the raising of which has for years been the principal industry of the Azores—promise to follow in the wake of the Azorean orange. The orange was destroyed by a parasite; the pine-apple industry promises to be destroyed by overproduction and the reduced purchasing capacity of Hamburg and London markets since the war. In fact, the war has forced ruinous prices upon the local growers, many of whom are turning to different lines—some to tomato cultivation and some to the orange—while others are emigrating to the United States. A once flourishing industry, yielding nearly £200,000 a year to the people of St. Michael, has thus come to a standstill. The 1913 exports were valued at £109,000, and in 1914 they had declined to £64,000.

According to a report by the United States Consul at St. Michael, the pine-apple industry of the Azores dates back to 1860, when it was discovered that the soil and climate of St. Michael lent themselves to the production of a superior fruit. Because of their size and luxuriant foliage St. Michael pine-apples sold as high as £1 each in the early days of the industry. Fortunes were made in a very few years. The expectation of fabulous returns prompted hundreds to plant the fruit. All became wealthy.

Now thousands are engaged in pine-apple culture. The result has been, as stated, overproduction. When the production reached 50,000 cases annually, or 600,000 pine-apples, fancy pine-apple stock still brought 6*s*. to 8*s*. each in the London market. To-day, when the production is more than 2,300,000, the producers are obtaining only 6*d*. to 1*s*. 9*d*. each for their fruit.

When the war destroyed the European market, the local growers endeavoured to dispose of their fruit in New York, Lisbon, and Gibraltar, but nowhere with marked success. The Azorean pine-apple being a high-priced fruit, it was soon discovered in New York that it could not compete with the cheaper Hawaiian product. At the time the report was written only Lisbon was buying in considerable quantities, and was proving to be an unprofitable market. Growers in St. Michael, it is said, were actually selling their crops at 25 to 50 per cent. below the cost of production.

In former years Hamburg took about 65 per cent. of the St. Michael pine-apple crop for distribution in Germany, Austria, and Russia; London took 20 per cent., mostly the finest fruit; and Italy and France took the remainder. The decline in the industry is well illustrated by the following figures of exports during the five years ending 1914:—

Year.	Cases.	Value.
1910	128,000	£140,400
1911	134,000	£116,600
1912	145,000	£104,400
1913	170,000	£108,800
1914	175,000	£64,400

EXPERIMENTS IN OPTICAL PYROMETRY.

In a recent publication of the United States Bureau of Standards, a new method for determining the "effective wave length" of the colour and absorption screens used in optical pyrometry is described as applied to several specific screens and glasses. The shift of effective wave length with change in temperature of the source, and the effect this shift may have upon the accuracy of temperature measurements, are discussed. It is shown, both theoretically and experimentally, that for precise work at high temperatures, with pyrometers using colour screens, a thorough knowledge of the change of the effective wave length with temperature is required.

This publication, Scientific Paper No. 260, "The Centre of Gravity and effective Wave Length of Transmission of Pyrometer Colour Screens, and the extrapolation of the high-temperature Scale," may be obtained by persons interested from the Bureau of Standards, Washington, D.C.

RE-DEVELOPMENT OF SERICULTURE IN SPAIN.

Sustained efforts by civic bodies and individuals in the Valencia district, aided by similar influences in other parts of Spain, to create an interest in and develop the long decadent silk industry, have at last produced definite results, the Spanish Government having drawn up and presented to the Cortes a bill with this object in view. The proposed legislation includes a grant of 840,000 pesetas (about £33,600) a year, 300,000 (£12,000) of which are for the support of experiment stations, 100,000 (£4,000) for free distribution of mulberry trees, 60,000 (£2,400) for free distribution of silk-worm seed, and the remainder for premiums to sericulturists and spinners of raw silk.

In reporting on this subject to his Government, the U.S. Consul at Valencia points out that the proposed law is of particular interest to that district, as sericulture is now and has always been chiefly centred in three of its provinces, viz., Murcia, Valencia and Alicante (in order of importance).

The preamble of the proposed law states that prior to the epidemic in 1848, when the decline began, the Spanish production of cocoons was 12,400,000 kilogrammes (kilogramme = 2·2 lb.),

valued at 70,000,000 pesetas (£2,800,000), whereas at the present time, after a partial revival, it is only 1,250,000 kilogrammes, valued at 4,500,000 pesetas (£180,000).

Corresponding to the preponderating interest of the Valencia district, the largest and best equipped silk experiment station in Spain is in Murcia Province. It was given an official status by Royal Order of May 3rd, 1892, having existed for some time previous through the initiative of public-spirited individuals. The activities of this station include the theoretical and practical encouragement of the silk industry in all its phases, with gratuitous distribution of young mulberry trees and silkworm seed, and advice for obtaining the best results. Government silk stations are also maintained, chiefly for the cultivation and distribution of mulberry trees, in Puerta de Santa Maria (Cadiz) and Aranjuez. Under the proposed law the activities of the stations will be broadened, but the Murcia station will still be the chief Government agency for the rehabilitation of sericulture in Spain.

ENGINEERING NOTES.

The Kiel Ship Canal.—Owing to the paramount interest of the political and commercial world in this undertaking, which shortens the route from London to Petrograd by 238 miles, and from Hamburg to Petrograd by 424 miles, it is not surprising that its engineering features are, to a great extent, lost sight of. During the war, however, German warships are alone admitted, and commerce derives no benefit from the world's greatest ship canal; for, with the sole exception of the Suez Canal, which is only greater as regards length, the Kaiser's canal is pre-eminent in dimensions. The Kiel waterway was opened in 1887, the cost being £8,000,000, but was enlarged in 1895 at an additional cost of about £4,000,000, to accommodate the super-Dreadnoughts which the warlike ideas of the Kaiser's advisers rendered necessary. Both ends of the canal are strongly fortified. As to dimensions, the following figures transferred approximately from the *London Magazine* will be clear in this respect. The canal is about 63 miles in length as against 41 miles, which is the length at Panama; the width at bottom is 144 ft., and at top 344 ft., affording passing places at moderate speed. The locks, two at each entrance, which may be pumped dry to serve as dry docks, are 1,150 ft. long, 147 ft. wide, and 46 ft. deep, comparing with, respectively, 1,000 ft., 110 ft., and 39 ft. at Panama. Special attention was paid to the curves, the water-levels at these places being considerably widened. Moreover, at suitable intervals new sidings were built, some of them stretching a distance of 4,000 ft. In these sidings alone, there being eleven all told, a fleet could lie at anchor without interfering with the passage of other vessels. The canal is crossed by two road bridges, five railway bridges, and sixteen wire-rope ferries. The railway bridges have each a clear elevation of 150 ft.

Tank Tests with Ship Models.—In a paper read by Mr. G. S. Baker, the Superintendent of the National Physical Laboratory Tank, at Teddington, Middlesex, before the Liverpool Engineering Society, he remarked that the cost of overcoming ship resistance forms one of the largest items on the balance-sheet of any vessel in the Mercantile Marine. In arriving at an estimate of the power that will be required, the designer makes use of existing data derived either from existing ships, or from model experiments, or, better still, from a combination of both. The data must be to hand in a standard tabular or diagrammatic form, and with their help it is often possible to make a reasonable estimate, sufficiently accurate for preliminary purposes, even for quite large departures in dimensions and type from any existing ship. An unnecessarily high estimate of power means an unnecessarily high outlay on the engines and their upkeep, and a reduced cargo capacity for the life of the vessel. The routine testing of models is a proper thing from the designer's point of view, as it prevents any error in shape and is an advantage to the owner, as he can rest assured that his coal bill will be a minimum if the ship is properly handled. From progressive trials, if they are carefully conducted and properly analysed, the efficiency of the ship and propeller can be approximately determined, but their complete analysis is impossible without tank experiments. The designing office may use a tank to its own advantage in many ways. For instance, a good collection of data from model screw experiments is now in existence, which can be used for rapidly determining the proportions of propellers for any vessel. A detailed description of the National Physical Laboratory was published in the *Journal* of the Royal Society of Arts on December 26th, 1913.

Electrical Power in Ontario. — The Canadian correspondent to the *Electrical Review* writes: One of the most important occurrences in the electrical supply situation in the Province of Ontario is the recent arrangement made by the Provincial Government to purchase, at a cost of over £1,600,000, all the interest of the Trent Valley power companies whose operations cover the territory lying east of Toronto, along the shore of Lake Ontario. This means that the water rights and properties of these companies are purchased for the people, and that they will be put directly under the administration of the Hydro-Electrical Power Commission of Ontario, and it also means that with the exception of the large companies on the Canadian side, at Niagara Falls, practically all the large power sites and projects are now held by the people and controlled by the Commission. As was recently pointed out in these notes, the territory at the present served by this Commission

is almost as large as England, while its powers, extending over the whole province as they do, cover an area three and half times as large as the British Isles. The Provincial Government has decided to approve of the power development scheme proposed by the Commission for the Niagara River, whereby an ultimate capacity of 600,000 h.p. will be made available. For this scheme turbine and generators in units of 50,000 kws. capacity are being considered.

The Conversion to Electricity of a Swiss Railway: Direct Current, Three Phase or Single Phase.—The General Management and the Standing Committee of the Swiss Federal Railways have just submitted a report to the Council of Administration in regard to the projected conversion of the Erstfeld Bellinzona section of the St. Gothard Railway. It is first pointed out that the three-phase system would be unsuitable for the purpose in view, whilst the advocates of the direct current method base their contentions on experience with lighter trains, and pressures far below 3,000 volts. The single-phase system, which is already employed on the Lotschberg Railway, can now be recommended for adoption without reserve. No other electric railway exists which can be placed on an equality in regard to the varied nature of service, the number of locomotives, length of the track, and extent of services rendered, with that of the New York, New Haven, and Hartford Railway. At the same time this railway is the first which, owing to the system used, has proved itself to be extensible at will, and capable of being accommodated to all kinds of services. In the case of the Lotschberg Railway, the interruptions in working were attributed chiefly to the difficult circumstances under which the electrical equipment had to be provided. The report also discusses the problem of uniformity in the form of current and periodicity, which it is sought to attain in the distribution of energy throughout Switzerland. The Amsteg and Ritom power-stations, which are proposed for the working of the Erstfeld Bellinzona section, will be able to furnish energy not only for this section, but also for the whole line from Lucerne to Chiazzo, the conversion of which will not be long deferred.

ARTS AND CRAFTS.

Home Arts and Industries.—The annual exhibition of the Home Arts and Industries Association has been held for so many years at the Albert Hall that it seemed strange last month to find it confined within the comparatively narrow limits of a private house. The society is one which has for so long quietly, persistently, and unostentatiously urged the claims of craftwork and craftworkers, and which has had so large a share in the revival of home arts and of peasant industries, that it would have been a real calamity had the war seriously interfered with its activities. Apparently the reduced size of this year's show is due not so much to classes having stopped, as to some inevitable falling-off in numbers, and still more to the various difficulties in the way of holding a large exhibition of this type in war time. As was only natural under the changed circumstances, the great majority of the exhibits consisted of needlework, lace and textiles of various kinds; but some toys were shown and a fair amount of leatherwork, the best of which came from Leighton Buzzard and was largely the work of cripples. There is not, of course, a very great demand for expensive leatherwork, and the doing of it takes some skill; still the work is not heavy and, with the exception of bookbinders' tooling, does not involve a great outlay in tools, so that it really seems as though this were one of the crafts which disabled soldiers and sailors could take up, if not exactly as a means of livelihood, at least as something more than a pastime. In some of the London shops at the present time there is a good deal of handmade leatherwork on sale which seems to be finding a market. Be that as it may, Lady Egerton claimed that her exhibit of what, for want of a better name, may be called Greek embroideries, illustrated a type of work which could be readily learnt and successfully carried out by crippled or disabled men. They would want capable direction no doubt to begin with, but that they might eventually make good needlemen there is no reason to doubt. The great bulk of the best embroidery, not only in the Far East, but so near home as Brittany, is done by men, and those who have first-hand acquaintance with the working of the Brabazon scheme generally find that in workhouses at least the best work of this kind is done not as they would have expected by the women, but by the men. Amongst the needlework at the Home Arts, the embroidery on linen from Fisherton-de-la-Mere stood out as showing distinction in workmanship and conception, and the Celtic designs of the Dun Emer Guild carried out in linen thread coloured by vegetable dyes had an interest all their own, and added considerably to the attractiveness of munition workers' overalls and suchlike practical garments without making them look in the least unfit for their purpose. The gold and silver lace from Kingston Bagpuize was good, and it was satisfactory to note that the workers are now making shaped collars as well as straight lace by the yard. Some fine examples of Buckingham and other lace were shown, and weaving was represented by the work from the Barclay Workshops for the Blind and the London School of Weaving. Altogether the exhibition, small as it was, proved the vitality of the movement which it represented.

Hangings, Covers, and Wall Decoration.—Decoration on a large scale, except in a few exceptional cases, is practically at a standstill; but there is a fair amount of less important work which has to be done, and for which the shops are catering. Many

people, for instance, must have new curtains and covers, or find a room or two badly in need of repapering, and the wise householder naturally will not allow his places to fall into disrepair unnecessarily. What strikes one most is the prevalence of cotton furnishing fabrics. A few handsome silks are to be seen, and there is some tapestry about, but the textiles shown in the shops at present are in the main cotton. That is by no means equivalent to saying that they are cheap. It appears, indeed, as though there is a very large demand for expensive cotton fabrics, which is perhaps accounted for by the fact that people who normally would buy silk are content with cotton, but want something distinguished. Amongst these cotton goods, the desire to give the effect of some texture other than their own is almost as apparent as in wallpapers. By various means it is sought to make the ground, or sometimes the whole pattern, suggest a richer material than mere cotton. Shadow fabrics, again, are common. With regard to design, there is very little that is fresh, and Victorian and "Early English" patterns are very much in evidence, though there seems to be some return to all-over patterns of a more formal type. Indeed, the one thing needful at the moment seems to be for patterns to be full, and to cover as large a proportion of the ground as possible. Spots, sprigs, and very open scroll patterns and lattices appear to be quite things of the past. The tone is, on the whole, rather drab and sombre, although many of the designs are printed in a remarkable number of hues. This may be due to the difficulty of obtaining colours and a desire to make up for the poorness of the individual tints by introducing as many as possible and so confusing the eye. Certainly the colour of plain stuffs is not now as a rule satisfactory. On the other hand, there are a few examples of very bright, not to say staring colour, but they occur mainly in the case of fabrics in which the drawing and design is rather uncouth and the printing not very refined. Many of the more expensive wallpapers, especially those of a more or less Chinese character, are still being produced on black grounds, and one London firm is showing hangings, etc., of black satin, ornamented with bright pink roses in high relief made of the same material; but ordinary taste is demanding something at once lighter and more simple. Some of the wallpapers now to be seen come from America. This is to be regretted from two points of view. There was a time when paperstainers reckoned to export to the States, not to have Americans sending their goods over here, and business at present is not easy for British firms; further, it seems futile to be obtaining from the other side of the Atlantic just now commodities which we can produce as well, if not better, at home, while there is so much which has to be imported which is of primary importance, and which for the moment we cannot make ourselves.

CORRESPONDENCE.

EARLY CHINESE ZINC.

From 1893 to 1900 specimens of Chinese zinc were examined and found to be of very uniform appearance and quality. From inquiry the samples were said to have been taken from slabs, sometimes spoken of as "Ming" zinc. One such slab submitted to me weighed one picul (133⅓ lb.), and bore a date in deep well-moulded Chinese characters corresponding to 1585 A.D. The Ming Dynasty extended from 1368 to 1644 A.D. It was stated that although they were found to contain no silver the slabs had at one time been used as coins. There was much rumour as to the place of storage of these ingots. It was gathered that a large number were hidden in a hill near Lien Chow in the northern part of the Kwantung province. Also that the natives in the vicinity were much opposed to any sale or removal, on account of *Fung Shui*—the superstition which regards with extreme disfavour any interference with the soil. However, it is probable that difficulties were overcome, as after about 1900 no more was heard of this particular brand of Chinese zinc. All samples contained over 98 per cent. of metal, with very small quantities of iron and lead. Modern Chinese zinc is of about the same standard of purity.

The ore is said to be abundant in Hunan, Hupeh, Kweichow, and Yunnan, and in this last district to be extensively smelted.

FRANK BROWNE, F.I.C.,
Formerly Government Analyst, Hong-Kong.

MANUFACTURE OF RADIUM IN THE UNITED STATES.

I see in the *Journal* of March 24th a reference to the work of the Bureau of Mines in recovering radium from carnotite.

Dr. Kelly, of John Hopkins University, and I have provided the money for this small factory and for the cost of extraction, exclusive of the pay of the Government officials in the laboratory. Dr. Moore, who has charge of the laboratory, has quite fulfilled all his anticipations, both as to the cost of the radium and the quantity recovered.

The contract with the Government will expire on the first of next January, and not until after that date can the actual commercial cost of the radium be determined. Nevertheless, the cost is going to be considerably less than the market prices charged for radium.

Four grams of radium element have already been delivered to Dr. Kelly and myself—two grams to each of us—and I have very little doubt that as much more, if not three grams more to each, will be forthcoming.

My radium is now being used most effectually in the General Memorial Hospital here in New York. The hospital staff is satisfied that the full therapeutic effects of radium can only be obtained by using large quantities.

There will be no secrecy as to the chemical and

mechanical methods pursued at our Denver works, and therefore, when the experiments are closed, I will be very glad to give you complete detailed information. JAMES DOUGLAS.

NOTES ON BOOKS.

ON THE RELATION OF IMPORTS TO EXPORTS. Second Edition (enlarged). By J. Taylor Peddie. London: Longmans, Green & Co. 5s. net.

The appearance of a second edition of Mr. Peddie's volume so soon after the publication of the first, is only one among many signs that the question of our national economic system is at last beginning to receive the attention that its importance deserves. German methods of warfare have thrown fresh and lurid light on German methods of trade, and driven many former champions of Free Trade to the conclusion that their ancient faith must be modified when we come once more to meet the enemy on the fierce battlefields of peace. It is obvious that the more the whole question is discussed at present the better for the prospects of our future success, and Mr. Peddie's work, which is written in a reasonable and non-party spirit, must be welcomed as a sensible contribution to the subject, though we venture to think it might have been still more effective if he had taken greater pains with the manner of presenting his thesis.

In the principal addition which he has made to the second issue, the author sets himself to show that Adam Smith was not an advocate of Free Trade as it has come to be understood at present, but rather, as he puts it, of freedom of trade. It is a little surprising to find a question so academic being discussed by one who prides himself on being, above all things, a practical economist, and who has before this set himself to "ginger" up the old universities in the hope that they might be induced to make themselves and their teaching less remote from the realities of modern life; but although Mr. Peddie is apt to dispose of those economists who differ from him as mere theorists and scholars, he is not above a desire to secure for his own views the authority of "The Wealth of Nations":

"It is quite true to say that he [Adam Smith] sowed the seed of the present system, but it has been used and perverted by subsequent theorists in the development of their own vicious schemes, and who have manifestly misunderstood the intentions Smith had in view."

This sentence indicates the gist of Mr. Peddie's views on Adam Smith's economic followers, and incidentally illustrates the peculiarity of his literary style, to which attention has already been directed.

ENGLISH MURAL MONUMENTS AND TOMBSTONES. By Herbert Batsford and W. H. Godfrey, F.S.A. London: B. T. Batsford. 12s. 6d. net.

In this volume we are presented with a collection of eighty-four photographs of wall tablets, table tombs, and headstones of the seventeenth and eighteenth centuries, which have been selected by Mr. Herbert Batsford, "as representative examples of the beautiful and traditional types in the English parish church and churchyard, for the use of craftsmen and as a guide in the present revival of public taste." A brief introduction is contributed by Mr. W. H. Godfrey, and there is a short account of English mural monuments and tombstones, but the illustrations are the most important part of the work. The subjects have been chosen with great care and taste; among them are some very well-known specimens, such as the monument to John Stow in the church of St. Andrew Undershaft; but the reader will also find a great many examples—some of them very interesting and artistic—from remote corners of the country with which he is probably not familiar.

The book has been compiled with a very definite object, and it is to be hoped that it will be studied by designers of mural tablets and tombstones, for they will find in it much to stimulate their interest and guide their taste. A careful consideration of the photographs confirms one in one's predilection for severe simplicity and heraldic, or at all events conventional, ornament. Figures, unless they are carved by first-class sculptors, can hardly ever be satisfactory. Even in the monument erected by Sir Christopher Wren to his wife in the crypt of St. Paul's, the cherub who is wiping his eye with his finger is rather comical; and one knows what a dreadful thing an angel may become in the hands of the Kensal Green monumental mason.

We have before this had occasion in these columns to compliment Messrs. Batsford on the manner in which they turn out their books, and it seems hardly necessary to mention that in the case of a volume for which Mr. Herbert Batsford is himself almost entirely responsible, none of their usual care has been spared by the publishers.

GENERAL NOTES.

BACTERIOLOGY IN QUEENSLAND.—Special efforts have of late years been made in Queensland for the application to practical purposes of bacteriological research. A well-equipped experimental station has been established near Brisbane, with the special object of carrying out tests and inquiries on the application of bacteriology to purposes connected with Queensland industries. Chief amongst these is the prevention of disease in sheep and cattle, they also include the improvement of methods of meat-canning, and the development of cheese manufacture. In these and other branches of industry important results have already been obtained by the special researches of the Queensland bacteriologists.

EXPORT OF GRAPES FROM ALMERIA IN 1915.—The export of grapes from Almeria, which forms one of the principal resources of that province, shows a falling-off of 466,323 barrels, or 26·11 per cent., last year, as compared with that of the

previous one, which was considerably less than that of 1913. The total quantity of grapes shipped from the port of Almeria during the last three years was:—

	Barrels.
1913	2,049,320
1914	1,785,320
1915	1,318,997

On the other hand, the quality of the fruit was superior, and obtained higher rates on the English and American markets, where the prices ranged from 8s. to 18s., and from $4 to $6 per barrel respectively.

MEETING OF THE SOCIETY.

INDIAN SECTION.

JUNE 29, 4.30 p.m.—SIRDAR DALJIT SINGH, C.S.I., Member of the Council of the Secretary of State for India, "The Sikhs." The RIGHT HON. AUSTEN CHAMBERLAIN, M.P., Secretary of State for India, will preside.

MEETINGS FOR THE ENSUING WEEK.

TUESDAY, JUNE 27...Colonial Institute, Northumberland-avenue, W.C., 5.15 p.m. Mr. T. B. Browning, "Indian Title in Canada."

WEDNESDAY, JUNE 28...ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 4 p.m. Annual General Meeting.

Geological Society, Burlington House, W., 5.30 p.m. 1. Dr. A. S. Woodward, "On a New Species of *Edestus* from the Lower Carboniferous of Yorkshire." 2. Mr. A. Holmes, "The Tertiary Volcanic Rocks of Mozambique."

THURSDAY, JUNE 29...ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 4.30 p.m. (Indian Section.) Sirdar Daljit Singh, "The Sikhs."

Institution of Municipal and County Engineers, Blackpool, 11 a.m. (Annual General Meeting and Conference.) 1. Presidential Address. Selections from following papers:—2. Mr. J. W. Hipwood, "Some Experiences of a Municipal Engineer on Active War Service." 3. Mr. C. J. Jenkin, "A Municipal Engineer in Serbia." 4. Mr. J. S. Sawdon, "Municipal Work at St. Anne's-on-the-Sea," with special reference to the Ashton Gardens, and Open Air Swimming Baths. 5. Mr. T. Arnall, "The Destruction of Roads." 6. Mr. W. H. Scholfield, "Improvement of Highways to meet Modern Conditions of Traffic." 7. Mr. C. H. Cooper, "Road Signs." 8. Mr. A. E. Gattie, "Transport Reform." 9. Mr. H. A. Brown, "Public Abattoirs." 10. Mr. F. R. Phipps, "The Diesel Engine in Municipal Work." 11. Professor Abercrombie, "Civic Design." 12. Mr. J. H. Drew, "Surveyors: their Tenure of Office and Defence." 13. Mr. R. Brown, "Diagrammatic Statistics for Municipal Engineers."

FRIDAY, JUNE 30...Institution of Municipal and County Engineers, Blackpool, 11 a.m. Conference continued.

Physical Society, Imperial College of Science, South Kensington, S.W., 5 p.m.

London: Printed by WILLIAM CLOWES & SONS, LTD., Duke Street, Stamford Street, S.E., and published for the Royal Society of Arts by G. BELL & SONS, LTD., York House, Portugal Street, W.C., in the Parish of St. Clement Danes, in the City of Westminster.—June 23, 1916.

Journal of the Royal Society of Arts.

No. 3,319. VOL. LXIV.

FRIDAY, JUNE 30, 1916.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

PROCEEDINGS OF THE SOCIETY.

ANNUAL GENERAL MEETING.

The one-hundred-and-sixty-second Annual General Meeting for receiving the Report of the Council, and the Treasurers' Statement of Receipts and Payments during the past year, and also for the Election of Officers and New Fellows, was held in accordance with the By-laws on Wednesday last, June 28th, at 4 p.m., DUGALD CLERK, D.Sc., F.R.S., Chairman of the Council, in the chair.

The SECRETARY read the notice convening the meeting, and the Minutes of the last Annual Meeting.

The following candidates were proposed, balloted for, and duly elected Fellows of the Society:—

Bandaranaike, Sir Solomon Dias, C.M.G., A.D.C., Horagolla, Veyangoda, Ceylon.

Bates, Mrs. Adah Lilian, 16, Summerland Mansions, Muswell-hill, N.

Bates, Thomas Bradford, 16, Summerland Mansions, Muswell-hill, N.

Bates, Thomas House, 21, Summerland Mansions, Muswell-hill, N.

Bilimoria, A. J., Navsari Buildings, Fort, Bombay, India.

Cropper, L. Cuthbert, F.C.A., Spencer House, South Place, E.C.

Davies, Henry James, Wingfield-park, Lucknow, United Provinces, India.

Gaby, Frederick Arthur, Hydro-Electric Power Commission of Ontario, Toronto, Canada.

Ghose, S. C., 221, Lower Circular-road, Calcutta, India.

Gordon, William John, 83, Thurleigh-road, Balham, S.W.

Hendley, Colonel Thomas Holbein, C.I.E., L.R.C.P., M.R.C.S., 4, Loudoun-road, St. John's Wood, N.W.

Kaul, Indra Krishna, B.Eng., Assoc.M.Inst.C.E., A.M.I.E.E., State Electrical and Waterworks Engineer, Bahawalpur, Punjab, India.

MacFarlane, George Edward, F.I.A.A., A.C.I.S., 121, New Chester-road, New Ferry, Cheshire.

Mirams, Arthur Edward, F.S.I., M.R.San.I., Consulting Surveyor to Government of Bombay, Poona, India.

Moro, Arthur Reginald, 87, Gloucester-terrace, Hyde-park, W.

Phillips, Gwilym, 22, Leslie-terrace, Porth, South Wales.

Piggott, Sir Francis Taylor, M.A., LL.M., Little Woolpits, Ewhurst, Guildford, Surrey.

Richards, James Garfield, Sydney-on-Vaal, District-Barkly West, South Africa.

Tyrie, Colonel David A., V.D., A.D.C., 21, Strand-road, Calcutta, India.

Vail, Theodore N., LL.D., 26, Cortlandt-street, New York City, U.S.A.

Venables, William Henry, 129, Fordwych-road, Cricklewood, N.W.

Waterbury, John I., 14, Wall-street, New York City, U.S.A.

White, Kenneth M., Minas Schwager, Coronel, Chile.

The Chairman appointed Mr. Byron Brenan, C.M.G., and Mr. Ernest Alexander West scrutineers, and declared the ballot open.

The SECRETARY then read the following—

REPORT OF COUNCIL.

I.—ORDINARY MEETINGS.

Of the twenty papers which were read before the Society during the past session, fifteen were more or less directly connected with the war, while five dealt with other subjects. It may also be added that the opening address, which Dr. Dugald Clerk delivered as Chairman of the Council on November 17th, may be included in the former category, since he chose for his subject "English and German Methods Contrasted." The address was an able defence of English methods as compared with the much-vaunted system of Germany. As Dr. Clerk said, German methods have for long been extolled as scientific, accurate, and far-sighted, while

those of benighted England were set down as amateurish, inaccurate, and short-sighted. This view has been taken by men representing various branches of science, literary men, politicians, and even sailors and soldiers. Its falsity was vigorously demonstrated by the Chairman, who, after first appealing to statistics, went on to prove that alike in most branches of natural knowledge, and in their application to practical purposes, Englishmen had not only been pre-eminent in original discovery, but also in the development of industry and science. The arguments employed need not here be repeated, but the last words of the address may well be quoted: "All the appearance called unpractical, illogical, or muddling through, is but appearance. England is not unpractical. She is the most practical nation in the world. She is not formally logical, but she is idealistic, her ideal being that of freedom for her sons and for the whole world of nations, small and large alike."

The demand for copies of the address proved to be so large that it had to be reprinted, and after its publication in the *Journal* a separate edition of 2,000 copies in pamphlet form was issued and distributed.

All three of the papers which occupied the attention of the Society at the meetings before Christmas dealt with matters connected with the war. On November 24th Sir Edwin Pears utilised his long experience of Turkey and the Turks in an admirable account of "Constantinople, Ancient and Modern," in which he summarised the history of that marvellous city, and from it deduced its probable future. The conclusion he eventually drew is that anybody who thinks that the great bulk of the Eastern trade will be attracted through Mesopotamia and Turkey is "a dreamer who ignores facts."

At the following meeting Dr. Arthur Shipley, the Master of Christ's College, Cambridge, dealt with the curious but unpleasant subject of "Insects and War." It is certain that before the outbreak of this war few of us generally realised the special part played by insects as carriers of disease and pestilence in war. Recent investigations have, of course, made us familiar with the action of insects in the carriage of malaria, and in the distribution of various filth diseases; but probably few, if any, had realised the noxious effect of these loathsome little pests.

At the second meeting in December, Colonel W. A. Tilney impressed upon his hearers the importance, from a military point of view, of an elementary knowledge of astronomy, and described the simple system which he has devised for rendering soldiers so far familiar with the principal stars as to enable them to find their way about at night-time.

Of the papers read at the meetings after Christmas four treated the effects of the war upon commercial supplies. The first of these, by Mr. J. Arthur Hutton, Chairman of the British Cotton Growing Association, dealt with the Effects of the War on Cotton Growing in the Empire and its prospects in the future. The paper was in effect a summary of the work of the British Cotton Growing Association, and showed how much had been done by it in encouraging the growth of cotton within the Empire. The value of this work may be appreciated from Mr. Hutton's statement that the Colonial revenues are now benefiting to the extent of something like £150,000 a year in direct consequence of the cultivation of cotton, while the cotton and seed produced under the auspices of the Association now amount in value to over £1,000,000 per annum, and the demand for British manufacturers has been increased to the extent of at least £500,000 a year.

Mr. Charles Phillips' paper on "Paper Supplies as affected by the War" came at a singularly appropriate time, because it practically synchronised with the Proclamation restricting the imports of paper materials; in fact, Mr. Phillips was able to announce unofficially that the Commission had decided on a restriction of 33⅓ per cent., an announcement which was immediately confirmed by the formal Proclamation.

The third paper coming within the same class was the one by Mr. Edward P. Stebbing, Head of the Department of Forestry at the University of Edinburgh, on "Forestry and the War." The main point of Mr. Stebbing's paper was his insistence on the immediate need for the development of forestry and the increase of the area devoted to the raising of timber. There can be no doubt that the depletion of our home woods and forests, caused by the need of replacing supplies previously provided from external sources, gravely emphasises the special need for re-afforestation after the war.

Sir Henry Cunynghame, in his paper on the "Supply of Food in Time of War," which was read at the first meeting after Easter, laid stress on the diminution of our wheat supplies which regularly takes place in the summer, the store

of wheat in this country falling from seventeen weeks' consumption in November down to about five in August. With a view of remedying this condition of affairs, Sir Henry Cunynghame drew attention to the scheme he had submitted to the Royal Commission on Food Supplies in 1903, under which importers would be encouraged to store their wheat by the imposition of a duty on all imported wheat which was not stored for a certain period. Under this arrangement it was proposed that the tax might be, say, 4*s.* a quarter, that the importer should bond his corn, and that the duty should be reduced a shilling for each month during which the corn was stored; so that if he kept it for four months he would pay no tax at all. The proposal, though received with appreciation, was not entirely approved by those who took part in the discussion, special importance being attached by the Chairman (Captain Charles Bathurst, M.P.) to the greater need of supplementing our imported supplies by home-grown corn.

A considerable variety of topics was discussed in the papers yet to be mentioned as included in the class of war papers, and to these reference may now be made.

The Hon. Lady Parsons, in her paper on "Women's Work during and after the War," gave a careful summary of the more important occupations into which women have been attracted since the war began, and indicated the lines on which she hoped that the employment of women in professional and intelligent work would be developed as a result of the special conditions now existing.

Mr. Charles Darling, whose lecture on Field Telephones in July last is mentioned in another part of this Report, gave a clear and interesting account of the Optical Appliances specially used in Warfare. The account was as complete as it could be made, having regard to the restrictions on the publication of any of the most recent developments of such apparatus as range-finders, periscopes, searchlights, and the like.

In her paper on "Serbia as seen by a Red Cross Worker," Miss H. B. Hanson, M.D., gave an interesting account of the escape from Serbia of the hospital staff employed in that unhappy country when it was overwhelmed by the Teutonic invasion.

Dr. R. W. Seton-Watson's paper on "Pan-German Aspirations in the Near East," was a brilliant account, by one possessing a minute knowledge of the country, of what he believed to be the real German aims and objects in the Balkans and beyond.

In his paper on "Neutral Merchants and the Rights of War," Sir Francis Piggott gave a lucid exposition of the present law of blockade, and urged the necessity, while he pointed out the justice, of the system now adopted by Great Britain to prevent supplies reaching the enemy by the aid of neutral nations.

Although Professor J. A. Fleming's paper on "The Organisation of Scientific Research" did not ostensibly deal with the conduct of the war, or with conditions brought about by it, it must yet be considered as connected with the results of the war, because the question has really been brought to the front by a realisation of the necessity for our organising all our resources, alike scientific and industrial. Professor Fleming was urgent on the need for some more definite organisation for the carrying out of experimental research and invention, and sketched out a scheme by which he thought this might be effected, and by which employers of labour might be encouraged to make greater use of scientific expert advice than they have hitherto done. The paper produced an excellent discussion, in which opinions, both for and against the proposals of Professor Fleming, were brought forward, and it was a valuable contribution to the settlement of a question which is now occupying much public attention.

Two papers yet remain to be mentioned whose sole connection with the war is the sad one that they deal with the country which has undeservedly suffered most from it—Belgium.

The first of these was the joint paper, on December 15th, by M. Josef Denyn, the well-known Carillonneur of Malines, and Mr. William Starmer, who is the best-known English authority on the same subject. These gentlemen gave a most interesting account of the mechanism and methods involved in the campanological art of which the former is so eminent a practitioner. The second was a delightful essay on modern Belgian literature, read in French, by M. Charles Delchevalerie, who took for his actual subject, "Maeterlinck, Verhaeren et les Lettres belges."

Of the five papers which had no bearing on the war, the first was the one read on January 19th by Mr. Lawrence Chubb, the Secretary of the Commons and Footpaths Preservation Society, on the history of the Preservation of the Common Lands of London. The Society of which Mr. Chubb is secretary had intended to celebrate their Jubilee (the

meeting at which they were founded was held at the Mansion House on January 24th, 1866) by a suitable public meeting. This proposal was abandoned in consequence of the war, and the occasion was commemorated by the reading of Mr. Chubb's paper, the date being purposely arranged as near as might be to the fiftieth anniversary of the Society's inauguration. The paper, therefore, was practically a brief history of the work of the Commons Preservation Society, and a most interesting record of valuable public service it proved to be. Lord Eversley, the founder of the Society, excused himself on the ground of his age from taking the chair, which was filled by Lord Farrer, who has for many years taken an active part in the Society's work.

The next paper belonging to the same category, that by the Rev. P. H. Ditchfield on the "England of Shakespeare," was also associated with a commemoration as it was in the nature of a contribution on the part of the Society to the celebration of Shakespeare's Tercentenary. This had been looked forward to for several years, and had we been at peace would certainly have been a national ceremony of the greatest interest and importance. Mr. Ditchfield illustrated his description of Shakespeare's environment by a number of interesting photographs of churches, houses, and other buildings contemporary with Shakespeare and still existing in more or less complete preservation.

The three remaining papers to be dealt with were read in April and May. Mr. A. S. Jennings gave a very full account of the various ways by which mechanical methods have been made to replace the old system of applying paint and varnish to buildings and implements by means of a brush. To a large extent these methods were a development of the device for spraying colour on surfaces invented by Mr. C. L. Burdick, and described by him in the paper on "The Fountain Air Brush," which he read here in March, 1894. Besides this, the system of dipping, even for articles of very considerable size, has been greatly elaborated, and mechanical methods for effecting this were also described by Mr. Jennings. The whole paper, though it dealt with purely technical processes having a certain limitation in their application, was an interesting example of the manner in which in one industry after another—often in a very unexpected fashion—mechanical appliances are coming to take the place of the work of the human hand.

Students of textile history are well aware of the extent to which Europe in the eighteenth and the previous century was dependent upon the East for its supply of calico, either plain or printed; but probably very few, even of those who have paid a good deal of attention to the subject, knew what a large amount of handwork was employed in India for the production of coloured cotton fabrics. While it was known that very considerable quantities of block-printed calicoes had been imported into England, it certainly was not generally realised that a goodly proportion of these decorative fabrics was produced by hand. Mr. George P. Baker, in his description of the "East Indian Hand-painted Calicoes of the Seventeenth and Eighteenth Centuries," and even more by the very remarkable collection of such fabrics with which he illustrated his paper, threw a flood of light upon a subject to which really very little attention has previously been directed.

The work of the session was concluded by the reading in abstract by Mr. John C. Moulden of the Essay on Zinc for which he was awarded the Peter Le Neve Foster Prize. Reference to the foundation of the prize will be found in another portion of this Report. It may be sufficient to say here that the essay by which the prize was gained was a very full and extremely valuable monograph on the whole subject brought down to the present date. The importance of the information conveyed was very greatly enhanced by the fact that there is at the present time an enormous demand for zinc for war munitions, and a very great deficiency in the supply. Some of the principal sources from which the metal is derived were at once cut off at the outbreak of war. But other sources have been, and are now being, rapidly developed, and in the future it may confidently be hoped that one result of the war will be a very great enlargement of the supplies of this valuable metal to be derived from places within the limits of the Empire.

II.—Indian Section.

At the opening meeting Mr. C. C. McLeod dealt with the flourishing Indian jute industry, an industry which, as was pointed out, has been built up solely by British capital and British energy. In 1829 only twenty tons of the raw product, a monopoly of Bengal, were exported, and until 1855 Calcutta did not possess a single jute-mill. In 1913 the exports of the raw material amounted to 80,000 tons and the number of mills on the banks of the Hooghly

was about fifty, providing employment for a quarter of a million native operatives. The total value of the exports, manufactured and unmanufactured, is now £40,000,000. Mr. McLeod earnestly maintained that Germany should be prevented from accomplishing after the war certain designs she is believed to have harboured before the war, or from continuing to enjoy the privilege of competing on equal terms with those who have made the trade what it is.

Two hundred millions of our Indian fellow-subjects are dependent upon agriculture or subsidiary industries. What is now being done to solve an immense problem was explained by Mr. James MacKenna, the Agricultural Adviser to the Government of India and Director of the Agricultural Research Institute, Pusa, in an able paper on "Scientific Agriculture in India." The Indian Budget of 1905-6 made provision for the creation of a much-needed Central Imperial Staff with an adequate supply of scientific investigators and experimental farms in each of the provinces. Results of far-reaching consequence have been already obtained, especially in the production at Pusa, by cross-breeding, of new varieties of wheat. It is, Mr. MacKenna says, a modest estimate to assume that in the course of a very few years the area under these wheats will reach at least 5,000,000 acres.

Another paper bearing on the economic resources of our Eastern Empire was that read by Professor Wyndham R. Dunstan, on "The Work of the Imperial Institute for India." Besides surveying past achievements, especially since the Institute became a Government institution thirteen years ago, he discussed the lines on which further progress can be made, not only in the extended utilisation of Indian products in British industries, but also by the promotion of industrial enterprise in India itself.

The official records of the great triangulation of India are contained in many voluminous Government reports. The interesting paper read by Sir Thomas H. Holdich had to do with the "romance" of Indian surveys, including the "tide of adventure" which, while the mapping of India itself was in progress, flowed into regions beyond our border and led to the accumulation of stores of geographical information. Trans-frontier explorations have been discouraged for many years in order to avoid "complications." In consequence of the adoption of this policy of excessive caution, as some consider it, a good deal of the romance which often clings to individual initiative and effort has for the present disappeared.

In a scholarly paper on the early dawn of the Maratha power, Mr. C. A. Kincaid sketched a literary and religious movement which, as he claimed, made possible the coming of Shivaji the Great, and stopped a large tract in India, the Deccan, from turning Mussulman. The beneficial effect of the sympathetic study by English officials in India of subjects such as the one under consideration was referred to in the discussion.

III.—Colonial Section.

Four excellent papers were read in this section: "Next Steps in Empire Partnership," by Mr. Percy A. Hurd; "Recent Developments in Jamaica: Internal and External," by Sir Sydney Olivier, K.C.M.G.; "The Forest Resources of Newfoundland," by Sir Daniel Morris, K.C.M.G.; and "Some Native Potentates and Colleagues," by the Right Hon. Sir William MacGregor, G.C.M.G.

Mr. Hurd took as his text some notable words of the Prime Minister of Australia, the Right Hon. W. M. Hughes, one of whose earliest speeches in England was made at a meeting of the Society in 1907. "We have," said Mr. Hughes, "arrived at the hour of our supreme trial and of our supreme opportunity." Mr. Hurd emphasised the necessity of our taking advantage of the "supreme opportunity" to perpetuate and enlarge the Empire partnership that has resulted from the war, and suggested numerous proposals by which he thinks the desired end can be obtained.

Just about thirty years ago the depressed condition of the cane-sugar industry brought the largest of our West Indian Colonies to the most difficult and critical stage of its economic history. The development of Jamaica which Sir Sydney Olivier discussed falls within these last thirty years. The two principal internal changes have been the development of small-holders' agriculture and the development of the banana trade. The external progress has been associated with the growth of the banana trade as between Jamaica and the United States, and in a less degree as between Jamaica and the United Kingdom, as well as by the colonisation of Central American countries by Jamaican labour.

The Prime Minister of Newfoundland, Sir Edward Morris, when on a visit to England two years ago, said: "Even to-day Newfoundland is not in the public eye, and it is only

occasionally that attention is drawn to its valuable resources and its great possibilities in the future." One reason why Newfoundland is not more in the public eye may be due to the fact that it has no Agent-General in this country. Doubtless Newfoundland will, in the circumstances mentioned by its Premier, be grateful to Sir Daniel Morris for consenting to make the public at home better acquainted with the principal industries of our oldest and nearest colony. He pointed out that since the war a new trade has sprung up—the production of pit wood—and Lord Northcliffe, one of the pioneers of the colony's thriving paper and pulp industry, informed the meeting that he had seen trenches in Flanders supported by pit props imported from Newfoundland.

With the exception of a celebrated African chief, the Alake of Abeokuta, the "native potentates" portrayed by Sir William MacGregor were men associated with his eminent services in the Pacific—Fijians, Tongans, Papuans, etc. He observed that in the rush of modern life we are too apt to overlook the important position such men occupy in the constitution and life of our "coloured Empire." Many of the members of these native races are, he claimed, our equals, and not a few of them superior to most of us. The Chairman (Viscount Bryce), in his comments on the paper, said that what Sir William MacGregor had told them had enlarged our ideas about those whom we are in the habit of calling barbarous or savage peoples.

IV.—Cantor Lectures.

This year there were two courses of Cantor Lectures. One of these was delivered before Christmas by Dr. Walter Rosenhain, and dealt with the subject of Optical Glass—a subject of special interest because of the increased demand for glass suitable for the construction of various appliances used in war, and also because the supply of all the best forms of such glass was cut off. As is well known, the great improvements which during the last twenty years have been made in optical glass have come from the Jena laboratory, where the researches of Abbe and his colleagues provided the makers of optical instruments with glasses in which high refractive power is combined with low dispersion, and high dispersive power with lower refractivity. Although the production of such glass has not been entirely neglected in this country, practically the whole of the supplies came from Germany. Dr. Rosenhain, in the three lectures which he gave on the subject, explained the special requirements for the production of such glass, gave a short history of its manufacture, and a full account of the present processes for making it.

The second course consisted of four lectures by Dr. J. Erskine-Murray, given in the month of May, on "Vibrations, Waves, and Resonance." Starting from the elementary idea of periodic motions, Dr. Erskine-Murray went on to discuss the various waves in ponderable matter and in the ether, leading up eventually to a summarised description of the principles of wireless telegraphy, and the methods adopted for what is known as tuning in such telegraphy. His lectures were illustrated by a considerable number of interesting and original experiments, though the present regulations with regard to the use of wireless telegraphy prevented any practical demonstration of it being given.

V.—Fothergill Lectures.

Two courses of lectures were given under this Trust. The first was by the Rev. G. Herbert West, D.D., on "National and Historic Buildings in the War Zone." Dr. West has made a special study of Gothic architecture in England and France, and was therefore able to show his audience a remarkably fine collection of lantern-slides dealing with the great buildings in Belgium and Northern France, so many of which have been destroyed by a ruthless and barbarous enemy. The first of his course of three lectures dealt specially with Belgian Architecture and History, the second with Gothic Architecture, French and English, and the third with French Mediæval Sculpture.

The second course consisted of three lectures by Mr. E. A. Reeves, the Map Curator of the Royal Geographical Society, and dealt with the subject of Surveying. Mr. Reeves gave a summarised, yet complete, account, historical and practical, of the various devices and means which have been employed for the production of maps down to the most recent modern instruments and methods of geographical surveying.

VI.—Juvenile Lectures.

As usual there were two Juvenile Lectures given during the Christmas recess, and the duty of delivering them was kindly undertaken by two members of the Council, who each undertook to give a single lecture. The first lecture was delivered by Professor John Millar Thomson, who illustrated his subject—Crystallization—with a singularly beautiful

series of experiments, the most remarkable of them being certainly those dealing with the crystallization of supersaturated solutions—an interesting subject of which Professor Thomson has made a special study.

The second lecturer was Mr. James Swinburne, and his subject the "Science of some Toys." The toys, the scientific nature of which was explained, included kites, sailing boats, spinning tops, and various musical instruments.

Both of these lectures were extremely interesting, and were well appreciated by large audiences. The Council desire to express their sense of the obligation which two of their members conferred upon the Society by generously providing two such attractive discourses.

VII.—Special War Lectures.

It was thought that members would be glad of an opportunity for gaining information about the manufacture of implements and materials for war, and the Council therefore arranged with the late Professor Vivian B. Lewes for the delivery during the recess of a short course of popular lectures on "Modern Munitions of War." Professor Lewes's special qualifications for dealing with the subject were well known, as he was for many years Professor of Chemistry at the Royal Naval College, Greenwich, while he had few rivals in his capacity for making a difficult scientific subject intelligible to a general audience. The Council deplore the fact that his death last October makes these lectures the last of the many services he has rendered to the Society.

The course consisted of three lectures delivered on three Wednesday afternoons in July and published in the *Journal* in August.*

The first lecture dealt with "Guns and Propellants," the second with "Mines, Shells, and High Explosives," and the third with "Poison Gases and Incendiary Bombs." The cost of the lectures was defrayed from the funds of the Fothergill Trust.

Tickets for the course, besides being given to Fellows for their friends, were also issued gratuitously to any persons interested in the subject who liked to apply to the Secretary. The result was that the lectures were attended by large and interested audiences, so that the experiment was fully justified. The necessary limitations under which information on such a subject could be published of necessity precluded Professor Lewes from dealing with its most recent developments, or, indeed, from stating anything not previously familiar to experts, but even under these difficult conditions he fully satisfied his hearers, and the lectures may be pronounced a brilliant success.

Professor Lewes's interesting course was supplemented by a very valuable lecture on field telephones which Mr. Charles R. Darling, Lecturer in Physics at the City and Guilds Technical College, Finsbury, very kindly offered to the Society. This was delivered on July 28th, the week following the last of Professor Lewes's course.

The telephones to which we are accustomed in civil life require, for various reasons, considerable modifications before they are suitable for use in the field. For this purpose special instruments have been devised, and the description of such instruments, and the methods of using them, formed the subject of Mr. Darling's very useful and practical lecture.

The lecture attracted a full audience, including a number of Army signallers and men being instructed in signalling connected with the various London units, to whom tickets had been issued. The number of the *Journal* containing the lecture has since been rather widely circulated, and the practical result has been the formation of various classes for instruction in field telephony in London and elsewhere.

VIII.—Albert Medal.

The Albert Medal of the Society for the current year has been awarded by the Council, with the approval of the President, H.R.H. The Duke of Connaught and Strathearn, K.G., to Professor Elias Metchnikoff, For.Mem.R.S., "in recognition of the value of his investigations into the causes of immunity in infective diseases, which have led to important changes in medical practice, and to the establishment of principles certain to have a most beneficial influence on the improvement of public health."

The discoveries of Professor Metchnikoff in regard to the nature of immunity to infective diseases have contributed, more than the work of any other living man, to the control of such diseases, and to the consequent improvement in the health of great European populations, and the safeguarding of those who have to face the dangers of bacterial infection, whether on the battlefield or as pioneers in tropical climates.

For many years, as Professor of Zoology at Odessa, he was an ardent student of lower forms of life. It was by the study with the microscope of the cell activities of sponges and

* See *Journal*, August 6th, 1915, Vol. LXIII. p. 821.

transparent marine organisms that he arrived at his discovery of Phagocytosis.

These researches into the development and metamorphoses of invertebrates prepared the way for his great discovery, as he was led by the observation of the action of the mesoderm cells in the embryonic organs of echinoderms to the knowledge that the white blood-cells or phagocytes devour the invading microbes in vertebrates also, and he was thus able to show the universal applicability of his generalisation.

Professor Metchnikoff's services to zoology and pathology are of world-wide repute, and have already been recognised by the award of the Nobel Prize for Medicine, and of the Copley Medal of the Royal Society. In announcing the last-named award, Lord Rayleigh concluded an admirable summary of Metchnikoff's investigations with the words: "It is not too much to say that the work of Metchnikoff has furnished the most fertile conception in modern pathology, and has determined the whole direction of this science during the last two decades."

It may be not amiss to add, on the authority of one of his intimate friends, and the one best qualified in this country to express an opinion at once on the value and the intention of his life's work, that his definite purpose has always been philanthropic, and that he has consistently striven to arrive at a true understanding of infective disease with the aim and object of enabling humanity to control it.

IX.—Medals for Papers.

The Council decided that the number of medals for the papers read before the Society during the present session should be reduced to four in all—two for papers read at the Ordinary Meetings and one each for the Indian and the Colonial Sections.

The following awards have been made:—

At the Ordinary Meetings:—

J. Arthur Hutton, "The Effects of the War on Cotton-Growing in the British Empire."

George Percival Baker, "East Indian Hand-painted Calicoes of the Seventeenth and Eighteenth Centuries, and their Influence on the Tinctorial Arts of Europe."

In the Indian Section:—

James MacKenna, M.A., I.C.S., "Scientific Agriculture in India."

In the Colonial Section:—

Sir Sydney Olivier, K.C.M.G., "Recent Developments in Jamaica: Internal and External."

Of recent years it has been the practice that no medals should be awarded to readers of papers who had previously received medals from the Society. Acting on this rule the Council were precluded from considering the following papers:—

At the Ordinary Meetings:—

Professor J. A. Fleming, D.Sc., F.R.S., "The Organisation of Scientific Research."

Charles R. Darling, A.R.C.Sc.I., F.I.C., "Optical Appliances in Warfare."

In the Indian Section:—

Colonel Sir Thomas Hungerford Holdich, R.E., K.C.M.G., K.C.I.E., C.B., D.Sc., "The Romance of Indian Survey."

Professor Wyndham R. Dunstan, C.M.G., M.A., LL.D., F.R.S., "The Work of the Imperial Institute for India."

In the Colonial Section:—

Sir Daniel Morris, K.C.M.G., M.A., D.C.L., D.Sc., F.L.S., "The Forest Resources of Newfoundland."

The Council, however, desire to express their high appreciation of these papers.

X.—Owen Jones Prizes.

These prizes have now been awarded annually for thirty-seven years since the year 1878 on the results of the annual competition of the Science and Art Department, and its successor, the Board of Education. The awards have always been made on the recommendation of the examiners for the "National Competition."

Six prizes were offered for competition in 1915, each prize consisting, as in previous years, of a bound copy of "The Leading Principles in Composition of Ornament of Every Period," from the "Grammar of Ornament," by Owen Jones, and the Society's Bronze Medal.

A list of the successful candidates has already appeared in the *Journal*.*

The Council had hoped to renew the offer for the current year, but a difficulty arose. The Board of Education decided to suspend the "National Competition," in connection with which the Owen Jones prizes have always been awarded, and so that competition was no longer available as a basis for the award of the prizes in 1916. The prizes under the terms of the Trust are only open to "Students of the Schools of Art," and though the Board expressed their readiness to assist the Society, it appeared that there was no convenient arrangement under which the proper adjudication could be carried out.

* See *Journal*, July 16th, 1915, Vol. LXIII. p. 773.

In these circumstances the Council felt that they had no alternative but to suspend the offer of the prizes for the year, in the hope that later on some suitable way may be found for carrying out the conditions of the Trust.

They regret that the series of awards, which have been so successfully carried out for a long period of years, should be interrupted. They realise that the Owen Jones prizes have been greatly appreciated by the numerous students who have received them, and that they have served as a useful stimulant to the study of decorative design. They hope, therefore, that before long it may be possible to devise some suitable scheme for their continuance.

XI.—North London Exhibition Trust.

For some years past the interest on the sum of £157, the surplus of the North London Exhibition held in 1864, has been devoted to the award of prizes to students of the Artistic Crafts Department in the Northampton Polytechnic Institute, Clerkenwell. At present an annual sum of £5 is placed at the disposal of the Governors of the Institute. This year one prize of £1 10*s*. was awarded in the senior section of the Department, and three in the junior section, one of £2, and two of 15*s*. each. The awards were made on the recommendation of Mr. Alan S. Cole, C.B.

The names of the successful candidates have already appeared in the *Journal*.*

XII.—Peter Le Neve Foster Prize.

It was announced in last year's Report that Mr. Reginald Le Neve Foster had presented the Society with a donation of £140 for the purpose of founding a prize in commemoration of his father, Mr. Peter Le Neve Foster, who was Secretary of the Society from 1853 to 1879. The original gift of £100 was made up to £140 so that an annual sum of £5 might be available.

The Council after careful consideration decided to add a Silver Medal, and to offer it with a sum of £10, being the amount of two years' interest, for an essay on "Zinc, its Production and Industrial Applications." An announcement to that effect was published in the *Journal* in August,† and December 31st was fixed as the date by which the essays were to be sent in. By that date twelve essays were received, and these were referred to a committee of judges appointed by the Council. On their recommendation the prize was awarded to Mr. J. C. Moulden, A.R.S.M., M.Inst.M.M., of Seaton Carew, Co. Durham. Honourable mention was also awarded to Mr. Ernest Alfred Smith, A.R.S.M., M.Inst.M.M., Deputy Assay Master of the Sheffield Assay Office, for his essay.

The adjudicators reported that the two essays above mentioned were distinctly superior to the others, several of which, nevertheless, were of interest and value. An essay by Mr. Ramji Das Vaishya, of Gwalior, Central India, contained a good deal of information with regard to the production and utilisation of the metal in the East Indies.

The prize essay, as mentioned on a previous page, was read in abstract at the Ordinary Meeting of the Society held on May 24th. Dr. Dugald Clerk, the Chairman of the Council, presided, and presented the medal to Mr. Moulden. The paper was published in two successive numbers of the *Journal*, May 26th and June 2nd.

XIII.—Examinations.

It was a matter of regret, though not of much surprise, that the number of entries for the examinations in the two divisions again showed a diminution. In the year 1914 the numbers examined reached the high total of 37,993, practically 38,000. The diagram, on which the figures since the year 1880 have been plotted out, shows an absolutely continuous ascent up to the year 1911, in which year the numbers had reached 28,644. There was then a fall for two years down to 28,400, which was caused by special circumstances well recognised at the time, and then a sudden upward ascension to the number above mentioned.

It was anticipated that in consequence of the new arrangements under which a double examination was held, instead of all the examinations being held at one period of the year, the rate of increase would have been still more rapid. These calculations, however, were upset by the war, and there was last year a considerable diminution in numbers. It was certain that a further loss would be felt this year, but there was some hope that the falling-off might have been comparatively small, and this was encouraged by the fact that, compared with last year, the entries for the first division of the examinations, held in April last, showed an increase of some 1,500 over last year. For the second division however, held in May and June, the falling-off was very large and amounted to nearly 7,700.

* See *Journal*, January 21st, 1916, Vol. LXIV. p. 173.
† See *Journal*, August 13th, 1915, Vol. LXIII. p. 837.

In all there were this year 25,968 entries, whereas last year there were 32,129—a total decrease of 6,161. Of these 4,549 were from London—a decrease of 1,933—and 21,419 from the provinces—a decrease of 4,228. The decrease is obviously due to the same causes as last year, the calling to the army of men just of the age of our candidates, and the absorption of others, young women as well as men, to take the places of the new soldiers. This year the decrease has been accentuated by the fact that many provincial authorities have abandoned their evening classes altogether.

The financial result of this was that the Society's balance-sheet for the year shows the cost of the examinations as £3,831 against examination fees received of £2,796, or a deficiency of £1,035. This, however, as explained in the paragraph dealing with Finance, is not a loss on this year's working, since the receipts are those for 1916, and the amount on the other side represents the payments on the previous year's examinations. The receipts, therefore, are diminished in consequence of the reduced number of this year's candidates, while the payments are those incurred for the larger number examined in 1915. It is not possible to speak very definitely, as the amounts have not yet been fully worked out; but it seems almost certain that the actual cost of this year's examinations will be about met by the amount paid in fees.

The Council were reluctant last year to suggest any increase in the fees, or to adopt any other method of reducing the present loss on the examinations; but it is certain that some steps will have to be taken with regard to the future, as the Society cannot reasonably be called upon to defray a considerable annual deficiency. It must, however, be remembered that in the event, as may certainly be anticipated, of the numbers after the war resuming their former average, there would be at once an apparent profit on the working of years showing a considerable increase.

The usual money prizes which are awarded in each subject were abandoned this year, but the liberality of the Worshipful Company of Clothworkers, for whose consistent support for many years the Society is so greatly indebted, enabled the usual medals to be provided. These medals are very highly esteemed by the successful candidates, but it is believed that the disappearance of the money prizes will not really be much felt.

It is interesting to be able to report that it was found possible to provide examinations for some of the interned prisoners at Ruhleben, in Germany, and at Groningen, in Holland; and in both cases the usual fees were remitted.

In response to a suggestion from one of the local centres, an examination in English was arranged for Belgian refugees, and this proved extremely successful, for in all nearly 600 candidates worked papers. In this case it was thought desirable to charge the usual fees. But the work of setting the papers and marking the answers was done gratuitously, and the fees usually paid to the examiner will be handed over to a Belgian charity.

For a good many years past the Society has held an examination in Russian, but the number of candidates has been extremely small. This year, however, a special notice was sent round to the various schools where classes in the Russian language had lately been established, and the result has been that no less than 160 candidates entered for the examinations in this language.

XIV.—Viva Voce Examinations in Modern Languages.

Up to the present date seventeen examinations have been held this year in London and Manchester, but it is doubtful if any more will be arranged before next spring.

At these examinations 380 candidates presented themselves in the following subjects: French, 259, of whom 212 passed (83 with distinction); German, 34, of whom 29 passed (20 with distinction); Spanish, 15, of whom 12 passed (2 with distinction), and Russian, 19, of whom 16 passed (2 with distinction).

There was also a special examination in English for Belgian refugees in this country; 53 candidates were examined, of whom all but one passed, 34 obtaining distinction.

It will be noted that Russian appears for the first time on the list of subjects.

XV.—Journal.

During the past year it has been found necessary to make serious alterations in the *Journal* with a view to increased economy in its production. In August last it was decided to abandon the coloured cover in which the *Journal* has been published ever since November, 1872, and to substitute a white one. The cost of printing was thereby considerably reduced. The reduction was also justified by the considerable loss in the advertisements, the

revenue from which was greatly diminished by the war.

The suggested abolition of the halfpenny rate of postage in October threatened to make a further addition to the cost of the distribution of the *Journal*. The Council, therefore, after very careful consideration, decided that it might be necessary to make very considerable alterations in the publication of the *Journal*, and they had practically determined to issue it fortnightly instead of weekly, and perhaps during the recess but once a month. The decision, however, of the Government not to make any alteration in the newspaper rates rendered these changes unnecessary, and the Society has been able to continue the weekly publication of the *Journal*, which was commenced in 1852.

In the spring of the current year the restrictions on the supply of paper caused further difficulties, and it was feared that it might be impossible to procure sufficient paper for the *Journal* even at an enhanced price. These difficulties, however, were overcome, and the Council trust that the regular publication of the weekly *Journal* has been secured at all events for a considerable time to come. Still, it was found absolutely necessary to restrict the size of the *Journal* as much as possible, and since the middle of March it has been cut down to the smallest possible size. Of necessity much interesting matter has had to be omitted, and for the last three months the *Journal* has contained very little except the bare record of the Society's Proceedings. All these, however, have been regularly published, though in a few cases there was a little delay in the appearance of certain of the sectional papers. This enforced reduction of a most important part of the Society's work has been a matter of deep regret to the Council. But they feel certain that the Fellows generally will approve of their efforts to carry on the regular issue of the Society's official organ under exceptional and adverse circumstances.

XVI.—Afternoon Meetings.

Before the commencement of the session the Council determined that, having regard to the darkened condition of the streets during the winter, it would be desirable, at all events as a tentative measure, to alter the hour of the Society's meetings. An announcement was accordingly made that they would, in the early part of the session, be held in the afternoon. The change seems to have commended itself to the great body of the Fellows, as there were almost no objections, and many of the Fellows expressed themselves in favour of it. It has therefore been continued during the whole of the session. The wisdom of the alteration has been shown by the fact that the attendance has not at all fallen off—in fact, the attendance at the meetings appears to have been, if anything, above the usual average.

XVII.—Society's Staff.

Three members of the Society's clerical staff have been called up for service—A. G. Toye, H. T. Broad, and J. G. Morris. The Council have felt justified in continuing to pay in each case such a proportion of the original salary as would suffice, with army pay and allowance, to bring it up to the usual amount. All the other members of the Society's staff are over military age or are medically unfit. F. A. Scorey, for some years assistant to the office-keeper, who had been in the army and had served in the South African War, volunteered last year, and was seriously wounded in Gallipoli. In his case also a suitable allowance was made.

The staff was still further reduced by the fact that the Assistant Secretary (Mr. G. K. Menzies) has been seriously ill for the past four months. It will therefore be seen that the Society's work has been carried on under circumstances of considerable difficulty.

XVIII.—Conjoint Board of Scientific Societies.

In February last the Council received a communication from the Royal Society stating that that Society proposed to form a Conjoint Board of Scientific Societies to be composed of representatives of twenty-six learned Societies, of whom the Royal Society of Arts was one.

The objects of the Board were stated as follows:—

"Promoting the co-operation of those interested in pure or applied science, supplying a means by which the scientific opinion of the country may, on matters relating to science, industry, and education, find effective expression; taking such action as may be necessary to promote the application of science to our industries and to the service of the nation; and discussing scientific questions in which international co-operation seems advisable."

The Society was invited to nominate two delegates, and the Council thereupon appointed Sir Philip Magnus and the Secretary (Sir Henry Trueman Wood). The delegates have held several meetings, and have formulated a con-

stitution for the proposed Board, which has been sent round to the constituent societies for their approval.

XIX.—New Council.

The following Vice-Presidents retire by seniority: Sir William Abney, Earl Brassey, Sir Mortimer Durand, Sir Thomas Holdich, and Sir Henry Miers. Mr. Carmichael Thomas also retires that he may resume the position of Treasurer. In their place the Council recommend for election: Sir William Duke, K.C.S.I., K.C.I.E., a Member of the Council of India; Mr. Edwin Landseer Lutyens, A.R.A., the well-known architect; Sir Philip Magnus, M.P., who has served for some time on the Council; Lord Northcliffe; Lord Sanderson, who was Chairman of the Council from 1911 to 1913, and acted last year as Treasurer; and Mr. Alan A. Campbell Swinton, who has served for the last four years on the Council.

The four members of Council retiring by seniority or by non-attendance are: Lord Aldenham, Sir Steyning Edgerley, Sir Philip Magnus, and Mr. Campbell Swinton. In their place the Council recommend Sir George T. Beilby, LL.D., F.R.S., the eminent chemist and metallurgist, to whom the Society is much indebted for the assistance he gave in adjudicating on the essays on Zinc sent in for the Le Neve Foster Prize, Mr. Edward Dent, an old Fellow of the Society who has long been a member of the Committee of the Colonial Section, Sir Robert Hadfield, D.Sc., F.R.S., and Sir H. Capel Holden, K.C.B., F.R.S. Sir Robert Hadfield and Sir Capel Holden have held office on the Council in former years.

XX.—Obituary.

The death of Lord Alverstone in December last deprived the Society of one who had long taken a most active interest in its welfare. On the death of King Edward VII., in 1910, he was elected President of the Society, on the Council of which he served from 1883 down to the time of his death. Until the commencement of the illness which terminated fatally, he had been a regular attendant at the meetings of Council, and certainly no one of recent years took a more active interest in the Society's concerns.

Lord Ridley served on the Council for a year, and on one occasion presided at one of the Society's meetings. Sir Colin Scott-Moncrieff joined the Society in 1895, and served as a Member of Council from 1908 to 1910; he was a member of the Indian Section Committee from the time of his election on the Council until his death.

Sir Andrew Noble, who first joined the Society in 1882, received the Albert Medal in 1909. Sir Thomas Fowell Buxton was a member of long standing, and for many years served on the Committee of the Colonial Section. In 1875 he presided at the meeting when the Rev. Horace Waller read a paper on Livingstone's Discoveries. Professor Vivian Lewes was well known to a very large number of Fellows, for he was one of the most popular lecturers who ever appeared on the Society's platform. Sir Patrick Playfair was a member of the Committee of the Indian Section. Sir Hay Frederick Donaldson, the eminent Superintendent of the Royal Ordnance Factories, was one of those who with Lord Kitchener were drowned in H.M.S. "Hampshire" on the 5th of the present month. Mr. Elmer Lawrence Corthell, the well-known American engineer, was a Fellow of some twenty-five years' standing, and always took a warm interest in the Society's welfare. Lord Glantawe (Sir John Jones Jenkins) was a member of the Society since 1873. Sir Michael Nairn was a very old member, as he joined the Society in 1866. Sir Thomas Jackson and Sir William Mitchell were both elected in 1900. Mr. Matthew Hamilton Gray was a member of a family many members of which were connected with the Society, his brother Robert having served for many years on the Council; but he himself never took any active part in the Society's work. Mr. George Wheeler, who was elected in 1903, bequeathed a sum of £100 to the Society on the condition that the money should be expended in paying the fees of a number of life Fellows to be nominated by his executors.

Obituary notices of all the above, and of other Fellows who have died during the past year, will be found in the columns of the *Journal*.

XXI.—Finance.

The annual statement of receipts and expenditure was published—in accordance with the usual practice—in the *Journal* last week. It shows the revenue and expenditure for the financial year ending May 31st last, the assets and liabilities of the Society, its investments and the trusts standing in its name.

That the result of the year's working should show a diminished balance is not to be

wondered at, and indeed the Fellows may congratulate themselves that the deficiency is no larger. But for the falling-off in the number of candidates entering for the Society's examinations, it would hardly have existed at all and the difference between the two sides of the account would have been negligible. The statement made in last year's Report may here be repeated, that the apparent heavy loss on examinations is not a loss on the year's working, but is the result of the Society's financial year not coinciding with the calendar year. The examination receipts are those for 1916, while the payments are those for 1915.

Apart from this one item the financial statement is by no means an unsatisfactory one under present conditions. The annual subscriptions have naturally fallen off, but the difference is nearly balanced by a considerable increase in life contributions, so that the total deficiency in subscriptions is under £70 as compared with last year. This increase in life subscriptions is partly due to a legacy from the late Mr. George Wheeler, who left the Society £100 on condition that five of his friends were to be elected Life Fellows. Apart from this, however, the amount of life subscriptions was about £100 above that of last year.

The Society's dividends from its investments have of course fallen in consequence of the heavy tax, and the *Journal* advertisements, once a source of considerable revenue, now produce very little.

It may be mentioned that the amount of 2½ per cent. Consols standing in the Society's name, £1,650 12*s*. 6*d*., was in the autumn of last year converted into £1,100 8*s*. 4*d*. 4½ per cent. War Loan.

THE CHAIRMAN (Dr. Dugald Clerk, F.R.S.) moved the adoption of the report, which showed the activities of the Society during the past year, and was on the whole, he considered, very creditable. They were greatly indebted, he said, to Sir Henry Wood for the preparation of such an excellent and full report of the Society's work.

COLONEL SIR THOMAS HOLDICH, K.C.M.G., K.C.I.E., C.B., D.Sc., had much pleasure in seconding the adoption of the report, which illustrated the manner in which the Society had adapted itself to the new and unexpected conditions of the present time. He thought it was a matter for congratulation that they had been able to carry their activities so far afield as to the Ruhleben Camp in Germany, where some of our unfortunate countrymen were interned, and thereby to lighten, he hoped, to a certain extent the pains and penalties of their imprisonment there. On the whole he thought the report was most satisfactory, and though they deplored the decrease in revenue and in the number of Fellows, still he did not imagine that there was another public institution in the kingdom which had weathered the storm better than the Royal Society of Arts.

The adoption of the report was then agreed to.

THE CHAIRMAN proposed a cordial vote of thanks to Sir Henry Trueman Wood, the Secretary, and the other officers of the Society for their services. The Society, he said, had gone through a very trying time, and it was surprising how well Sir Henry Wood, with his depleted staff, had managed, He was glad to say that Mr. Menzies, the Assistant Secretary, was now on the way to recovery. He had the greatest pleasure in proposing the vote, as Sir Henry Wood and his staff thoroughly deserved their most hearty thanks—indeed, the position of the Society was mainly due to their labours.

The vote of thanks was seconded by Mr. PETER MACINTYRE EVANS, and supported by Mr. ERNEST A. WEST.

THE SECRETARY returned thanks for this expression of continued confidence in himself and in the other officers of the Society. Owing to the regrettable absence of the Assistant Secretary through illness, his duties had considerably increased during the past four months. He would, however, like to bear testimony to the special help which two members of the staff—Mr. George Davenport and Mr. J. H. Buchanan—had rendered him in connection with the Examinations and the editing of the Society's *Journal*. This was the forty-fourth annual meeting since he first entered the service of the Society, and with the exception of 1893, when his duties with the Royal Commission took him to Chicago, he thought he had been present on every occasion.

The ballot having remained open for half an hour, and the scrutineers having reported, the CHAIRMAN declared that the following had been elected to fill the several offices. [The names in *italics* are those of members who have not, during the past year, filled the office to which they have been elected.]

PRESIDENT.

H.R.H. The Duke of Connaught and Strathearn, K.G.

VICE-PRESIDENTS.

Sir George Ranken Askwith, K.C.B., K.C., D.C.L.
Right Hon. Arthur James Balfour, O.M., LL.D., D.C.L., M.P., F.R.S.
Sir Steuart Colvin Bayley, G.C.S.I., C.I.E.
Sir George Birdwood, K.C.I.E., C.S.I., M.D., LL.D.
Lord Blyth.
Sir William Duke, K.C.S.I., K.C.I.E.

Lord Faringdon.
Lord Inchcape, G.C.M.G., K.C.S.I., K.C.I.E.
Edwin Landseer Lutyens, A.R.A., F.R.I.B.A.
Major Percy A. MacMahon, R.A., LL.D., Sc.D., F.R.S.
Sir Philip Magnus, M.P.
Right Hon. Lord Moulton, K.C.B., M.A., LL.D., F.R.S.
Lord Newlands, LL.D.
Duke of Norfolk, K.G., G.C.V.O.
Lord Northcliffe.
Hon. Richard Clere Parsons, M.A.
Ernest H. Pooley, M.A., LL.B.
Lord Sanderson, G.C.B., K.C.M.G.
Alan A. Campbell Swinton, F.R.S.
Professor J. M. Thomson, LL.D., F.R.S.
Sir John Wolfe-Barry, K.C.B., LL.D., F.R.S.

ORDINARY MEMBERS OF COUNCIL.

Sir George Thomas Beilby, LL.D., F.R.S., F.I.C., F.C.S.
Dugald Clerk, D.Sc., F.R.S.
Alan S. Cole, C.B.
Edward Dent, M.A.
Peter MacIntyre Evans, M.A.
Sir Robert Abbott Hadfield, D.Sc., D.Met., F.R.S.
Colonel Sir Henry Capel Lofft Holden, R.A., K.C.B., F.R.S.
Major Francis Grant Ogilvie, C.B., LL.D.
Sir Robert William Perks, Bt.
Sir Boverton Redwood, Bt., D.Sc., F.R.S.E.
John Slater, F.R.I.B.A.
James Swinburne, F.R.S.

TREASURERS.

Carmichael Thomas.
William Henry Davison, M.A.

SECRETARY.

Sir Henry Trueman Wood, M.A.

On the motion of the CHAIRMAN a vote of thanks to the scrutineers was carried unanimously.

MR. CARMICHAEL THOMAS proposed a very hearty vote of thanks to the Chairman. It hardly seemed a year, he said, since the Chairman took the office, but he felt sure that every one would agree that he had proved a most excellent Chairman, and they were all very sorry indeed that his year of office had expired.

SIR ROBERT PERKS, Bt., said he had very much pleasure in seconding the vote of thanks. He had been much struck with the versatility of the Chairman, for there was hardly a subject brought forward at the meetings of which he did not seem to be a master.

THE CHAIRMAN, in acknowledging the vote of thanks, said that this last year had been a very interesting one for him, and that he had thoroughly enjoyed his work with the Society.

The meeting then adjourned.

GENERAL NOTES.

THE LA CEIBA TREE.—According to a report by the United States Consul at Ceiba, the tree known as la ceiba is one of the dominating features of the landscape in the Ceiba district of Honduras. It rises to a height of 70 or 80 ft. before branching, and then a broad top spreads out like a huge umbrella. The trees are commonly 6 ft. or more in diameter, but the wood is soft and not considered valuable for lumber. It is white and many persons think it would be valuable for paper pulp. The tree bears a silky cotton, which is used to some extent for stuffing cushions.

POISON GASES IN WAR.—Dr. A. C. Cumming, Lecturer in Chemistry at the University of Edinburgh, recently gave an address on poison gases, with illustrative experiments, in the Morningside Church Hall, Edinburgh. The use of gases in warfare was, he said, no new thing, but in most civilised countries it was regarded as barbarous and inhuman, and had consequently fallen out of favour. In some of the early attacks the Germans had used bromine freely. Soon after the war began it was practically unobtainable in this country, whereas so much of it was produced at Stassfurt that the Germans had more of it than they could use or sell. There was good reason to believe that the practice of using poison gas was losing favour with the Germans.

UTILISATION OF WASTE.—It is pointed out, in a paper recently published by the Bureau of Mines, that within the past five or six years marked progress has been made in Europe in the utilisation of various kinds of refuse material not ordinarily given much consideration. The manufacturers of gas-producers report the successful use of a large variety of fuels, including wood shavings, wood blocks, sawdust, excelsior, coffee husks, rice husks, coconut shells, straw, and spent tan bark. The figures on fuel consumption reported by the manufacturers are about as follows: With reasonably dry wood (say mixed oak, ash, and elm) the consumption has been as low as 2 lb. per brake h.p. hour; with sawdust the consumption averages 3½ lb. brake h.p. hour; and with spent tan bark containing 50 per cent. moisture, it is about 4½ lb.

DETERMINATION OF CARBON IN STEEL.—The direct combustion method for determining carbon in steel and iron has been tested at the United States Bureau of Standards, to ascertain whether a higher combustion temperature would give higher carbon percentages. The results of the work, published in Technologic Paper No. 69 of that Bureau, show that, even when the temperature is above 1450° C., which exceeds the fusion temperature of the iron oxides formed, the carbon is only about one-hundredth per cent. higher than that obtained by the direct combustion method as usually practised.

FRIDAY, JULY 7, 1916.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICES.

EXAMINATIONS.

The results of the Intermediate (Stage II.) Examinations, held from April 10th-17th, were posted to the centres concerned on June 30th. The results of the Elementary Stage, held at the same time, will be sent out about the middle of the current month.

INDIAN SECTION.

Thursday afternoon, June 29th, 4.30 p.m.; THE RIGHT HON. AUSTEN CHAMBERLAIN, M.P., Secretary of State for India, in the chair. A paper on "The Sikhs" was read by SIRDAR DALJIT SINGH, C.S.I., Member of the Council of the Secretary of State for India.

The paper and discussion will be published in a subsequent number of the *Journal*.

PROCEEDINGS OF THE SOCIETY.

INDIAN SECTION.

A meeting of the Indian Section was held on Thursday, June 1st, 1916; THE RIGHT HON. LORD ISLINGTON, P.C., G.C.M.G., D.S.O., Under-Secretary of State for India, in the chair.

The paper read was—

THE WORK OF THE IMPERIAL INSTITUTE FOR INDIA.

By PROFESSOR WYNDHAM DUNSTAN, C.M.G., M.A., LL.D., F.R.S.,
Director of the Imperial Institute.

In response to the invitation of the Indian Section of the Royal Society of Arts, I shall endeavour in this paper to give some account of the work of the Imperial Institute for India during the last twenty years, but more especially during the thirteen years in which the Institute has been a Government institution.

The initial operations of establishing and equipping the Imperial Institute for the great work which was originally planned for it occupied the first governing body several years after its formal opening by Queen Victoria in 1893, during which time the Institute was seriously handicapped for want of funds for its current expenditure, and the unsuccessful attempt to provide these funds by popularising the Institute is too well known to need more than a passing comment. This plan of providing income failed in its object before the real foundation of the work of the Institute had been laid. The princes and people of India had responded generously to the appeal of H.R.H. the Prince of Wales, afterwards King Edward VII., for subscriptions to the general building fund, and from these subscriptions, in great part, a small and wholly inadequate endowment fund was formed. The Government of India made no contributions to the General Fund, but soon after the opening of the building by Queen Victoria, in 1893, an Indian Section was formed to be devoted to the exhibition of Indian raw materials and industries, which was subsequently placed in charge of a separate Indian Committee, and with an annual contribution from the Government of India by means of which a special Indian Curator was appointed as the executive officer of this committee. On the establishment of the Scientific and Technical Research Department, in 1896, the Government of India made a small contribution to the support of this department of £100 a year, which some years later was increased to its present amount of £200 a year, and with this extremely modest endowment for Indian research a vast amount of useful work has been done. In 1906 the Indian Section Committee was discontinued and the management of the Indian Section was merged in the general administration of the Institute, and at the same time the contribution of the Government of India to the support of the Indian Section was reduced.

The responsibility of the Imperial Government

for the management of the Imperial Institute dates from 1903, when I became Director, and the Institute passed to the control of the Board of Trade under the Act of that year.

The present is an opportune time to consider in brief review the work which has been accomplished for India in that period of thirteen years, since a new Act has just been passed by which the control of the Imperial Institute has been transferred to the Colonial Office, and the actual management of the Institute vested in a large and representative Executive Council, on which India will occupy an important place.

The Indian Collections of the Imperial Institute.

The Indian Collections of the Imperial Institute, which have been completely reorganised in recent years, constitute the Indian Section of the Public Exhibition Galleries. They include a representation of the important raw materials of India, illustrations of its chief industries and their results, tabular information and diagrams respecting Indian trade and commerce, maps, pictures and photographs of its cities and industries. All important exhibits are provided with descriptive labels which enable the visitor at once to gain general knowledge of the sources and uses of the materials shown.

The contributions made by the Government of India to these collections in recent years have not been numerous, partly because there is no longer an officer in India to whom can be delegated the duty of collecting the material required, so that additional exhibits have to be obtained separately from the various Provinces and Departments in India. Fortunately, however, private contributions have done much towards making the Indian Section representative of the resources and industries of modern India. To the interest and generosity of Their Majesties the King and Queen are due some hundreds of illustrations of Indian industries in all materials, as well as photographs and pictures of India, including many interesting souvenirs of Indian loyalty.

The principal Indian fibres are shown, together with native manufactured materials, accompanied by labels descriptive of the origin, composition and uses, actual and potential, of these fibres. The great Indian tea industry is illustrated by specimens of tea of various grades, maps showing the tea areas of Southern India, photographs of tea gardens and factories, statistics of production and destination, and printed statements explanatory of the production and preparation of tea in India. The industries of silk, opium, lac, and metal-working are similarly illustrated and explained, whilst all the raw materials of India which find their way into European commerce are also shown and explained. The principal minerals of India are likewise shown and their composition and uses described.

The value of the Indian Collections cannot be over-estimated, and it is hoped that in future they may be further augmented. In furnishing material for research they have proved of great service, not merely to the scientific investigator, but to the commercial man in search of materials for industrial purposes. Their special value in this connection is enhanced by the fact that the commercial inquirer can also find at the Imperial Institute full information respecting the sources, composition, and uses of raw materials, and that he can, through the Institute, obtain particulars as to supplies and also trial consignments for manufacturing purposes.

The fear has often been expressed that the position of the Imperial Institute at South Kensington would be a serious drawback to its utility for business purposes. Whatever drawbacks there may have been in early days when means of communication were not as numerous or as convenient as they now are, the record of the operations of the Institute in the past decade is sufficient proof that its geographical position has not seriously interfered with the prosecution of a very large body of important work in which manufacturers and merchants have been intimately concerned, and at the present time the number of inquiries received from the same sources are such as to severely strain the capacity of the staff allotted to this work. So far as India is concerned, the chief purpose in view is to interest the British manufacturer in her raw materials, and in those cases in which a visit to London from manufacturing centres in the provinces is needed, the actual *locale* of the Institute is of small importance if the information required is obtained. Each year there are nearly a quarter of a million visitors to the public galleries, few of whom are mere sightseers.

In reorganising the Indian Section, one object which has been kept steadily in view is to render the Indian Collection intelligible and attractive to the general public, whose interest in the countries of the Empire has so greatly increased in recent years, and to enable schools to use this unique representation of modern

India in connection with the teaching of the commercial geography of the Empire. In order to provide more effectively for this important use of the Indian Collections, it has been part of the duty of the superintendent of the section to conduct a large number of parties from schools through the Indian Section and explain the principal exhibits. The demand for this assistance, both on the part of the general public as well as schools, has now become so great as to require the services of a special demonstrator. For want of funds no permanent arrangement is possible at present, but a beginning has been made with a series of short illustrated lectures on the countries of the Empire, followed by demonstrations in the corresponding sections of the Public Exhibition Galleries, and the number of requests for admission shows that in this way the Indian and Colonial Collections of the Imperial Institute can play an important part in a much neglected branch of education. This scheme has more recently been supplemented by a further series of short illustrated lectures on "Our Tropical Industries" (tea, coffee, rubber, sugar, etc.), illustrated by the collections in the Public Galleries.

Scientific and Technical Research Department.

Some of the earliest work of the Scientific and Technical Research Department was on Indian problems, to which I shall refer in detail hereafter. This department, which has been very greatly extended since its inception, includes research laboratories and technical work-rooms with a staff of trained workers in the several aspects of the utilisation of raw materials for industrial purposes. Of the important work accomplished by this department for India I shall speak presently. At this point it is only necessary to say that whilst many special investigations of a scientific character have been carried out, *e.g.*, on Indian drugs and oils, the chief Indian researches have been technical and commercial, and of a character which renders it desirable that they should be carried out in whole or in part in this country rather than in India.

Technical Information Bureau.

Ever since the department was started a most important part of its work has been, in addition to conducting researches, to collect and critically collate all published information respecting the production and industrial uses of raw materials, and it has gradually come to be recognised as a central clearing-house for information of this character. Merchants and manufacturers in this country, as well as producers in India and the Colonies, have applied in increasing numbers for information on these subjects. In order to be in a position to deal more effectively with such inquiries, a special branch of the department was formed in 1914, whose business it is, in collaboration with the Staff of the Scientific and Technical Research Department, to collect and distribute technical information. Since the war this branch, known as the Technical Information Bureau, has been very full of work, and has not only dealt with a large number of inquiries as to Indian materials and their possibilities, but has taken the initiative with British manufacturers and merchants in bringing to their notice important Indian materials which await a new market.

The three principal agencies for promoting the Indian work of the Imperial Institute, the Indian Collections, the Scientific and Technical Research Department, and the Technical Information Bureau, have now been generally described, and it is only necessary to refer to the library and map rooms, which are important auxiliaries to this work, and to the *Bulletin of the Imperial Institute*, which has played a conspicuous part in making known throughout the Empire the results of researches conducted at the Institute, and the records of progress in the various aspects of the production and utilisation of commercial and economic materials. For some years the *Bulletin*, in an enlarged and extended form, has been published for the Institute by Mr. John Murray, and shows an increasing circulation throughout the world. A glance at the contents of the thirteen published volumes will show how much attention has been given to Indian subjects of importance.

I now propose to describe in some detail the results of the more important work which has been accomplished for India at the Imperial Institute, and especially that carried on by the Scientific and Technical Research Department, and its branch the Technical Information Bureau. Before doing so, I will show, as lantern-slides, some views of the various departments of the Institute:—

1. Imperial Institute.
2. Imperial Institute: Corner of Indian Pavilion.
3. Imperial Institute: Indian Gallery.
4. Indian Section: Jute exhibit.
5. Indian Section: Drug exhibit.

6. Indian Section: Mineral exhibit.
7. Indian Section: Leather and Dyes exhibit.
8. Imperial Institute Laboratories: Rubber Testing Room.
9. Imperial Institute Laboratories: Oils, Gums, Resins, Rubber, etc.
10. Imperial Institute Laboratories: Instrument Room.
11. Imperial Institute Laboratories: Fibres, Foodstuffs, Essential Oils, etc.
12. Imperial Institute Laboratories: Drugs and Essential Oils.
13. Imperial Institute Laboratories: Minerals I.
14. Imperial Institute Laboratories: Minerals II.

The Work of the Scientific and Technical Research Department.

The Scientific and Technical Research Department of the Imperial Institute has had as its chief purpose the investigation of economic products and raw materials of the Empire, with a view to their utilisation in industries and commerce. India had at the time of the initiation of this department an officer called the Reporter on Economic Products, whose principal duty was to make a survey of the economic products of India and to take steps to secure their investigation, and the introduction to commerce of those not fully or at all utilised.

The work of this officer, Sir George Watt, was naturally closely connected with that of the Scientific and Technical Research Department of the Imperial Institute, and for some years he provided a large number of subjects for investigation. Results of great importance were obtained, and, in fact, for some years Indian materials were those which chiefly occupied the attention of the department.

Soon afterwards other countries, and especially the tropical Colonies, began to take advantage of the facilities thus provided by the Imperial Institute for the investigation and commercial utilisation of raw materials, and the increasing use made of the department by the manufacturer and merchant at home gradually led to its present extended operations, which have now developed in many directions. The Scientific and Technical Research Department and its recent offshoot, the Technical Information Bureau, are now utilised, not only by the Colonies and India in finding outlets for raw materials, in gaining information as to how these are best prepared and marketed, but are extensively used by manufacturers and merchants in this country for obtaining trustworthy information as to supplies of raw materials or of materials from new sources, and also in gaining information as to their uses and in overcoming technical difficulties in regard to their industrial employment.

I propose now to consider the work which has been accomplished for India, the difficulties which have been encountered, and the lines on which further progress can be made, not only with reference to the extended utilisation of Indian products in British industries, but also to the promotion of industrial enterprise in India itself through the extended industrial utilisation in India of some of the vast resources of that country.

At the basis of the operations of the Scientific and Technical Research Department is the principle that the uses to which raw materials may be put or adapted can best be determined in the first instance by scientific and technical investigation of their composition and properties, by which their industrial use is determined.

The question whether a new material is of value, for example, for tanning leather must depend first on the nature and amount of its constituents, which can be ascertained by chemical analysis. This is the scientific aspect of the question, which must be dealt with in the laboratory, but scientific results are at the beginning and not at the end of the inquiry. If the necessary constituents needed for tanning leather are proved to be present, the actual suitability of the material for tanning leather and its capacity for tanning certain classes of leather have next to be ascertained. This is the technical aspect of the matter which must sooner or later mean consultation with the practical tanner. If the material is proved to be suitable for tanning certain kinds of leather, the commercial question is the next to be determined, the price which will be paid for it. and at this stage the views have to be ascertained of several manufacturers of the particular classes of leather for the production of which the material has proved to be suitable. Assuming that the price provisionally fixed is one which is satisfactory to the manufacturer, the next question is whether this price will be profitable to the exporters in India. Inquiries have, therefore, to be made as to the sources of supply in India, the amount which could be annually exported from India, the export price and the arrangements for export. At this stage reference to India, therefore, becomes necessary, and ultimate success will depend on the means which

exist there for assisting the enterprise. Lastly, assuming that everything is satisfactorily arranged in India, the next step is for a large trial consignment to be exported to test the market at home and to open the new channel of business. This, which may be regarded as the final stage, requires preliminary arrangements on this side with brokers and merchants as well as with manufacturers.

The system is a comprehensive one designed to do all that is needed to initiate the commercial utilisation of a new material, the entire work being controlled by one organisation specially adapted for the purpose. Stress may be laid on the supreme importance, if success is to be attained, of one organisation being responsible for the whole of the operations described, for this secures unity and directness of purpose, avoids waste of effort, overlapping of work and misunderstandings.

Much is heard of the apathy of the British manufacturer, of his want of initiative and enterprise, and his indisposition to recognise the importance of science in relation to his business. The experience of work at the Imperial Institute is that success in initiating new industrial development depends very largely on the manner in which the case is prepared and presented to the manufacturer, and the extent to which the requirements of an industry and the manner in which it is conducted have been ascertained and studied, and especially on the completeness and clearness with which the case is put in relation to the technical developments required.

It is not enough to have obtained in the laboratory a definite result of scientific interest. It is necessary in addition to demonstrate the practical applications with precision, and to indicate the probable commercial results for the industry affected. The power of interesting the manufacturer depends, therefore, not only on knowledge of the scientific result, but in large measure on the ability to discuss this result in connection with the details of the manufacture concerned. For this reason the work of the Imperial Institute has not been restricted to scientific investigations of raw materials, but has included a study of the uses to which they are put throughout the world.

Before proceeding to describe more in detail the machinery of this organisation, it should be mentioned that the possibility that the raw material in question may be industrially employed in India has always been kept in view, but as this question is a separate and complicated one its special consideration is best dealt with later.

I may now proceed to describe the details of the organisation at the Imperial Institute for dealing with the separate stages of the problems which have been referred to.

The Imperial Institute is provided with research laboratories, technical testing plant and machinery for conducting the whole of the work in the scientific or first stage, and for all the preliminary work in the technical or second stage. The staff of the department includes trained workers to whom are allotted separate sections of the materials to be dealt with, which include fibres, oil-seeds, tanning materials, rubber, feeding-stuffs, minerals, etc., etc. On the technical and commercial side there are men qualified to deal with these aspects of the problems to be solved.

In addition to the analysis and investigation, the required arrangements exist for small-scale technical trials to determine provisionally the suitability of a material for a specific purpose before the matter is referred to the manufacturer. Between thirty and forty scientific and technical investigators are thus employed in groups allocated to the chief raw materials. The work is controlled by superintendents whose business it is to supervise these investigations, and communicate with the manufacturers concerned and keep themselves in touch with industrial requirements. In all important industries it has been found that representative firms are ready to consider the employment of any new material as to which precise and accurate information can be supplied as the result of the various researches conducted at the Imperial Institute. To revert for illustration to the case of a tanning material, the composition and properties of which have been investigated in the laboratories, small-scale trials of the material as a tanning agent will also have been made at the Imperial Institute, and various samples of the leather produced will be available. These results are sufficient to induce the manufacturer to give immediate attention to the subject, and to decide whether the material is worth development; in which case he is usually ready to make further large-scale trials with it in the factory.

The Institute has established relations with manufacturers and users of all classes of raw materials, who are ready to assist the Institute to discover new industrial openings for the raw materials of the Empire.

A department charged with the complicated and many-sided problems which have been

referred to requires to have within its organisation, not only a staff of thoroughly competent laboratory investigators, but in addition efficient arrangements for collecting information respecting the existing sources of supply of the raw materials of commerce and the advances which are being made in their utilisation in all countries. For some years this information has been systematically collected at the Imperial Institute and arranged for use. There has been a steadily increasing flow of inquiries from British manufacturers, merchants, and brokers for information of this character.

In addition to the requests for information received from this country, similar requests are received from the Colonies and India, and the Technical Information Bureau has since the outbreak of war found its hands very full of important work.

The operations of the Scientific and Technical Research Department have now been outlined and illustrated. It should be added that samples of the products which have been investigated in the department are added, with full descriptive labels, to the collection of Indian products shown in the Indian Section of the Public Galleries. This collection has served on several occasions to initiate important investigations, and has also been used as a means of verifying the nature of materials used by manufacturers, and has been invaluable as a reference collection of Indian materials, and as affording to the inquirer samples of materials which have been investigated and valued.

The position of a material which has reached the stage of having been proved by investigation at the Imperial Institute to be of commercial value may now be considered.

It is necessary to arrange for supplies, and to interest Indian exporting firms to do all that is needed to develop enterprise in India. It is in this connection that the Institute has so far experienced the greatest difficulty. There is no Government organisation in India whose special business it is to deal with this side of the question, and the utilisation of several materials is thus delayed. The work is outside the scope of a special Department such as that of agriculture or forestry, which is able to assist chiefly in the collection of information as to the principal sources of supply available for export. At present neither the Department of Commerce and Industry nor the Commercial Intelligence Department can undertake this work in its entirety. The Chambers of Commerce, as well as the Directors of Industry who have now been appointed in many places, may, however, be able to render considerable help in the future, since there is a general awakening to the importance of utilising, so far as possible, our own materials for our own industries.

So far as the advancement of the utilisation by British manufacturers of the raw materials of India is concerned, the exceptional value is evident of a central scientific and technical organisation in London with special knowledge of Indian raw materials, and in close and direct communication with the manufacturers, through whom their utilisation will be chiefly secured.

It is natural that every country should desire to do within its own territory the most it can do to develop its own resources, and the question of how much can be done in India is obviously important.

In this connection it should be pointed out that there is still much to be done in interesting British capitalists in industrial development in India, and the work of the Imperial Institute in bringing Indian raw materials to the direct notice of British manufacturers is of great value in this direction.

In the development of agriculture India has made great strides, as Mr. MacKenna has shown in a paper recently read before this Society. On the scientific side the Central Research Institute at Pusa has devoted itself to the investigation of the scientific problems of Indian agriculture, and has rendered great service, notably in the subject of plant-breeding in its relation to the selection of the type of plant best adapted for the production of the economic product required, of which the work on wheat furnishes a striking example. The scientific work conducted at Pusa, involving as it does systematic investigation of agricultural problems, is a necessary part of the scheme for improving and developing Indian agriculture. The Institute at Pusa is, in fact, rendering to Indian agriculture the same kind of service as that which has been for so many years rendered to agriculture in this country by the Rothamsted Experimental Station. On another occasion (Presidential Address, International Congress of Tropical Agriculture, 1914) I ventured to point out that in a vast country like India it would be a mistake to suppose that rapid advances and far-reaching results will be obtained through the operations of only one centre for research in India.

The Provincial Departments of Agriculture require to be as effectively equipped for systematic research as the various local agricultural

colleges and institutes are in this country. The conclusions reached in one province or district of India require to be confirmed, and in many cases amplified by experimental trials, before they can be accepted as true for another province where the agricultural conditions may be very different. In this connection the experimental farms which have been established in many of the provinces of India are of great importance. These farms are essential to the practical adoption of the results of agricultural research, for it must not be forgotten that practical tests of the suggestions of scientific research and actual observations and demonstrations by the trained agriculturist in the field are as essential to the actual progress of agriculture as the observations and tests of the clinical observer are to the advancement of medicine. The real problem for India is how to bring these two directions of progress into effective co-operation. It is not, however, my purpose in this paper to discuss the organisation of agricultural research, except in so far as it is necessary in considering the manner in which the economic resources of India are to be developed.

The Provincial Departments of Agriculture in India are now in direct communication with the Imperial Institute. In determining the relative quality of the actual products of Indian agriculture, in ascertaining their suitability for particular purposes and suggesting new fields for their use, the Imperial Institute, as I shall show, has rendered great service to India; and no unprejudiced observer can doubt that work of this kind, which requires knowledge of European industrial conditions at the moment, of the requirements of the various markets, and which needs discussion with manufacturers and merchants at home, can best be conducted through one central organisation in London which possesses special facilities for the expert examination of materials and for ascertaining the facts at first hand, and this is true whether the materials are to be exported or utilised in India in new Indian industries.

In forestry the Forest Department in India has, especially through the Forest Research Institute at Dehra Dun, an organisation which can render great service in developing the utilisation of the forest products of India. It will, however, be unfortunate if it is assumed that such an organisation in India, however ably equipped, can by itself reach complete commercial or industrial success. Whether the problem is to find an outlet for the export of a forest product or to secure its utilisation in India, it will be essential to consider the results of similar technical and commercial undertakings in Europe, and it is this information which the Imperial Institute is organised to provide.

Research in India is mainly concerned with improvements in the production of existing materials to suit the purposes of the commercial user, as in the cases of wheat and cotton where it is to the interest of India that better descriptions should be grown, or with securing the production of new materials which have been proved to be of value, of which several illustrations are given in this paper. Such work must necessarily be conducted in India.

Research at the Imperial Institute, in communication with Indian Departments, is mainly concerned with ascertaining the value of raw materials for the purposes of British industry and commerce—that is, in investigating and introducing new materials and in finding new uses for materials already known. This work can only be efficiently conducted in this country in close co-operation with manufacturers.

These two lines of work may often be inter-related. Both are of importance, the one in India leading to the production of the material required, the other at home for securing its use.

The operations of the Commerce and Industry Department of the Government of India should in future be in closer touch with the work of the Imperial Institute, and especially through the Commercial Intelligence Department in Calcutta, which has been recently rearranged. In particular, by means of its publication, the *Indian Trade Journal*, much can be done to make known in India the openings for Indian raw materials and the possibilities of industrial enterprise. During the directorship of the late Mr. F. Noel-Paton this department worked with the Imperial Institute on several subjects in which technical information and commercial suggestions were required.

In the future the Commerce and Industry Department might well furnish in India the link which is needed between those in India who are anxious to see the raw materials of India more fully utilised, as far as possible in India itself, and the Imperial Institute, which is equipped and ready to supply information and undertake the special investigation and research at home which is needed.

The Directors of Industries and the Chambers of Commerce in the Provinces should also become powerful agencies for the same purpose,

and during the present crisis their co-operation with the Imperial Institute has proved to be of great value.

Much could be also accomplished in this direction by the publication in the *Indian Trade Journal* of the results of inquiries and researches conducted at the Imperial Institute which are likely to be important to Indian commerce.

The investigations of Indian raw materials in the laboratories of the Scientific and Technical Research Department of the Imperial Institute, and the inquiries now undertaken by the Technical Information Bureau, cover a very large field. There are but few important materials mentioned in Sir George Watt's comprehensive "Handbook to the Commercial Products of India" which are not referred to as having been investigated and their commercial value ascertained by this department of the Imperial Institute. Many of these materials which proved to be of probable commercial value were not sufficiently abundant at the time in India to render commercial development feasible. In some cases, however, these materials have since been produced in quantity, whilst several have been cultivated and are now exported. The main purpose of the joint work of the Reporter on Economic Products and of the Imperial Institute was a comprehensive survey of every class of the raw materials of India, so that their possible uses might be ascertained and put on record. The importance of such an inquiry, conducted, as it has been, at the Imperial Institute with the assistance of British merchants and manufacturers, is very great, and perhaps this importance will be more generally realised at the present time, when it is obvious that every effort must be made to develop and utilise the natural products of India for the benefit of the Empire as a whole, and not least for the benefit of India herself.

There are important and abundant materials which cannot, at present at all events, be utilised in India itself. Many of these have hitherto been exported to Germany and other foreign countries, and the Indian producer has recently experienced the disadvantages of an almost exclusively foreign channel of trade.

Some striking illustrations of Indian dependence on the predominant utilisation by foreign countries of her raw materials have been given in a monograph on "Oil Seeds and Feeding Cakes" (London: John Murray), which was issued by the Imperial Institute last year. Oil seeds of the value of several millions annually have hitherto gone from India to Germany and other foreign countries. Hides and skins for tanning, also to the value of several millions annually, have also gone to foreign countries, and chiefly to Germany. Medicinal plants for the manufacture of drugs are in the same case, and there are many others.

The information accumulated at the Imperial Institute respecting Indian materials, as the result of many years' work, has enabled the Institute to be of very material assistance in relieving these difficulties caused by the war. Through the recently established Technical Information Bureau, it has taken every step to draw the attention of the British manufacturer to the uses of ground nuts, hitherto little known in this country, as a source of edible oil and of a most valuable feeding cake for animals. Thymol, a valuable drug hitherto produced in Germany, has been shown to be easily obtainable from the ajowan seed of India, which had hitherto gone to Germany for the purpose.

In both these instances, as I shall show later, practical results have followed. Ground nuts are being taken by English seed-crushers, and thymol is being made in this country from Indian ajowan seed.

The future of the Indian hide, skin and leather industry is under active consideration, and there seems to be no reason why selected Indian hides should not be used in the United Kingdom to a far greater extent than they have been in recent years, and also converted more largely into leather in India and exported tanned or partly tanned.

It should be possible to make in India large quantities of paper pulp, sufficient not only to provide for the manufacture of paper used in India, a large proportion of which comes from abroad, but in addition to supply the United Kingdom with pulp for paper manufacture. Canada and Newfoundland are at present the chief sources of paper pulp within the Empire, but most of the pulp used for paper manufacture is still imported from foreign countries—notably Norway, Sweden and the United States. In Canada and Newfoundland the cost of labour is an obstacle which in India would not be so great, and for this reason the making of paper pulp, like the tanning of leather, appears to afford good openings for additional Indian industries, since the raw materials are to be found in abundance.

I may now give a brief description of some of the more important commercial products of India which have been investigated from the scientific, technical and commercial standpoints in recent

years at the Imperial Institute, and a number of which have been introduced into commerce.

DRUGS.

Opium.—The opium of India very early received attention. It was shown by detailed investigation of the opium produced in various districts throughout India that whilst some samples are so poor in morphia as to justify the popular belief that Indian opium is inferior to Turkey and Persian opium for medicinal use and for the manufacture of morphia, the opium produced in the majority of the opium districts of India is as a rule sufficiently rich in morphia to render it suitable for both these purposes. Samples of Indian opium were as rich, and some even richer, in morphia than good specimens of Turkey and Persian opium, whilst certain of these samples possessed the advantage of containing more of the valuable alkaloid codeine than is usually contained in other opiums. Trials of selected specimens in medicine arranged by the Imperial Institute at St. Thomas's Hospital showed that the therapeutic results are entirely satisfactory, and trials of Indian opium for the manufacture of morphia and codeia proved to be equally satisfactory. The attention of the Government of India was in consequence drawn on several occasions to the possibility of exporting Indian opium for medicinal use, but before the outbreak of war the Government of India saw considerable difficulties in the way of permitting an export trade. Since the war, however, Turkey opium has become scarce, and there has been an increased demand for the drug. Under these circumstances the export of a certain amount of provision and excise opium has been allowed to this country, where it is being employed chiefly for the manufacture of morphia and codeia.

The matter ought not, however, to rest here. Provision and excise opiums are of comparatively poor quality, being an average mixture of a number of samples reduced to a definite consistence, the result being a relatively poor material. By selecting for export those varieties of opium which have been shown to be the richest in alkaloids a much more valuable material would be furnished. Scientific experiments in breeding a poppy which will under Indian conditions produce opium of good quality have been already commenced, and will no doubt eventually furnish important results. In the meantime, by selecting for growth in the opium districts those varieties of poppy which have been shown by the investigations at the Imperial Institute to yield the best opium, an increasing output from India of opium of better quality could be arranged without delay. A detailed report on Indian opium embodying the results of all the researches conducted at the Imperial Institute during a number of years has now been published, together with suggestions and recommendations, in the *Bulletin of the Imperial Institute* (1915, Vol. XIII. pp. 507-546).

There can be no doubt that India might in the future contribute the whole of the opium required for medicinal purposes in this country, and, if need be, throughout Europe and the United States.

Podophyllum Emodi.—One of the best-known purgatives used in medicine is the root of the American plant *Podophyllum peltatum.* Detailed researches at the Imperial Institute have shown that Indian podophyllum (*P. Emodi*) can be employed for the same purpose. Extensive and wholly satisfactory medical trials having been made, the Indian drug has for some years been in demand. The supply of the wild plant from India until recently has been small, but it has now been put under cultivation, and it is hoped that supplies will be increased. The drug is now included in the British Pharmacopœia.

Aconites.—The investigation of the composition and therapeutic value of the various Indian aconites is, from the scientific point of view, one of the most important investigations which has been conducted for India at the Imperial Institute. As a result of researches which have extended over a number of years, the alkaloids have been isolated and their chemical characters determined, whilst, with the valuable co-operation of Professor J. T. Cash, F.R.S., of the University of Aberdeen, their precise mode of action and therapeutic value have been ascertained. It has been made clear that several of these alkaloids are valuable therapeutic agents. A series of important papers on the pharmacology of Indian aconites has been published in the *Philosophical Transactions and Proceedings of the Royal Society*, whilst a similar series of papers on their chemistry has been published in the *Transactions of the Chemical Society.*

Henbane.—The recent dearth of the alkaloid atropine and its congeners hyoscyamine and hyoscine (scopolamine), and the high prices commanded by these solanaceous alkaloids which are largely used in ophthalmic medicine, are due to their manufacture having been carried on in Germany. Some years ago a solanaceous plant (*Hyoscyamus muticus*), closely allied to

common henbane and growing wild in Egypt. proved on investigation at the Imperial Institute, to be a most valuable source of these alkaloids, and since the outbreak of war the Imperial Institute has arranged for large quantities to be sent from Egypt to this country, where it is now being employed by manufacturers. Before the war Germany had taken nearly the whole supply from Egypt.

The same plant grows in India, but investigations at the Institute have shown that the wild plant from Northern India apparently may contain less alkaloid than that from Egypt. In view of the demand for the drug which is not likely to be met from Egypt alone, the question as regards the Indian plant deserves further investigation.

The same is true of the related plant, *Datura Metel*, which examination at the Imperial Institute has shown to contain the valuable alkaloid scopolamine, though with Indian samples in smaller amount than is usual in the plant grown in other countries.

On the other hand, *Datura Stramonium* from India has furnished quite satisfactory amounts of alkaloid, and if procurable in quantity would be of value.

The question of the production in India of solanaceous plants is one which is worth further consideration. For commercial production the collection of wild plants could not be depended on, and cultivation would have to be undertaken. This should not be difficult, as the plants grow readily in Northern India.

Tanning Materials and Leather.

A large number of investigations have been made at the Imperial Institute of the value of Indian tanning materials, with a view to the export to this country of those which are rich in tannin, but were not known or used by the British tanner, and to the utilisation of those such as the barks of cassias, acacias, shorea, and mangrove, which are too poor to repay export in the crude state. Some of these, however, might be profitably manufactured into extracts in India, and partly utilised there and partly exported for tanning purposes in this country. This work has involved not merely investigation of the constituents of the materials, but technical trials in communication with tanners.

Much of this work has been done in co-operation with the Forest Department and with the Forest Research Institute at Dehra Dun. After many years' work some progress has been made, and the manufacture of extracts from these materials is about to be tried systematically.

There is a great opening for the development of tanning extract manufacture and of the tanning industry in India, including the extension of native tanneries.

The supply of suitable hides and skins is enormous, and a large part of these which have hitherto been exported chiefly to Germany should in future be tanned in India. No doubt, in some instances, chemical or chrome tannage could be adopted with advantage, but vegetable tannage should remain an important Indian industry and receive development on scientific lines. A definite scheme of operations is required, in connection with which the needs of Indian tanners and those of the British purchasers should be taken into account.

Among the unutilised vegetable tanning agents of India which have been investigated at the Imperial Institute is *Caesalpinia digyna*, a common plant in many districts of Assam and Burma. Investigations at the Imperial Institute have shown that the shells or cases of the seed pods of this plant contain about 60 per cent. of tannin. Technical trials as a tanning agent on a small scale showed that the material produced excellent leather, and this conclusion has been confirmed by trials on a large scale in the tan-yard. A demand in consequence arose for the material in this country, but so far the supply has been small, but whenever the pod-cases of *C. digyna* have been offered they have been sold readily at good prices. It would appear that the cost of collecting and shelling pods from the wild plant will interfere with the extended use of this promising material, and that further progress can only be made through the cultivation of the plant in India, which is now under consideration.

Turpentine Oil and Rosin.

The pine forests in the Punjab and the United Provinces have been worked to a certain extent, and several factories for the distillation of turpentine oil and the preparation of rosin have been in operation for some years by the Forest Department. All the turpentine oil and rosin at present produced is used in India, and there is at the moment no question of these products being exported from India to Europe, although it is possible that such an export may be undertaken in the future. Most of the turpentine oil is obtained in India from *Pinus longifolia*, as this species is the most abundant and accessible; but other species, such as

P. excelsa and *P. Khasya*, also occur which might be used.

The oils of these species have been examined at the Imperial Institute as well as the crude turpentine (oleo-resin) of *P. excelsa* and *P. Gerardiana*, and the resin (colophony) of *P. longifolia*, *P. excelsa*, and *P. Gerardiana*.

The oil of *P. longifolia* from India was found to differ from the American and French turpentine oils. There seems little possibility of the oil from the Indian *P. longifolia* being accepted in commerce as similar to the best grades of American and French turpentine oils, and it would have to be sold on its own merits as Indian turpentine oil. The Indian oil, however, is as good as Russian oil, for which there is a large market in the United Kingdom, and in recent years, owing to the rise in price of American turpentine, various methods of utilising inferior turpentines have been devised, so that when Indian turpentine from this species is produced in excess of Indian needs there will be no difficulty in finding a market for it in the United Kingdom.

The oil from *P. Khasya* is rather better than that from *P. longifolia*, and is quite equal to the lower grades of American turpentine.

The oil of *P. excelsa*, on the other hand, when properly prepared, is comparable with the best French turpentine oils of commerce.

Further information is needed as to the yield of turpentine from these Indian pines, but from what has already been done there seems no reason to doubt that the yield is as good as from French and American pines.

The rosin from *P. longifolia*, *P. excelsa*, and *P. Gerardiana* was found at the Imperial Institute to be very similar in composition to that from the United States and France, and could be used for the same purposes; but its manufacture needs to be improved to produce pale-coloured rosin of the best type.

In addition to the chemical investigations of Indian turpentine and rosin, steps were taken to bring them to the notice of manufacturers in the United Kingdom. In this connection an article on "The Production and Uses of Oil of Turpentine," including references to the Indian products, was published in the *Bulletin of the Imperial Institute* in 1906, and other reports dealing more especially with Indian turpentine have been published at intervals since that time.

A large plant of French design has recently been installed in the Government turpentine factory in the Punjab, which should result in turpentine of better quality being produced.

As a result of this action, inquiries have been received at the Imperial Institute from several British manufacturers, and in some cases trial consignments of Indian turpentine oil have been obtained on their behalf. These have proved fairly satisfactory; but in every case the price has been prohibitive, and for this reason alone it has not yet proved possible to import regularly Indian turpentine oil to this country.

The production of turpentine and rosin in India has, however, now been firmly established, a good local demand has been created, and as the industry is profitable the Forest Department is wisely extending it, and it is quite possible that eventually there may be an excess available for export. In any case, the Indian production has been of indirect benefit to British manufacturers, as it has increased the available supplies of turpentine and has made available for European use a large part of the French and American turpentine formerly imported to India. Prices of turpentine oil have been steadily rising for the last few years, and the rise would probably have been considerably more rapid if India had not come forward with additional supplies for her own use.

The Imperial Institute has throughout been in close co-operation with the Forest Department and the Forest Research Institute in India on this question. Up to the present the Government of India has itself worked the pines for turpentine, and the important point still remains to be settled as to whether this policy should be continued, or whether certain areas of pines at least should not be conceded for development by private enterprise.

The Imperial Institute is in communication with at least one important British firm that is willing to take up and work such a turpentine concession in India.

Burma Beans.

The edible beans most commonly grown in Burma are varieties of *Phaseolus lunatus*, large quantities of which are exported to the United Kingdom and the Continent, where they are commonly known as Burma or Rangoon beans. Those shipped are of two kinds, small reddish beans, and white ones resembling "small haricots" in appearance. During the course of an investigation conducted at the Imperial Institute on the production of prussic acid by certain plants, it was found that the Rangoon beans, when ground into meal and mixed with water, gave indications of the presence of this poison. In the case of the red beans, the quantity of prussic

acid formed was not exactly negligible though usually harmless, whilst the white Burma beans as a rule yielded little or none.

So far as is known, no harm has arisen from the use of the beans as a feeding-stuff. The export trade in these beans from Burma continues to flourish, but as the yield of prussic acid is variable, the beans are sometimes regarded with suspicion by agricultural experts in Europe; and for this reason they bring, in ordinary times, comparatively small prices in the market.

In view of these facts the Imperial Institute, in consultation with merchants in London, suggested to the Department of Agriculture in Burma that steps might be taken to encourage the natives to cultivate for export a better class of beans suitable for human food. In order to carry out experiments from this point of view, a special experiment station was established by the Department at Natywagon. The Imperial Institute forwarded samples of the large white butter beans (Madagascar beans) which are in demand in this country to the Department for trial cultivation, and later on two tons of similar beans were forwarded by the Institute for experimental cultivation by co-operative credit societies in Burma. These butter beans belong, like Rangoon beans, to the species *Phaseolus lunatus;* but through cultivation they have lost to a large extent their characteristic of producing prussic acid, and it was hoped they would retain this cultural peculiarity in Burma. It was also suggested by the Imperial Institute that trials might be made with the true white haricot bean, and a supply of one of the best varieties of the white haricot bean was forwarded to Burma for this purpose this year.

Madagascar beans have now been grown in Burma for three seasons, and the produce has been examined at the Imperial Institute. Although the beans were found to yield somewhat more prussic acid than the original beans, the quantity was negligible, and less than that yielded by the ordinary Rangoon beans.

If the Madagascar beans are found to give satisfactory yields in Burma, and to retain their characteristic of large size and minute yield of prussic acid, they would be far more profitable to grow than the Rangoon beans. In the case of one sample of Burma-grown Madagascar beans, a firm of merchants in London stated that consignments of equal quality should realise the ordinary price of Madagascar beans, which is about £20 per ton, against £6 per ton for Burma beans. These are, of course, pre-war prices. Samples subsequently received were smaller than the original beans, but it was stated by a firm of merchants that they would realise good prices. At the present time all edible beans command exceptionally high prices.

[The concluding portion of the paper, with the discussion, will be published next week.]

THE DEVELOPMENT OF THE TEXTILE INDUSTRIES.

Quilts, Indian and English.—The East Indian painted calicoes of Mr. G. P. Baker's valuable paper (*Journal*, May 19th) were assuredly used by our forefathers to make quilts. Other evidence might be tendered than Mr. Baker's citation from Defoe, and notably certain correspondence of the factors of the East India Company. Thus, in 1632, Thomas Woodson, at Masulipatam, informed Thomas Colly, of Surat, that he would be glad of a chintz to make a quilt. Quilts and cotton yarns "bought in Baroach and Cambaiett" were important articles of contemporary Dutch trade, but it is not clear that all the quilts were calico. Silk and satin quilts were part of the traffic of the Company, some of them inferentially of Indian origin, and others from "China, embroidered with gold," and from "Pitania, embroidered with silk." It is apparent that the calico quilts were stuffed with wadding and stitched by the needle, although this was not necessarily so in the case of the remainder. In our own country the making of worsted bed cloths and of woollen bed coverlets ranked among the early occupations of Norwich and York. A bed "of quoiltene and of materasz" is recorded in the thirteenth century, and "beddes of selk echon, Quiltes of gold thar upon" in the fourteenth. Of these, as of the "three flourished quilts for every bed," mentioned in Johnson's "Idler," it can be affirmed with some confidence that they were quilted by the needle.

The Society, in virtue of its eighteenth century awards, has inherited some interest in quilts, East Indian and British, and it may be permissible to quote the "History of the Society," showing that between 1761-65 a sum of £410 was expended in rewards for "Quilting in the loom." There was a prize for "a quantity of quilting, made in a loom in imitation of, and nearest in goodness to, the Marseilles or India quilting." Fine Indian quiltings are mentioned in two feminine diaries of the preceding half century, and it has been demonstrated that quilts had for long been brought from India. A theory can easily be constructed to explain the alternative name of "Marseilles," for the French had interests in India—they were leaders of fashion then as now—and Marseilles was their port for Eastern trade. The Society's premiums served their purpose.

Samples of a gradually improving character were produced in silk, cotton, linen and wool, and in 1765 the Committee on Manufactures reported the manufacture in this country to be sufficiently established.

The manufacture of Marseilles quilts and the weaving of other goods upon a like principle continues to this day. A short description should suffice, and for an example there is no need to go beyond a specimen exhibited before the Society by Mr. Baker, and obtained by him from Asia Minor, but possibly not of Asiatic manufacture. The pattern of diamonds and branchlike tracery is such as might be worked by the needle, and the black threads forming the low relief upon the quilted face simulate sewing-cotton passably well. But the fabric is a compound woven structure consisting of a close plain silk face cloth, with its own buff warp and weft, a spidery back fabric with a buff warp and a black cotton weft, with a bulky weft of buff cotton sandwiched between. There are two warps and three wefts, and the lifting of the back warp has been controlled by the jacquard to form a relatively large pattern by the singling out of threads for interweaving with the face fabric. The third thick weft, consisting in this case of a bundle of twelve cotton threads woven as one, is fully concealed by the face and semi-concealed by the back. The office of the third weft is the passive one of adding weight and warmth, and forming a filling for the pouchy high relief. The cloth could be woven upon any broad enough loom having two shuttle-boxes at each end, two warp beams, and a jacquard or equivalent attachment. Although the Marseilles quilt has been superseded largely by other compound woven structures, it remains a clearly identifiable article of commerce. To round off the relation between the Indian quilt and its British counterpart it may be said, on the evidence of Mr. T. N. Mukharji's "Arts and Manufactures of India," that in India quilts are *soznis* in the vernacular. In Bengal they are worked by the needle, and in Broach upon the loom. It was from "Baroach" that the seventeenth century quilts came, and it is not too improbable a supposition that they were produced by weaving in substantially the manner described. Mr. Mukharji's account of the Bombay method speaks of the weaving of little bags by uniting an upper and a lower fabric in the loom, but he suggests that these are stuffed as the work proceeds with cotton wool. The net difference lies between employing a bulky third weft to form a wadding, and inserting loose material with the fingers; an alternative that could certainly not be without practical inconveniences.

The Government's Wool Purchase.—The wool clip of the United Kingdom, of approximately 120,000,000 lb., equals one-seventh or less of the wools consumed in the manufacturing industries of this country, and about one-twentieth of the annual commercial supply of the world. Even so, its acquisition entire by the Government remains a considerable transaction involving probably £6,000,000. Had the prevailing market price been paid the bill must have been nearly £1,000,000 higher, and in buying the clip at 30 per cent. over the prices of 1914 the authorities may be said to have made a saving of that amount. Had large Government orders been given for cloths, and still more had exportation been freely allowed to neutral markets, the price must have advanced substantially, and conceivably to the amount of an extra million. It is understood that the Government, after allotting material to satisfy its own requirements, will dispose of the balance in open market, when a useful commercial profit may be reasonably anticipated. The scale of prices, which has been arbitrarily fixed, means that the producer should receive twice as much for this year's wool as for that of the low year 1908. Any excess value is diverted from the private to the public pocket, and in defence of this rather severe measure special circumstances can fairly be pleaded. Government contracts account for a large part of the actual and prospective rise in prices, and in protecting themselves against an unlimited rise, the authorities are doing in essence what has been done already in respect of some other indispensable commodities. A reputation they have acquired for the considerate handling of complex problems has gone far to soothe industrial opinion, which, until the general intention had been exposed, was fluttered and uncertain.

Wool Trade Organisation.—The British wool trade is to a considerable extent separate from that in colonial and foreign wools, with an organisation adapted to meet the elastic needs of the case. Between the farmer and the industrial consumer are a number of intermediaries, of whom the auctioneers in the country markets are among the first and most important. There are seedsmen, and, in Ireland, grocers, who take payment in wool, and who thus become sellers of the produce. Agents of various degrees add to their incomes by buying wool at a commission on behalf of distant wool merchants. Then there are the merchants or staplers, resident chiefly in the industrial area, who buy at auction or otherwise, and who sell fleeces, after more or less selection and rejection, to the manufacturer, and who meanwhile provide warehousing and other accommodation. The interests of these various parties are closely touched by the intervention of the State.

Types of British Wool.—To the outsider even the native wools are objects of a certain mystery, but a working knowledge of them is not difficult to attain. The British wools are classifiable into three main sorts: Long, Short, and Half-bred. The first division includes wools of 8–14 inch staple from Lincoln, Leicester, Romney and Roscommon breeds of sheep, useful for hard serges, linings, braids and buntings. Downs sheep provide the

short wools for hosiery and flannels. The half-breds are crosses between the long and short woolled varieties, producing wools of medium length and reflecting the characters of the parentage of the animal. The classification is a highly summary one, covering small differences infinite in number arising from the soil and climate as well as from ancestry. No such uniformity prevails as in the Colonial and South American wools, nor, in view of the size and physical geography of the country, is the production of large bulks of uniform kind practicable. The British wool trade is more complex than some others precisely because it is smaller and is carried on under conditions of less regularity.

GENERAL NOTE.

Arts and Crafts Exhibition.—An exhibition of the Arts and Crafts Exhibition Society will be held next October in the Galleries of the Royal Academy. The exhibition will be open to all craftsmen, whether members of the Society or not, and works will be received and exhibited under conditions similar to those of the summer exhibitions at the Royal Academy. The address of the secretary, Professor E. S. Prior, A.R.A., is 1, Hare Court, Temple, E.C. Based on the successful experiments in Ghent in 1913 and in Paris in 1914, the exhibition will take the form of a constructive demonstration of the creative possibilities of British folk. A series of interiors will be constructed which can be set up and removed without damage. These interiors will be decorated and furnished by different artists, and arranged within them will be individual works selected for their fitness to the scheme of decoration adopted. There will be a large municipal hall, with the side walls divided into bays. Each bay will be decorated by an artist or a group of artists working in harmony with an agreed scheme of decoration. Another gallery will be fitted up as an ideal council chamber. The central octagon of the series of galleries will be fitted up as a series of apsidal chapels, decorated by individual artists or groups of artists. Another gallery will be devoted to university or educational purposes, and will show the decorative possibilities of an ordinary lecture hall or class room. In the entrance gallery or ante-room will be constructed a panoramic suggestion for the reconstruction of Trafalgar Square. Special galleries will be devoted to textiles, metal work, and embroidery. The intention of the Society is to make the exhibition peripatetic—to send it to the principal cities in the kingdom, to the Colonies, the Americas, and perhaps to France and Russia.

PROCEEDINGS OF THE SOCIETY.

INDIAN SECTION.

THE WORK OF THE IMPERIAL INSTITUTE FOR INDIA.

By Professor Wyndham Dunstan, C.M.G., M.A., LL.D., F.R.S.,
Director of the Imperial Institute.

(*Continued.*)

Indian Paper-making Materials.

Although India possesses an abundance of fibrous materials suitable for the manufacture of paper pulp, less than one-third of the paper used in the country is made in the Indian mills, and even this is manufactured partly from imported wood-pulp.

The consumption of paper in India in the year ending March 31st, 1914, may be estimated as between 85,000 and 90,000 tons, of which only about 29,000 tons were manufactured in the country itself. The total imports of paper (excluding writing paper, the quantity of which is not recorded) in 1913–14 amounted to 57,607 tons, and of this quantity 13,685 tons were imported from Germany and Austria-Hungary. The imports of writing paper were of total value £259,964, the share of Germany and Austria-Hungary being £63,819.

The imports of wood-pulp and other paper-making materials in 1913–14 were 12,382 tons, of which 4,907 tons were contributed by Germany and Austria-Hungary.

These facts show that an extension of the Indian pulp and paper manufacturing industry might well be undertaken with a view to supplying the whole of the paper required in India. Subsequently it might be possible to create an export trade in paper with China and Japan.

Consideration might also be given to the possibility of establishing an export industry in paper pulp, of which Great Britain and other British countries could take large quantities.

The chief raw materials at present used in the Indian paper-mills are "sabai" grass (*Ischaemum angustifolium*), old rags, jute, gunny bags, hemp, old rope and waste-paper.

Other materials that are available are bamboos, soft Himalayan timbers such as Indian spruce and silver fir, and a large number of grasses. An investigation of many of these materials has been made by Mr. W. Raitt on behalf of the Forest Research Institute at Dehra Dun, and his results have been published in the "Indian Forest Records." I am glad to have had the opportunity recently of affording Mr. Raitt facilities for continuing some of these investigations in the research laboratories of the Imperial Institute.

Fibres.

The fibres of India may be roughly classified in three groups, viz.: (1) textile fibres, such as cotton, flax, silk, jute and jute substitutes; (2) cordage fibres, such as Sunn hemp, Manila hemp and plantain fibre, and Sisal, Mauritius and bowstring hemps; and (3) fibres suitable for other purposes, including upholstery work, the manufacture of explosives and paper-making. Work on Indian fibres of all these groups has been carried out at the Imperial Institute, but in the time at my disposal it is only possible to mention a few typical examples of such investigations.

As an example of the first group, viz., textile fibres, reference may be made to a fibre which appeared on the London market about fifteen or sixteen years ago under the name of Bimlipatam jute, the origin of which was not then known. Analyses, and a comparative examination of commercial Bimlipatam jute with the various Indian Hibiscus fibres contained in the Indian Collections of the Imperial Institute, proved that the fibre was the product of *H. cannabinus*. Consequent on this discovery, considerable attention has been devoted to the plant in India during

recent years, and improved races have been established.

Another fibre of the jute class, *Sida rhombifolia*, on examination at the Imperial Institute, was found to be of such high quality that it was recommended that its cultivation should be encouraged. A good deal of work has now been carried out by the Department of Agriculture in Bengal, and it has been found that the value of the fibre is about 10 to 20 per cent. in advance of "first-marks" Calcutta jute, but that the plant gives a smaller yield per acre and the fibre is more troublesome to prepare than jute owing to the interior of the stem being soft instead of hard and woody. These questions deserve further attention.

The second group, viz., cordage fibres, may be illustrated by reference to the fibre known as Sunn hemp, which is obtained from the stem of *Crotalaria juncea*. Samples of this fibre from Burma, Calcutta, and the Pabna district of Eastern Bengal have been examined at the Imperial Institute. All the samples were of good quality, those from the Pabna district being the best. This product finds a ready sale in the United Kingdom at good prices, and it was pointed out in the report that the cultivation of the crop could be safely extended. The annual exports of Sunn hemp from India during the years 1909–1914 amounted to about 30,000 tons, of which about one-half was consigned to the United Kingdom. Since the outbreak of war the demand for Sunn hemp in this country has greatly increased owing to the difficulty of obtaining Russian hemp, the imports in 1915 being about 28,000 tons as compared with 15,000 tons in 1914.

The third group, viz., miscellaneous fibres, may be illustrated by the products consisting of the seed-hairs of various plants, and known as flosses or silk-cottons. Those of the following Indian plants have been examined at the Imperial Institute and information supplied as to their value and uses:—*Eriodendron anfractuosum* (the true kapok tree), *Cochlospermum gossypium*, *Calotropis gigantea* and *C. procera*. There is an export trade in such materials from India, but it is probable that the source of most of the exported floss is *Bombax malabaricum*.

The use of these flosses has assumed increased importance during recent years. Formerly they were almost exclusively employed as stuffing materials for upholstery, but owing to their buoyancy and impermeability to moisture they are now being used extensively in the manufacture of life-saving jackets and similar appliances. Considerable demand has arisen for flosses for such purposes, and good prices are being realised.

Minerals.

A large number of Indian minerals have been investigated at the Imperial Institute in order to ascertain their suitability and value for various industrial purposes. These include coal, lignite, clays, mica, metallic ores, rare earth minerals, etc., etc. The composition and quality of the various coals of India have formed the subject of several extensive and important reports. In 1902 I gave an account of some of this work in a paper entitled, "The Coal Resources of India," read before the Indian Section of the Society of Arts at a meeting at which Lord George Hamilton, then Secretary of State for India, presided. The predictions I then ventured to make as to the future of the coal supply of India have been amply justified, but some of the difficulties with which a rapidly expanding industry have to contend are, I observe, still encountered. The war has served to emphasise the importance of many industrial positions, and among them the coal supply of India and its capacity to supply the markets of the East. In Egypt, where coal is not known to occur, increasing quantities are being used in connection with the extension of irrigation schemes, and Welsh coal is now obtainable only at prices which would usually be prohibitive. The present transport difficulties stand seriously in the way of Indian enterprise, and the admitted fact that most Indian coal is inferior to Welsh coal constitutes an objection which every engineer will press so long as supplies of Welsh coal can be secured at a reasonable cost. I cannot do more in this paper than briefly refer to this subject, which is full of interest and importance to India.

I must, however, not leave it without referring to the great possibilities which Indian coal offers as a factor of industrial importance to India itself, not only as a source of power, but in connection with the adoption of improved methods of carbonisation and the production of liquid fuel as well as of power gas.

The only other mineral to which I shall be able to refer in any detail in this paper is monazite, of which it is now known that India possesses the richest deposits in the world.

The constituent of this mineral of industrial importance is thorium, which is essential to the gas-mantle industry, an industry which until

lately has been entirely controlled by Germany. Germany, having secured the monopoly of the Brazilian supplies of monazite, was able to dominate the manufacture of gas-mantles in this country. The importance of discovering an additional source of thorium, under British control, was, therefore, very great.

Through the mineral surveys established by it in West Africa and Ceylon, the Imperial Institute was able to attack this problem. Monazite was found in numerous localities in West Africa, but nowhere in sufficient quantity to be of commercial importance. In Ceylon, however, in addition to scattered monazite a new mineral —thorianite—was found, and this proved to be the richest known ore of thorium, containing over 80 per cent. of thoria as against about 5 per cent. in Brazilian monazite.

This is not the occasion to tell the story of the competition of Germany for this new mineral of Ceylon, which was eventually secured by the Imperial Institute for British users by whom virtually the entire output of Ceylon has been taken. Unfortunately, the occurrence of thorianite in Ceylon is sporadic, and the supply is now reduced to small dimensions. The importance of the subject to the British industry was so great that the Imperial Institute drew the attention of the Government of India in 1905 to the German thorium monopoly which placed British manufacturing enterprises at a great disadvantage. It was suggested to the Government of India that a special search should be made in India for thorium minerals, since the existence of these minerals in Ceylon rendered it probable that they would also be found in India. The reply of the Government of India was that no special search was necessary as the Geological Survey were already alive to the importance of the subject, and there the matter rested until 1909, when a German prospector, Schomburg, discovered deposits of monazite sand on the coast of Travancore. Specimens secured by the Imperial Institute were examined, and it was found that the sand was rich in monazite, whilst the monazite contained nearly twice as much thoria as the monazite of Brazil. A company, the Travancore Minerals Company, was subsequently formed under German control, and Travancore monazite was worked in German interests. Since the war this company has been reconstructed, with Sir John Hewett as chairman, and it may, therefore, be hoped that its valuable produce will be secured for British industry. In addition to the area dealt with by this company, it is stated that other areas of the Travancore sands are to be worked by a second British company, so that in future it is to be expected that the gas-mantle industry in this country will be able to pursue a course of untrammelled development.

From this brief account of the mineral work of the Imperial Institute it is clear that it should be a valuable auxiliary to the operations of the Geological Survey of India.

It will be seen that the work of the Imperial Institute has been to an increasing extent industrial and commercial in its aims, and that its scientific and technical investigations have been necessarily directed to this chief purpose. Each report made to India consists for the most part of the co-ordinated results of the work of a number of individuals who have been concerned with different aspects of the problems presented, the ultimate purpose of the report being commercial and industrial and not scientific.

Although the complete investigation from the scientific standpoint alone of any large number of the subjects has not been possible for want of funds, individual workers have been encouraged so far as possible to prosecute research in this direction, the results of which have been communicated by them to scientific societies and published as papers by these individuals. Owing to the limitations imposed on work of this description by the smallness of the funds placed at the disposal of the Imperial Institute, arrangements have been made whereby external workers in special subjects have taken up researches at the suggestion of the Imperial Institute, and by this means a considerable body of scientific work has been accomplished for India, quite apart from the co-ordinated commercial work which forms the subject of the majority of the reports made to India, and which occupies the first place in the scheme of operations. In recent years more than fifty papers on Indian subjects have been communicated to scientific societies.

Work of the Technical Information Bureau.

So far I have briefly described some of the investigations conducted for India in the Scientific and Technical Research Department, and I may now refer to some of the operations of the recently established Technical Information Bureau, which has become of so much importance since the war. In the last

two years several hundred inquiries on subjects of importance to India have been dealt with by the Bureau, whilst the attention of users of raw materials in this country has been drawn by special circulars and notices in the Press to the suitability of Indian materials for certain purposes. Assistance has also been given to the India Office in selecting special officers for technical employment in India, and in several other directions.

It will be evident that there is great room for India in the future to contribute the raw materials, not merely for industries of its own, but for those of the United Kingdom and other countries of the Empire in preference to those of foreign countries. To take only three great groups of raw materials, cotton, copra and hides, the exports from India in 1913 and 1915 are shown in the following table:—

Exports from India, 1913 and 1915.

	Value of Total Exports. £	Percentage to Germany and Austria-Hungary.	Percentage to United Kingdom.	Percentage to other Countries.	
	Raw Cotton.				
1913	24,995,750	18·8	3·3	77·9	Chiefly to Japan.
1915	14,875,818	—	8·4	91·6	
	Copra.				
1913	979,335	77·5	3·8	18·7	Chiefly to Belgium & Russia.
1915	519,056	—	50·5	49·5	Almost entirely to France.
	Raw Hides.				
1913	5,329,656	56·5	3·8	39·7	Chiefly to Italy and the United States.
1915	3,959,117	—	14·3	85·7	

This table shows that in each case there has been a remarkable increase in the percentage exported to the United Kingdom. This, however, is not due solely to an increase in the exports to this country, but is partly the result of a decrease in the total exports. The actual increase in the exports to the United Kingdom in the case of copra and raw hides is shown in the tables on pages 611 and 612.

In the case of cotton nearly the whole has gone to foreign countries, and chiefly to Japan. The reason is that most of the cotton grown in India is coarse and of short staple. This is of little value to the British manufacturer, but is valuable in Japan. It is now known that cotton of the kind required by the British manufacturer can be largely grown in India, and steps are being taken to encourage and extend the cultivation of this kind of cotton. When it is remembered how greatly the British manufacturer is dependent on the United States for the cotton he requires, and how this source of supply has more than once been threatened since the war began, it may be hoped that these efforts in India may be redoubled, and concerted action taken to secure that the cotton grown in India shall be for the benefit of the British manufacturer no less than for that of the Indian producer.

Copra.

In the case of copra, more than three-fifths went to Germany and Austria before the war and a negligible quantity to this country. The figures are shown in detail on page 611.

On the outbreak of war, considerable difficulty was experienced in disposing of the supplies of Indian copra, as new markets had to be found for the product. There was, however, no reason why much larger quantities of Indian copra should not be utilised in the United Kingdom, which previously had imported large supplies of coconut oil from Germany, and soon after the beginning of hostilities the Imperial Institute issued a circular to oil-seed crushers and other firms likely to be interested calling attention to the position, and suggesting that the pressing of copra in this country should be considerably extended. Further information on the subject, including particulars as to the value of coconut cake as a feeding stuff for animals, was published in the *Bulletin of the Imperial Institute*, and also in the Imperial Institute monograph on "Oil Seeds and Feeding Cakes" (1915: John Murray).

As a result of this action arrangements have been made by several British firms to extend their plant for crushing copra, and large quantities are now being utilised in the United Kingdom. It is satisfactory to find that in 1915 the exports of copra from India to the United Kingdom amounted to 211,279 cwt., or about half the total, compared with 35,450 cwt. in 1914, and 29,843 cwt. in 1913. The other half is being taken by our ally, France.

Ground Nuts.

The facts are similar in the case of ground nuts, the great commercial value of which the Imperial Institute has done much to bring to

EXPORTS OF COPRA FROM INDIA.

To	1913.		1915.	
	Cwt.	£	Cwt.	£
United Kingdom	29,843	37,636	211,279	262,198
Russia	44,844	58,049	—	—
Germany	565,743	758,938	—	—
Holland	7,750	9,392	—	—
Belgium	49,691	65,212	—	—
France	23,371	30,405	219,862	252,783
Other countries	15,614	19,703	3,684	4,125
Total	736,856	979,335	434,825	519,056

notice in this country since the outbreak of war. The figures are given in the following table:—

EXPORTS OF GROUND NUTS FROM INDIA.

To	1913.		1915.	
	Cwt.	£	Cwt.	£
Germany	144,427	87,157	—	—
Austria-Hungary	273,260	144,080	—	—
France	3,947,772	2,198,895	2,267,074	989,002
Belgium	370,694	222,103	—	—
Hong Kong	213,012	99,765	1,123	534
Other countries *	152,162	140,242	323,754	131,289
Total	5,101,327	2,892,242	2,591,951	1,120,825

* Including United Kingdom.

The principal market for Indian ground nuts was France, 4,405,798 cwt. out of a total export of 5,237,006 cwt. being sent to that country in 1914; in 1915, however, owing to the disorganisation of the French trade produced by the war, only 2,267,074 cwt. of ground nuts were exported from India to France, and the total exports from India fell to 2,591,951 cwt. Ground nuts had not been previously crushed to any extent in the United Kingdom, and the Imperial Institute, therefore, took similar action with reference to this product as had been taken with regard to copra. A circular on "New Markets for British Indian and Colonial Ground Nuts and their Products," calling attention to the supplies available and to the value of the nuts for edible purposes and as a source of oil and feeding cake, was issued early in 1915 and was widely distributed to oil-seed crushers, merchants and others in the United Kingdom, and a full account of the ground-nut industry was given in "Oil Seeds and Feeding Cakes" (1915: John Murray). As the result of the publication of this information considerable interest was aroused in the subject, and several British firms are now regularly crushing ground nuts, and the imports to the United Kingdom, especially from West Africa, have very considerably increased, although France is still the chief purchaser.

The present activity in the oil-crushing and allied industries in this country leads to the belief that greatly increased quantities of Indian oil seeds will in future be taken by British firms—that is, if these firms can be assured that foreign

countries will not be able after the war to secure a controlling position in the industries and to obtain the command of raw materials which can be utilised in this country.

Raw Hides.

The case of raw hides is even more remarkable, since Germany and Austria were able to secure over half the total output from India, of the value of about three millions sterling. The figures are given in the following table:—

Exports of Raw Hides from India.

To	1913.		1915.	
	Cwt.	£.	Cwt.	£.
United Kingdom	52,507	201,893	135,777	567,700
Germany	408,737	2,015,542	—	—
Austria-Hungary	211,213	998,477	—	—
Holland	51,673	226,758	—	—
Belgium	21,192	93,186	—	—
France	25,638	98,195	20,872	63,569
Spain	55,919	327,332	48,741	265,892
Italy	107,494	541,161	322,883	1,806,916
Turkey, Asiatic	25,588	61,270	—	—
United States	147,957	669,746	239,450	1,019,033
Other countries	24,430	96,096	51,511	236,007
Total	1,132,348	5,329,656	819,234	3,959,117

These hides are now recognised to be of value to the British tanner, and since the outbreak of war they have been extensively employed for the manufacture of boots for our soldiers and those of our Allies. Whilst the exports to this country have more than doubled, large quantities have gone to Italy—quantities far in excess of those which Italy is believed to be in a position to tan. The entire question, which is obviously a most important one, is under consideration at the Imperial Institute. The problem is not merely to secure the use of these hides in this country at the present time, but to assure British traders that their business can be safely continued after the war. An extension of the tanning industry in India would do much to assist a satisfactory solution of this question.

The cases so far discussed are all large well-established Indian industries, and I may now turn to several cases of minor or new industries in which the Technical Information Bureau has given assistance.

Chank and Mussel Shells.

The Imperial Institute was recently consulted by the Honorary Director of Fisheries in Madras regarding a machine suitable for cutting sections from chank shells for the manufacture of the shell bangles which are extensively worn by the natives of India. At present the sections of the chank shells are all cut by hand, chiefly at Dacca, a heavy crescent-shaped saw being used for the purpose, and each cut through the shell takes about five minutes to effect. Attempts to find in Europe some form of machine-saw which would facilitate this operation had failed, and the question was therefore referred to the Imperial Institute.

As the result of practical trials carried out by a firm in this country, at the request of the Imperial Institute, it was found that a type of machine-saw used for cutting Trocas shells would serve admirably for cutting the sections from the chank shells. The saw in question is a circular power-driven saw running under water at a very high speed, and each cut through the shell required only a few seconds to make. Samples of the sections cut by this saw were forwarded to India and were pronounced to be quite satisfactory, and at the request of the

Director of Fisheries one of the saws has been dispatched to India for trial. The use of these machine-saws in India will effect a very great improvement in the manufacture of the shell bangles.

Further assistance has been rendered by the Imperial Institute to the Director of Fisheries in Madras in connection with the possible utilisation of the shells of fresh-water mussels for button-making. It was stated by the Director of Fisheries that fresh-water and other mussels occur abundantly in the Madras Presidency, and that in addition the culture of mussels was being undertaken in the fish farm recently established by the Department. Information was consequently desired as to the types of mussel shells already used for button-making in Europe and the United States.

In response to this request the Imperial Institute obtained and forwarded to India a complete set of the mussel shells which are used for industrial purposes, and also furnished information regarding the various species of shell and the machinery used in the pearl-button industry.

Reports on the value of fresh-water mussel shells which occur in India were also made. The results of the inquiries indicate that a market can be found in Europe for certain kinds of Indian mussel shells. At present these shells are utilised to some extent in India for making buttons and ornaments.

Indian Beeswax.

There is a very large demand for beeswax in Russia for the manufacture of church candles, and after the outbreak of the war the authorities of the Russian Church withdrew the prohibition of East Indian beeswax for the purpose. It was essential, however, that all wax supplied to the Russian Church should be free from adulteration, and considerable difficulty was experienced in obtaining commercial samples of Indian beeswax which fulfilled this condition. Out of forty samples of Indian beeswax examined on behalf of the Russian authorities, only four were pure, the remainder being more or less adulterated, chiefly with paraffin wax.

The Imperial Institute accordingly called the attention of the Government of India to the matter, and also consulted importers in this country with a view to preventing the extensive adulteration of beeswax which is at present practised in India. As a result of this action considerable publicity has been given to the question in India, and steps are now being taken to ensure that supplies of the pure wax will be forthcoming in the future. If consignments of pure Indian wax can be offered regularly on the London market it is probable that India will be able to secure a part of the Russian trade in beeswax, which was valued in 1913 at over £600,000, of which the amount contributed by Germany was valued at no less than £560,000.

The following are the figures:—

From	Cwt.	£
Austria	265	2,057
Great Britain	2,833	22,009
Germany	72,089	560,007
Holland	1,574	12,227
Denmark	710	7,263
Spain	49	385
Other countries	6,129	43,776
Total	83,649	647,724

The exports of beeswax from India are not recorded separately, but in 1913–14 the exports of wax of all kinds, no doubt almost entirely beeswax, were only 8,881 cwt., of which 2,604 cwt. went to Great Britain and 3,849 cwt. to Germany.

Thymol.

Thymol, a solid substance derived from the volatile oils of certain plants, including thyme, has been extensively used as an antiseptic during recent years and manufactured almost exclusively in Germany. The best commercial source of thymol is the volatile oil of ajowan seed (*Carum copticum*), a kind of caraway, which is abundant in India. Before the war almost the whole of the exports of ajowan seed from India went to Germany for the manufacture of thymol. As a result of the war there was at once a serious shortage of thymol in this country, and the price rapidly rose to eight times its usual level. There was, however, no reason why the manufacture of thymol should not be undertaken in the United Kingdom from the Indian ajowan seed. The Imperial Institute accordingly drew the attention of British manufacturers to the subject, and offered to put them in touch with Indian exporters of the seed, which was virtually unknown to manufacturers. In response to this offer a large number of inquiries were received at the Imperial Institute from firms in this country, some of whom obtained consignments

of ajowan seed from India for the purpose of starting the manufacture of thymol, which is now definitely established.

In addition to putting British manufacturers in touch with sources of supply of ajowan seed, the Imperial Institute also rendered assistance to them in connection with the process of manufacturing thymol from the seed. A general process for the preparation of crystalline thymol from ajowan seed was drawn up by the Imperial Institute, and was successfully adopted by manufacturers in this country. In some cases, however, difficulty was experienced in obtaining the thymol in the large transparent crystals formerly produced by the German manufacturers, and the Imperial Institute accordingly made a special investigation of this point. Methods of converting the opaque crystals of thymol into transparent crystals were successfully worked out in the Scientific and Technical Research Department and afterwards communicated to manufacturers. As a result of this action of the Imperial Institute thymol is now being made by several firms in this country, and the product is quite equal in quality and appearance to that previously imported from Germany.

Potash.

Recently the Imperial Institute has had under consideration the steps which should be taken to ensure in the future an adequate supply from British sources of potash, which is of immense value in more than one industry, and especially to agriculture. So far the valuable deposits of Stassfurt, in Prussia, have been the chief source of the world's supply.

In response to numerous requests for detailed information, the Technical Information Bureau published a pamphlet entitled "The World's Supply of Potash," in which the possible sources of supply are considered, including those of India. Of possible Indian sources the deposits in the Punjab Salt Range are the most promising, and the Imperial Institute is informed that the Government of India is taking steps to investigate further their value with a view to their commercial development.

The Imperial Institute is about to enter upon the third stage of its existence, which it may be hoped will see further development of its usefulness to India. The Institute is placed by the Imperial Institute (Management) Act of this year under the control of the Secretary of State for the Colonies, as representing the central authority for the Dominions, Colonies and Protectorates of the Empire. The actual management of the Institute will be with an executive council of twenty-five members, which, subject to the general control of the Secretary of State for the Colonies, will possess considerable autonomy and will be the governing body of the Institute. India is to be represented on this council by four members, one nominated by the Government of India, two by the Secretary of State for India, and one by the Secretary of State for the Colonies. In addition, it is understood that there will be a special Indian Committee of the Council with co-opted members—an arrangement which will greatly increase the connection of the Institute with Indian interests, and, it is hoped, will promote the development of those activities of the Institute for India which are most needed in this country. Contributory to the same end will be the several committees on technical subjects, some of which are already at work, whilst others are in process of formation. It is the earnest desire of all those associated with the operations of the Imperial Institute that it should become, even more than it has been, a centre of intelligence and research in this country for all the raw materials of the Indian Empire.

DISCUSSION.

The Chairman (Lord Islington), in opening the discussion, said he was sure he was expressing the sentiments of all present in saying they were exceedingly grateful to the author for the extremely comprehensive manner in which he had dealt with the various details of the commercial relations which existed between India and the home country. The first point that struck one as a result of the war was that practically every raw product necessary for manufacture and use in this country or elsewhere could be found in one or other of the vast possessions within the British Empire. The second point which had been discovered, and which was being appreciated more and more every day in the public departments, was that some of those raw products, many of which were exclusively grown within the Empire, were in large measure manufactured in foreign countries, and that this country had been dependent in the past for those manufactures upon countries outside the Empire, particularly Germany. Under the demands of the war that had caused great inconvenience in some instances, because it had been impossible to provide plant at short notice to manufacture those articles, some of which were of prime necessity in the conduct of the war. The question was, how was this state of things to be avoided in the future? In the first place, he thought it was clear that every encouragement and assistance should be given to enable

more active enterprise to be displayed by manufacturers throughout the Empire. By that means it would be possible to ensure in years to come that, to a far greater extent, our rich and abundant natural resources were employed within the Empire and not abroad. How was that to be done? One way that had presented itself to many people in the past, and had caused acute controversy, was whether there should be any modification, and if so to what extent, in the existing fiscal system of the country and its relations within the Empire. Committees appointed by the Board of Trade were now sitting dealing in detail with all the staple commodities in their relation to the Empire, and a Commission had recently been appointed with a view to establishing on broader lines the industries in India. He sincerely hoped that, as a result of that inquiry in India, recommendations would be made which would put on a firm and much wider basis a greater number of industries within that country for the manufacture of its raw material. The experiences and revelations of the last two years had placed the minds of all thinking people on a somewhat different platform of thought from that on which they were before. He desired to say without hesitation that he would look at the matter with a clear and open mind, without any undue pre-war convictions, but with the sole view that, in the future, the Empire should build up for itself, within reason and without undue disability, a strong commercial Imperial system. With regard to the work of the Imperial Institute, he was sure all present were agreed as to the overwhelming necessity of employing in manufacture at every stage at the present day the best possible scientific means, and the author had shown that the Imperial Institute had contributed no mean amount towards helping on scientific processes in manufacture. The growing importance of a centre for science and for commercial information, such as the Imperial Institute was in its relation to overseas producers and the home manufacturers, had been emphasised in the paper. It was frequently said that research was best conducted in the country of origin of the production, that countries possessing fine laboratory systems and well-equipped research institutes did not require any other centre than their own; and it was thought by some that that might be the case in India. He had had the opportunity of visiting India, and he was glad to see the splendid strides she had made in that connection in recent years. Anyone who had visited Pusa and Dehra Dun must be deeply impressed with the very valuable work that was being done there. Fine research work was not only being done in the main centres, but also in the provincial institutions. There was room for both provincial and Imperial institutes in India, and they should both be brought up to the very highest pitch of efficiency in regard to their research work; in fact, in the majority of cases the local institute could better experimentalise and deal with its own products than a central institute. He wished, however, to emphasize the point made by the author that whether a country be well equipped with research institutes or not — and India was well equipped—there was not only room but necessity for an institution on the lines of the Imperial Institute in this country. That Institute did not in any way overlap or supplant the institutes in the country of origin, but it was, he thought, a natural and necessary corollary. It had been found that products which had gone through the most careful experimental work in their own country, and had been brought to the highest pitch of excellence as a result of that work, had not always reached the exact stage when they could with the best efficiency be adapted by the manufacturers in this country. It had been found, in many instances, that products from India might have to go through some further investigation in this country, in close individual contact with the manufacturer, in order to present those articles as the best foundation for the manufactured article. That was where the Imperial Institute came in as a final centre for adjusting scientific application to manufacture, and also as a centre of easy and constant communication between the manufacturer who desired the article and the producer in the distant colony. That was the kind of work performed by the Research Department and the Technical Information Bureau of the Imperial Institute, and he believed there was a great future in front of the Institute in that connection, not merely for India, but for other parts of the Empire. He was sanguine enough to believe that, as each country came to realise the immense importance attached to work connected with such an Institute, it would come forward and render every possible assistance. As the author had stated, the Institute was now about to enter upon a new stage of its life. Under a recent Act of Parliament a new executive council had been appointed, or was in process of being appointed, and would soon get to work. The future of the Institute would largely depend on the earnestness and the enthusiasm of those who administered it; it would also largely depend upon the efficiency of its scientific staff, and last but not least upon the financial assistance that it received, not only from the Home Government, but from the Governments of the respective countries within the Empire. He hoped the work of the Institute in the future would be recognised as being of such importance that financial aid would be forthcoming from all parts of the Empire, because he was confident that, with a strong administration and the necessary financial aid, the Institute would constitute in years to come one of the recognised centres of Imperial commerce.

MR. C. C. MCLEOD said the greater part of India was connected with agriculture, but the natives had been allowed to go on cultivating the land in the old-fashioned way, without sufficient practical

nstruction being given them for the purpose of improving the tilling of the land and the utilisation of fresh seed. The last number of the *National Review* contained a striking article dealing with German agriculture, in which it was proved that agriculture in that country had been brought to a very high pitch of perfection. If the scientific application that had been devoted to agriculture in Germany were applied in India, the result would be beyond comprehension. The Commission that had been appointed to inquire into Indian questions would, he was sure, obtain a great deal of important information which would be not only useful to India itself, but to those connected with the Imperial Institute in organising further research towards the perfecting of those materials which came from India. In the ten years previous to the war the trade of India had doubled itself—in fact, it was so important that the Director of Government Statistics declared it showed that India was, in regard to trade, a land of undefined dimensions. No one could define the enormous resources of India. It was of the utmost importance that in the future the people of this country and not the Germans should use the resources of the Empire to the utmost. India was able to produce all that this country required if its resources were thoroughly and scientifically investigated.

COLONEL C. E. YATE, C.S.I., C.M.G., M.P., thought the illustration the author had given them of the attitude of the Government of India in 1905 in regard to thorium brought it home to everybody that the Government of India had been just as callous to the manufacturing interests of the country as the Government at home had been. It had been shown that they had done nothing for four years, and then had allowed the Germans to step in and obtain control. It was to be hoped that one of the great results of the war would be that both Governments would in future pay much more attention to the suggestions given them by people such as the author than they had hitherto done. The Imperial Institute, which for the last thirteen years had been carried on under the author's directorship, under the control of the Board of Trade, had now been transferred, in accordance with the new Act of Parliament, to the control of the Colonial Office, with a permanent committee of twenty-five members. When the Bill was first introduced in the House of Commons, he found that the Government of India was to be represented by two members on the committee, nominated by the Secretary of State, and only one member to be nominated by the Government of India itself. It was eventually resolved that four representatives of India should be elected—two by the Secretary of State, one by the Government of India, and one by the Secretary of State for the Colonies—and he hoped that as a result of that decision Lord Islington would, in the near future, represent India on the committee, where, as all would realise from the address he had just given them, he would be a valuable asset to that country. When the Bill was being discussed in the House of Commons he pointed out that, under the scheme, the Governments of India, Canada, Australia, New Zealand, South Africa and Newfoundland were each given one representative, although the total population of the five Dominions, other than India, was only 20,000,000 compared with 315,000,000 in India. It was hardly fair that Newfoundland, with a population of a quarter of a million, should be put on a par with India, with its 315,000,000. He argued that three of the Indian Presidencies and three of the great Provinces, with an average population of 35,000,000 each, should each have a representative. India was a great continent, not a country; and the Presidencies of Bengal, Madras, and Bombay, and Behar and Orissa, the Punjab, and the United Provinces were just as much entitled to their separate representatives as Australia and New Zealand. But he was a voice crying in the wilderness, and he did not succeed in getting more representatives for India appointed. He was glad to hear from the author that a special Indian committee of the Council with co-opted members was to be appointed. That would give an opportunity of electing some Indian representatives on the committee—a most desirable proceeding, which he had urged in the House of Commons. He trusted that the Indian industries would be well represented on that committee.

COLONEL T. H. HENDLEY, C.I.E., said that, as one of the few survivors of the first Executive Council of the Imperial Institute and the honorary secretary of its first exhibition, he congratulated the author upon his able paper. The departments of technical research and the scientific branches amply fulfilled the ideals that Council had in view. Some of their ideals had not been realised, such, for instance, as the greater popularisation of the Institute and the drawing together of their fellow subjects from the Colonies. He hoped the new departure which had been inaugurated would effect those objects. He had visited the principal trade exhibitions recently held in London, and was convinced that the manufacturers of this country did not realise what an enormous field was open for trade in India, which had been largely exploited in the past by the Germans, who first of all manufactured small articles that were required, with the result that they subsequently introduced larger articles on the Indian market, and thus acquired most of the business. He advised manufacturers to make more use of the Imperial Institute, because they would greatly profit thereby. He also hoped that the part of the Institute which had been surrendered to the University of London would be speedily restored to the Institute. It was most annoying to find the main entrance of the building practically reserved for the use of that body. He would be glad, too, if the original proposal to open a communication between the

Institute Indian galleries and the Indian Section of the Victoria and Albert Museum could be carried out, and a working arrangement made by which the collections in both places could be made to supplement each other.

MR. WILLIAM COLDSTREAM, who had represented the Punjab on the governing body of the Imperial Institute and been for many years a member of its Indian Committee, had watched the growth of Professor Dunstan's work almost from the beginning, and as he listened to the story of the importance and variety of its activities in recent years, experienced the feeling that the Institute had somehow come to its own. He thought there were three outstanding demands connected with the work of the Imperial Institute which it was necessary should be met. First of all, there should be some organisation in India for stimulating nascent industries connected with newly discovered products. Secondly, there should be strengthened the link (found in the Institute) between the producer in India and the manufacturer in this country. Thirdly, there should be (as there is in the Institute) a central co-ordinating organisation which dealt, not only with the products of India, but with those of all other parts of the Empire and of the world. A great many of the products to which Professor Dunstan devoted his attention were produced in other parts, and a central institute alone was in a position to estimate the respective values of the articles as supplied by different countries. Apart from the economic and commercial functions of the Institute, to which their attention had been directed that afternoon, the Imperial Institute, existing as it did as a permanent memorial of the beneficent and empire-welding rule of Queen Victoria, must, if it was to fulfil the aspirations of its founders, be worthy of that great object in its Imperial aims, operations, outward aspect, and public presentation. It should be largely representative of India, because more than a quarter of the cost of its erection was subscribed by India. As regards the magnificent building, he suggested that statues commemorating great men connected with India, both Indians and Europeans, should from time to time be erected on the pediments and in the spacious forecourts—a scheme which he had long advocated; and that the large entablatures which ran along the front of the Institute should be covered with legends and historical memoranda in the various scripts of the Empire.

SIR FREDERICK A. ROBERTSON, LL.D., in proposing a vote of thanks to Professor Dunstan, said he was one of those who suffered in the early days in India through being the head of an Agricultural Department. In those days the Government was not in the enlightened condition in which it was now, and was very much averse to any attempt at self-assertion on the part of departments of that kind. He remembered hearing one very eminent official remark, in connection with the establishment of the new Meteorological Department, that he utterly failed to see the advantage of any such department until it could be shown that it could manufacture clouds and rain. That was the official attitude towards scientific research forty years ago. At that time the Government of India had no particular love for scientific investigation. A very great change, which everyone welcomed greatly, had now taken place, India having, under the influence of one particular Viceroy, made a tremendous move in the direction of scientific investigation and study and its application to practical purposes. The equipment for study and investigation in India was now good, but it was not yet anything like as effective as in a western country which had been at work for hundreds of years; and for some time to come it must be recognised that much work in the way of investigation which could not be done in the country of origin must be done at the Imperial Institute. He congratulated the Imperial Institute on having secured a director remarkable alike for the power of taking broad views and of giving them practical effect.

SIR MANCHERJEE M. BHOWNAGREE, K.C.I.E., in seconding the motion, said he was not quite sure that the work to which the Imperial Institute was now restricted and the space it occupied bore any semblance to its original conception. A large part of the building had been given away for an entirely different purpose to that for which it was originally intended, and the large Imperial conceptions as to its activities had in manifold ways been modified. Until the whole edifice was reclaimed, the full development of its purpose could not be realised. The Institute had, however, under its reduced circumstances performed the best work that could be expected from it. The breadth of view the author had shown in controlling that work was the real cause of the prominent success that had been achieved by him. He did not know why the Institute had been placed under the control of the Colonial Office. If it was necessary to put it under some new administration, he thought joint control by the India Office and the Colonial Office would have been the proper thing. India had also received a very feeble and slender representation on the new body considering the large contribution it had made to the erection of the building, the interest which the chiefs and the people had taken in it from the very first, and the nature of the work which had been originally intended to be performed in the Institute for India. The paper was entitled "The Work of the Imperial Institute for India." The sort of work the author had described no doubt incidentally contributed in some small degree to the benefit and interest of India, but when its chief aim has been to investigate and analyse raw material taken to a country 6,000 miles away to bring it within the

knowledge of the manufacturers of that country, he demurred to the claim that that work was performed for the benefit of the country of origin. There was, however, some satisfaction in the thought that the advantage heretofore taken by other countries of the natural products of India might be derived by England through such operations as had been described by Professor Dunstan. It had required the present war to bring the knowledge of that possibility to the minds of the people of this country, and he was glad that at last some steps were being taken in the required direction. The connection between England and India was intimate, and it was as well to transfer Indian raw materials, from which Germany had hitherto derived so much advantage, to the manufacturers of Great Britain. But he deplored the fact that India herself should be unable to manipulate them and secure the benefit to which she was primarily entitled. The work of the Institute gave no help in that direction.

ARTS AND CRAFTS.

Exhibitions of Arts and Crafts.—Some months ago Mr. Clausen, speaking at a meeting held at the Mansion House, indicated that the Academy contemplated giving its benediction to an exhibition of Arts and Crafts. The announcement, therefore, that such an exhibition will be held at Burlington House in October does not come altogether as a surprise. All those interested in the Arts and Crafts movement will rejoice that at length craftsmen, designers, and the various types of workers in the arts not fine will have an opportunity of showing what they can do in the galleries which, in the eyes of the British public as a whole, undoubtedly hold the first rank. The time, too, is propitious. If many people have no leisure to spend on exhibitions, there are hundreds and thousands who are, from a practical point of view, asking themselves what will happen after the war. They are only too anxious to see how art and manufacture can act in concert and work towards that improvement in the artistic quality of British-made goods, which, more than almost anything else, will help towards the establishment and retention of our supremacy in a number of industries. In some ways, however, the outlook is less promising. The exhibition is apparently not to be managed by a committee of artists and craftsmen drawn from the most important societies connected with the artistic crafts. According to the shorter announcement appearing in the daily papers, it is to be simply an exhibition of the Arts and Crafts Exhibition Society held in the galleries of the Royal Academy. The notice which appeared in the *Journal* last week, comparing the forthcoming exhibition with those held at Ghent and Paris in 1913 and 1914 does, however, suggest a somewhat broader basis. The collections shown in those cities were, from the point of view of craftsmanship—of Arts and Crafts in the more limited sense—admirable, although they had very little to do with the larger industries of the country, with art as applied to our great exports and manufactures. The remark that the October exhibition will be open to all craftsmen—whether members of the society or not—hardly suggests that these important interests will be very seriously considered. There was a time when the appeal of the society would have been wider. Some of its earliest and most useful members were manufacturers. But, as one reads the notice to-day, one is tempted to wonder whether the show at Burlington House will bear much relation to the industrial life of the country at large. At the present time there is great need for all the forces which make for the betterment of applied art to unite. Unfortunately, nowadays, the Arts and Crafts Exhibition Society only represents a comparatively small portion of them. It is to be hoped that on the occasion of the first exhibition of Arts and Crafts to be held at the Academy, the hanging committee, as was the case at Paris at least, instead of being recruited entirely from the ranks of the society, will be more thoroughly representative, and that the competent artists connected with industrial design, and with those manufactures into which art enters to any marked extent, will be able to feel that their work stands a chance of being sympathetically shown. That reference is made to Ghent and Paris is a hopeful sign, though the exhibits even there were not as comprehensive as they might have been. If the exhibition were to be carried through on the lines of the exhibition held at the New Grosvenor Gallery a few years ago, a great national opportunity would be lost.

Artistic Toys.—Ever since the quite early days of the war people's attention has been turned towards the art and craft of toymaking. British-made toys have been exhibited at various places in London and elsewhere, they have been *en évidence* at a number of shows, and the British Industries Fair was fairly flooded with them. It has, however, been reserved for the Whitechapel Art Gallery to provide what is in many respects the most interesting and satisfactory exhibition of toys that has been held. At all the other shows there has been some idea of selling; at Whitechapel, on the contrary, the aim is simply and solely to demonstrate what has been and is being done, and incidentally to suggest what may be done in the future. On the whole the toys shown are very promising, especially from the artistic point of view. There is a genuine effort to break away from a dull and ugly tradition and to produce objects really attractive in themselves. On the other hand, some of the toys strike one as being more beautiful than fit for their purpose. Some of the charming little models exhibited by Miss M. V. Wheelhouse and Miss Louise Jacobs, for instance, suggest that the average child could only be trusted to gaze at them from a distance, except on rare occasions when there was someone by to

see that they were treated with due consideration. That type of toy is very attractive to grown-ups, but its charms generally leave children politely cold. The work sent by the Lord Roberts Workshops, on the other hand, is for the most part eminently practical—perhaps the soldiers who produce it have a fellow-feeling with the children —but it is at the same time on thoroughly artistic lines. The workshops lend an interesting series of wooden figures designed by Mr. Carter Preston, and their exhibit includes also some "chunky" toys by Miss Chloe Preston carried out more simply, but with much the same feeling. The collection of toys sent by Mr. Vladimir Polunin, divided into three groups—the cubic, the round, and the flat—is again admirable, and many of the wooden animals, simple as they are, are extraordinarily full of life. The farmyard and windmill lent by Homeland Toys, again, are distinctively decorative. The country toys contributed by the Peasant Arts Society are rather less satisfactory, though the idea of hedges of loofah stained green is really brilliant. The toys made by the pupils of the Streatham County Secondary School, under the direction of the Misses Polkinghorne, suggest many possibilities. They seem to be the work for the most part of children under twelve, and they show that under proper guidance toymaking may be a most instructive and interesting form of manual training for children, developing not only their powers of observation and invention, but also their artistic sense. Altogether, the exhibition at Whitechapel is one which ought not to be missed by anyone concerned either with craftwork or with the teaching of children.

ENGINEERING NOTES.

The Brasher Air Breakwater.—The cost and interest on capital expended on a breakwater to safeguard jetties or buildings on the sea front against storms will usually exceed the value of the property it is designed to protect. A novel scheme suggested by Mr. Philip Brasher, a young American engineer, which seems to offer a solution was recently described and illustrated in the *Engineer* of May 5th, 1916. This was, in brief, that, instead of employing a permanent structure to arrest the seas, he proposed to rob the waves of their power to do harm by means of an air breakwater or screen of bubbles rising from the water at a suitable point off the shore and directly across the line of advance of the storms. The method has been put to the test at El Segundo, California, where it was required to protect a pier situated in an exposed position. The installation consisted of pipes 3 or 4 in. in diameter conveying compressed air to points 100 to 150 ft. beyond the pier-head. The air supply service comprised two compressors having a combined output of 2,000 cubic feet per minute. The air pressure required is just that necessary to overbalance the hydrostatic head. A pressure of 25 lb. per square inch would usually suffice, as a breakwater would not be expected to operate in depths much over 50 ft. The installation at El Segundo had fortunately been made ready for service when in January last the Pacific coast was swept by a violent storm, which did great damage to property. The waves ranged from 12 to 15 ft. high, and would have seriously injured the pier had it not been for the intervention of the air breakwater. For twenty-three hours compressed air was fed steadily into the perforated conduits under water, and the action of the rising bubbles so subdued the waves that they rolled shoreward without even jarring the wharf when the storm was at its worst. Mr. Brasher claims for his system a very flexible protective power, especially for temporary applications. Salvage work on the s.s. "Yankee," wrecked on the coast of Rhode Island, was carried on as if the ship were in a lagoon after the air was turned on in the breakwater, while seas were breaking heavily outside. The subject of the above abstract was supplemented by a letter from "M.Inst.C.E." to the *Engineer*, of June 9th, regarding the theory of water pressure involved in the process described.

The Highest Arch Roadway Viaduct in the United States.—An example of a satisfactory solution of the problem continually arising—how to construct with the available funds a structure of pleasing architectural appearance—is found in the design of the recently completed high-level bridge for roadway traffic over the Cuyahoga River gorge near Akron, Ohio. This viaduct, built of ferro-concrete, is reputed to be the highest roadway structure, 190 ft. from bed of stream to level of road. The excessive height of the piers in the Akron bridge made the problems of construction more difficult than usual. Special care in erection was taken to avoid excessive unbalanced thrusts on these piers. The three-hinged steel arch centres, with 2-in. tie rods to take the thrust, are, of course, the most economical for such a location, the centres being placed by the construction cable. The total length of the viaduct is 781 ft. 9 in. The bridge has a 24-ft. roadway and two 4-ft. footways, and provision for a single-track electric road is made for the future. As finally built, the structure consists of five main arch spans 127 ft. long between centres of piers. Each arch has two main ribs, 20 ft. on centres, supporting spandrel columns. The three high piers are hollow, rectangular in section, reinforced with horizontal and vertical steel, and the walls strengthened by horizontal diaphragms about 40 ft. apart vertically. The loftiest pier is 110 ft. high. The approaches are of exactly the same floor construction as the main arch span, similar columns to the spandrel columns, spaced 9 ft. 5 in. on centres, being carried down to the rock foundation. On the south approach the columns, because of their great height, are braced by 12-in. by 12-in. longitudinal struts at about the mid-height, and transverse struts with knee braces are also used. The bridge was designed for a uniform

live load of 100 lb. per square foot on the roadway and 75 lb. on the footway, for an 18-ton truck on four wheels, 9,000 lb. per wheel, 5 ft. gauge and 10 ft. on centres, with 30 per cent. impact, for a 40-ton car with trucks 22 ft. on centres, wheels 10,000 lb. each, spaced 6 ft. apart, with 40 per cent. impact. Wind pressure was considered at 30 lb. per square foot. The allowable unit stresses were 750 lb. per square inch compression in concrete and 16,000 tension in steel. On the foundations about 5 tons per square foot for dead load and 10 tons for the worst condition of unbalanced thrust were allowed. The maximum compression on the concrete of these piers under full live load and wind pressure is about 400 lb. per square inch. The arch analysis was made in the usual manner, two street cars and two trucks being assumed. Stresses were computed to include the effects of a rise of temperature of 15° and a fall of 60°, the rib-shortening effect being included as 16° in the 60° fall. It was found that ribs 3 ft. by 3 ft. at the crown and 3 ft. by 5 ft. at the springing line would carry the stresses. These sections were increased when the design was changed, so that the ribs as constructed are 4 ft. deep at the crown and 6 ft. deep at the springing line. Seven transverse struts 4 ft. deep with end knee braces connect the two main arch ribs. Each rib is reinforced with twelve ¾-in. square rods, with ½-in. square ties on 3-ft. centres. In computing the stresses in the main ribs when the thrust line was outside of the middle third, the stresses were found as for eccentrically loaded columns, including the steel in both tension and compression. When the thrust line was inside the middle third the effect of the steel was neglected. It will be noted that the percentage of steel at the crown is only 0·39 per cent. This is due to the excessive section used for the modified design. The floor slabs are of two thicknesses, 8 in. and 6 in. Two-way reinforcement is used between the transverse floor beams and the longitudinal stringers formed at the side-walk curb and at the side of the central depressed 8-in. slab designed to carry the future electric railway track.

The Marseilles-Rhone Canal.—This canal, now under construction, is important in that it proposes to connect, through intermediate waterways, including rivers, the Mediterranean and the English Channel, carrying barges with loads of 600 tons. That a huge national enterprise can at the present time be resolved on, in spite of the temporary difficulties arising from the war, for it means the connection by methods of transhipment with New York, London, Antwerp, Rotterdam, and Hamburg, is a marvel of national activity. The canal itself is 51 miles long from Marseilles to Arles on the Rhone. The first 5 miles is in the sea protected by a breakwater. The next section is entirely in tunnel 4·6 miles in length in solid rock. The arch is segmental in form, 41 ft. in radius, and is 72 ft. 2 in. wide, including a towing-path of 11 ft. 2 in. The depth is 9 ft. 10 in. The third division is through a long cutting to near Marignane, thence along the southern end of the Lagoons of Bolman and Barre as far as Martigues, where it will unite with an existing canal between that place and Porte de Bouc. From here to Arles another existing canal will be remodelled. As to the tunnel itself, the width is to be about six times as large as an ordinary railway double line, and 50 per cent. more in cubical capacity than the two Simplon tunnels, and nearly double that of the St. Gothard. The material excavated will be more than in any tunnel yet driven. The works, having been in contemplation for many years, are expected to be finished in the course of three years, and will cost about £2,120,000.

GENERAL NOTES.

Exhibition of Designs for War Memorials.—The committee of the Civic Arts Association have arranged for an Exhibition of Designs for War Memorials, to be held at the Royal Institute of British Architects, Conduit Street, W., commencing on Monday, July 17th, when Dr. Arthur C. Benson, M.A., C.V.O., Master of Magdalene College, Cambridge, will give an address.

British Glass.—The *Daily Graphic* gives an interesting account of a visit to the laboratories at the Institute of Chemistry, at which the representative of the paper was shown a series of articles fashioned in glass from the formulæ worked out by Professor Herbert Jackson, Chief Professor of Chemistry in the University of London. Most of the articles had never been made in this country before. They ranged from glass eyes of every shade and colour to tiny glass tubes for holding iodine, etc., for the use of the soldiers. Mr. Richard Pilcher, of the Institute of Chemistry, explained that Professor Jackson's research work had resulted in the discovery of over thirty formulæ for the manufacture of glass. The samples exhibited included such different varieties as the thick and all but unbreakable glass used for miners' safety lamps, tubes and bulbs for chemical laboratories, the blue enamel used for sealing metallic wire into glass, opal glass, glass for optical lenses, for ampoules, and many other scientific purposes. It was not simply a question of copying German manufacture. Potash, easily obtainable in Germany, was scarce, and a substitute had to be discovered. Naturally, research work of this kind is costly, and until a grant was made by the Advisory Council for Scientific and Industrial Research, the expense was borne partly by the Institute and partly by Professor Jackson himself. King's College willingly furnished every facility for carrying on the work.

NOTICE.

CHAIRMANSHIP OF COUNCIL.

On Monday, the 17th inst., at their first meeting in the new session, the Council re-elected Mr. DUGALD CLERK, D.Sc., F.R.S., Chairman for the ensuing year.

It was resolved that a letter be addressed to Madame Metchnikoff, conveying to her tne feelings of regret and sympathy with which the Council had received the news of the death of her distinguished husband, to whom the Albert Medal of the Society had just been awarded.

PROCEEDINGS OF THE SOCIETY.

INDIAN SECTION.

A meeting of the Indian Section was held on Thursday, June 29th, 1916; the RIGHT HON. AUSTEN CHAMBERLAIN, M.P., Secretary of State for India, in the chair.

THE CHAIRMAN, in introducing the reader of the paper, said that his father, Sirdar Kunwar Bikram Singh, of the great house of Kapurthala, rendered yeoman service in the days of the Mutiny. He was a man of great distinction, both as a soldier and as an administrator; he was a distinguished Oriental scholar and a master of Indian classical music; he did a great deal to spread Western learning among his people and took a special interest in the education of women; he was one of the leading men of his Province, famous for his hospitality and charity, ever coming forward with offers of loyal service to the Government, by whom his advice was frequently sought. Sirdar Daljit Singh himself had a distinguished college career, and then devoted himself to the study of religion and philosophy. On the death of his brother he took a part in public life, and had played that part with usefulness to his country and with credit and distinction to himself. He had been a member of the Legislative Council of the Punjab; he was elected a member of the Legislative Council of the Governor-General by the Punjab Chiefs' Association, and he (Mr. Chamberlain) now had the satisfaction of having him as one of his colleagues on the Council of India. He was also the author of several works on Sikhism and on the philosophy of religion.

The paper read was—

THE SIKHS.

By SIRDAR DALJIT SINGH, C.S.I.,
Member of the Council of the Secretary of State for India.

It is a very big and difficult task to tell in one paper all about such "a singular nation," as Sir John Malcolm calls the Sikhs, the origin of their religion, the religion itseif, the lives of the ten Gurus who contributed to found it, the growth and history of the Sikh kingdom, its wars and constitution, and the part this people has played in the history of the Indian Empire down to the present day. But as the title of this paper is "The Sikhs" I have to include everything. I shall, therefore, make no attempt to say anything in detail, or to discuss anything, but just tell a sort of story from the beginning to the end. The paper may form, at all events, an introduction to a large subject, which should be called, "The Sikhs: their Religion and their Political History"; and as such I respectfully and with much diffidence offer it to this distinguished Society.

A RELIGIOUS BODY.

"Sikhs are excellent fighters." In these four words one may sum up all that is generally known of the Sikh people. But it is not the essential fact about them. They are, in the first place, devout disciples of a religious teacher, who in the process of evolution was the latest and most enlightened given to India. It was this circumstance, coupled with the true religious spirit of self-sacrifice aroused later by the tenth or last of their Gurus, that turned almost the whole sect into a nation. "Disciple" is the

meaning of the name they bear. Perhaps there could not be a better word than this. Customs, ceremonials, social and other laws had become so predominant a feature in almost all the religions of the time that the spirit was lost in form and had created barriers, even on the spiritual plane, that separate man from man and race from race. The very word Sikh is itself a symbol of self-surrender, giving at once an idea that religion is not a thing of outside world, but of heart, and not of form but of soul. The Sikhs consist, in fact, of two classes: (a) Peace-loving believers, to whom the name was first applied, and who are ignorantly grouped with the nebulous mass of Hinduism; and (b) the warriors, properly called "Singhs," a word meaning lions. The former constitute the field of recruitment for the latter. So vital is the religious spirit among them that one cannot become a Singh unless one receives a special baptism, called the *pahul*; and there is equally a form of baptism for the Sikh, known as Charan Ghal. Moreover, all who receive baptism, whether Aryans or aborigines, spiritual Brahmans or low-class "Shudras," Indians or foreigners, are alike admissible, and henceforth treat each other as members of the same family.

Numbers and Occupation.

It is difficult to estimate their exact number. Census reports put them at about 2,500,000, but take account of Singhs only. If we add those Sikhs who are classed as Hindus, the number must probably be doubled. The occupation of the Sikhs is, generally speaking, either the sword or the plough. It is a curious fact, and as old as the use of arms in India, that agriculture has always been held to be the proper means of livelihood of the warrior, and that from the best agriculturists the finest soldiers have always been drawn. Three-fourths of the Sikh population are tillers of the soil, and perhaps the best in India. In their proper home, the Punjab, they own nearly one-fourth of the cultivated land. Self-respecting and sentimental, the Sikh is a most willing and hard-working husbandman; and he is equally enterprising. He will go to any part of the world where he can find good labour; and so he is to be met with not only in the other Indian provinces, but in Afghanistan, China, Southern Asia, and America. Yet, wherever he may be, and whatever he may be doing, the Sikh cannot forget his sword and the spiritual tradition of his forefathers. The first sound of a call to arms will stir anew in him the spirit infused by his spiritual father, Guru Govind Singh, and find him ready to maintain that tradition at the cost of his life.

Number in the Army.

In normal times one-fourth of the Indian Army consists of Sikhs, and they have been described by such masters of the military art as Lord Roberts and Kitchener, and regarded by the whole administration of His Imperial Majesty, as the flower of the Indian fighting forces. Sir Lepel Griffin said: "The Sikh is always the same; in peace, in war, in barracks or in the field, ever genial, good-tempered and uncomplaining; a fair horseman, a stubborn infantry soldier, as steady under fire as he is eager for a charge. Hardy, brave, and of intelligence too slow to understand when he is beaten, obedient to discipline, devotedly attached to his officers, he is unsurpassed as a soldier in the East. There are many warlike races subjects of the Queen in India, but of these the Sikhs indisputably take the first place."

In trans-frontier skirmishes, in Afghanistan or China, Egypt or Abyssinia, within the boundaries of the Indian Empire or outside it, there has not been a single campaign in which Sikhs have not had the honour of fighting under the British flag and not kept up the worthy traditions of their Khalsa.

Early Conflicts.

The period from the middle of the fourteenth to the middle of the fifteenth centuries of the Christian era was remarkable, in the East as in the West, for political and mental upheavals, and for that religious and social awakening which always follows a time of storm. In Europe the Mohammedans had conquered Turkey and Greece, and had penetrated into Thrace and Hungary; in Asia Taimur had spread his kingdom from Siberia to the Arabian Sea, and from the Ganges to the Hellespont. There had been many wars and some great discoveries. For Europe the struggles of Luther and Calvin heralded the dawn of a new age of reform and reconstruction; and in India the monotheistic but quiescent teachings of saints like Kabir and Ramanand began to loose the fetters of superstition and priestcraft. The Punjab was a principal scene of conflict. Now known as the spear-head of the Indian Empire, it lay in the path of every invader; and in the fourteenth century frequent disturbance and bloodshed had lowered the moral standard and left a state of confusion. The fruit of this sowing began to be reaped in

the century that followed. The third day of the light half of the month of Baisakh (April-May) in the year 1469 A.D. is the first day of the history of the Sikhs. On that day the founder of the religion, Guru Nanak, was born at Talwandi, now called Nankana after the Guru's name, in the district of Lahore.

It is important to mark the significance of this event, and for that purpose to realise the state of society in which his teaching was to come as a new and great moral impulse, being distinct from any that had preceded it and singularly modern in certain aspects. The ancient "Dharma"—for religion is no appropriate name for it—had included all that is meant by duty and law as well as worship, from the most ordinary obligations of society and the household, sanitary precautions, customs and ceremonial rites to the national ideal, and from art, literature and daily prayers for the common human wants to the highest philosophy of the Vedanta. Such a system looks grand, nothing could be finer. But it is reduced to practice with difficulty, and the difficulty of adapting such a system to all times and civilisations is still greater. Nor could the religion of the invaders at once command sympathy. The need was keenly felt in the Punjab for a religion that should be simple, pure, and free of superstitions and dogmas based on morality; and this it was left for Guru Nanak to found.

Guru Nanak.

Guru Nanak was the only son of his parents, Baba Kalu and Tripta. Kalu, a Hindu and by caste a Kshattriya, held the respectable post of accountant in his village of Talwandi. Guru Nanak promised preternatural gravity from his childhood; and his retiring and meditative temperament, indifferent to the petty life around him, was a constant cause of anxiety. Trying to turn the channel of his thought, Kalu once gave him a sum of money and advised him to go to town and buy something that might be sold at a profit in the village. The future Guru had not gone far on his errand when he met a party of faqirs whom extreme hunger had deprived of the power of speech. He hurried to obtain provisions and feed the dying faqirs. The money that had been intended for some bargain was all bestowed in this work of mercy and compassion; and, when questioned by his father, Nanak said: "No bargain could be better than I made, for it is with God, not to perish with this body but to be reaped in the world to come." Kalu's anxiety continued, and he got Nanak married at the age of sixteen. When this availed nothing, he sent him to his only sister, Nanki by name, who was devoted to him, and whose husband, Jai Ram, procured employment for him under the Sultan Doulat Khan Lodhi. In vain. The Guru did his duties honestly, but he spent his leisure in the company of holy men or in deep reflection. At the age of about thirty-four, being then the father of two sons (Sri Chand and Lakhmi Das), and being a man of ripe experience and thought, knowing what it was that he had wanted, Nanak began to preach his gospel. He made four great tours in doing so. Two of them were within the boundaries of India, embracing all parts of it from Karachi to Assam and from Kashmir to Cape Camorin. The others covered Tartary, Turkey, Arabia, Afghanistan, Kandahar and Tibet, with Ceylon and some of the southern islands; and in most of these countries devoted disciples of the master are still found. It is characteristic that in these journeyings he was accompanied by his first disciples, Mardana, the musician, and Bala, who were so inseparably his associates that in all old paintings of the Guru they are included. Mardana was formerly a Musalman and Bala a Hindu Ját. Music took a conspicuous part in his life, his devotions and his meditations; and it is essential to the Sikh worship. In his later days, completing a long life of devoted effort, he settled down with his family near Batala, on the banks of the Ravi, one of the "five rivers" of the Punjab, and there expounded his doctrine to thousands who came to him. There, too, he devised and consecrated rites of morning song and evensong—rites of singular beauty and the most poetic appeal. Imagine the daily scene. Immediately before the sun appeared at dawn, the morning song was intoned by a reverent host. It preceded the service, as if invoking the Spiritual Sun to shed His rays and illumine the darkest chambers of the heart; and so, as the light came, it inspired a glad uprising of the spirit. At nightfall, again, when the sun's last beam was withdrawn, the hymn of the Reh Ras—the Right Path—moved the worshippers to inward contemplation. There, in 1538, the Blessed One passed away. That he was revered by Hindus and Mohammedans alike is plain from the fact that the sheet which covered his body at the time of his passing—for there was only the sheet left to them, the body not being found—was divided between these adherents, the one half to be buried by the Mohammedans and the other burnt by the Hindus according to their respective customs.

His Unique Teaching.

What were the distinctive features of this great teacher's gospel? Where we find a purely spiritual religion, it must always be difficult to distinguish it from others and to discriminate between them, for, after all, the truth is universal, and that which is not essential everywhere is not true. Guru Nanak taught that there is nothing higher or better, nothing more exalting, nothing more peaceful, nothing more full of joy and bliss, than to love God and to surrender oneself to Him by devotion.

"Sing and hear and put His love into your hearts:
So shall your sorrows be assuaged, and ye be absorbed in Him, who is the abode of happiness."

Of God he said: "He is one, His name is true, He is the Creator, the Primordial Being, devoid of fear and enmity, timeless, unborn, self-existent." These are universal truths. But there were important respects in which the Master's teaching was unique in India. In the first place, unlike the saints who had preceded him, he taught that good men were not to withdraw themselves from the world as the faqirs did, or to shirk those duties which Nature had laid upon them, but were so to live in the world, "as a lotus in water," that their virtue should subdue the evil in it, and, by "losing self in the Universal Self," transform the world's misery into happiness. Then, distinctively from Hinduism, he prohibited all kinds of worship except that of the Absolute, the Dweller in All Beings, and preached the equality of men, abolishing the caste system and founding a democratic brotherhood. He held that the true way of self-surrender is in service done to others, and that the key to all such service is a pure and high morality. Living the good life, men were to love the world because it is God's, and to love each other because God is in all men and they in Him. Ceremonies, laws and customs, he said, are the expression of passing phases of the human mind. He saw that they cannot suit the changing conditions and civilisations of different ages, and that they are valuable only as they declare at any time the pure moral law. The form is always changing, the spirit is eternal. This highest axiom of philosophy he found applicable to daily life; for, as the moral law, devotion and the selfless life are alone matters of the spirit, he regarded everything else as form, and, therefore, as liable to change according to the needs of the time. I think you will agree that there was something very remarkably modern and great in this outlook, something at once noble and practical, destined to affect India profoundly if it could prevail.

Some Sayings of the Master.

You will wish to hear some of the sayings of such a teacher, and of the stories told of him, recorded by his immediate successor. When he was seven years of age his father, Kalu, wished to celebrate the ceremony of investing him with the sacred thread of the Hindus, which can be worn by three higher castes only. In the midst of an assembly of relatives and friends, and in presence of the great Brahmin priests, he caused astonishment by refusing to wear the knotted thread of cotton, which was perishable and served no purpose. His protest is chronicled in verse which I translate—

Let the staple of your life be mercy, spun into a thread by contentment, strengthened by truthfulness, knotted by self-control.
Such a thread is needed for the soul, O priest: if you have such a one, invest me with that.

The saying lays down the four cardinal virtues that Nanak preached, "without which life is in vain" and "devotion impossible." There is a story that illustrates both his attitude to caste observances and his thought of right living. When staying in Emnahad at the house of a disciple called Lalo, a carpenter, he declined the hospitality of one Malik Bhago, the governor of the place. Insisting, the governor remarked that his food was surely better than that of a man of lower caste; but the Guru, with his usual calmness, replied that on the contrary the carpenter's food was much the purer, for it was rightly earned, while the Malik's was no better than blood sucked from the poor. His preaching may be illustrated by two quotations (sayings addressed to Mohammedans and Hindus respectively). To Mohammedans he said on one occasion—

Make kindness thy mosque, sincerity thy prayer carpet, what is just and lawful thy Koran,
Modesty thy circumcision, civility thy fasting; so shalt thou be a Musalman.
Make right conduct thy kaaba, truth thy spiritual guide, good works thy creed and thy prayer,
The will of God thy way, and God will promote thine honour.

When invited to share the worship of the Hindus at Jaggannath, he declared a purer sense of ritual and a disdain of idolatry in this hymn—

The sun and moon, O Lord, are Thy lamps; the firmament thy salver, the orbs of the stars the pearls enchased in it.

The perfume of the sandal is Thine incense, the wind is Thy fan, all the forests are Thy flowers, O Lord of light.

What worship is this, O Thou Destroyer of birth? Unbeaten strains of ecstasy are the trumpets of Thy worship.

Thou hast a thousand eyes and yet not one eye; Thou hast a thousand forms and yet not one form;

Thou hast a thousand stainless feet and yet not one foot; thou hast a thousand organs of smell and yet not one organ. I am fascinated by this play of Thine.

The light which is in everything is Thine, O Lord of light; from its brilliancy everything is brilliant.

By the Guru's teaching the light becometh manifest.

What pleaseth Thee is the *real* worship.

O God, my mind is fascinated by Thy lotus feet as the bee with the flower: night and day I thirst for them.

Give the water of Thy favour to the sarang Nanak, so that he may dwell in Thy name.

Before his passing away, and while in perfect health, the Guru selected his successor, a recent convert whose devotion and fidelity he had quietly marked; and by this choice he was the first Indian teacher to honour the fittest without respect to rank or parentage.

The Guru Succession.

A saintly line of Gurus, making ten in all, watched over and guided the development of the new religion, which presently declared against such specific errors and was sharply defined by events. Space and time being too short, I cannot dwell on the lives and sayings of each one of these; I can only try to show how far, besides imparting spiritual instruction as they followed in the footsteps of their Master, they affected the social, political and literary world around them. The religion owed to Guru Angad, the first of them, the invention of the Gurmukhi character, which has proved to be best suited for the Punjabi language. The first book that its inventor wrote in this script was the life of the Blessed One, from the lips of Nanak's lifelong companion Bala. The third Guru, Amar Das, forbade suttee and upheld the marriage of widows, reforms that make a landmark in Indian history. To the fourth, Guru Ram Das, the Moghul Emperor Akbar gave that piece of land at Amritsar, "the Pool of Immortality," where now stands the Golden Temple, the Mecca of the Sikhs. The fifth of the line, Guru Arjan, compiled the Granth, the sacred book of the Sikhs, enshrining the sayings of himself and his predecessors; which to this day both serves and is respected as "the living Guru" for purposes of spiritual teaching. He was a great supporter of education, and from him emanated the system of primary education in the form of "Dharamsalas" dealt with later on. So far, there was no hint of a warlike spirit in the new religion.

Nationality.

But at this time the Moghul rulers began to show signs of a different policy, and the gulf between the ruler and the ruled had widened to its full width, into the details of which I need not enter, but which led the sixth Guru, Har Govind, to take up arms; and it was now that, under the stress of events, the latent spirit of nationality first awoke, and peace-loving men began to change into a militant race. The spiritual leadership was continued by the Gurus Har Rai, Harkisan, and Tegh Bahadur; and it was not until the days of the famous tenth Guru, Govind Singh, that the Singh warrior class was constituted.

A Great Martyrdom.

Guru Govind Singh was the son of Tegh Bahadur, whose martyrdom directly furnished the motive for that development. The Emperor Aurangzeb had required that the Hindus of Kashmir should embrace his own faith, and had been answered that they would be guided by Guru Tegh Bahadur. The Guru was at once summoned to Delhi. He knew that he must sacrifice himself to save them; but, wishing before his departure to test his son, then nearing his majority at fifteen, and to see if he had the true temper of a leader and successor, he asked Govind what he thought. The boy answered, nobly, that there could be nothing better than such a sacrifice, and the Guru set out for Delhi with a light heart, satisfied. At Delhi two memorable things befell. One was the utterance of a remarkable prophecy, which was to knit a close tie between the Sikh people and the English when it was remembered long after. The Guru, as he stood one day on the roof of the house where he had been lodged, was accused of gazing at the harem of the Qazi across the way. He answered: "I look towards the West"; and, when asked what he meant by this, he said: "I do so, because it is from the West that a

people must come, a nation of men wearing hats on their heads, who shall bring with them justice, prosperity and peace." The other event was his death, the manner of which was very striking. A miracle had been demanded in proof of his claim to be a divine teacher, and he had declined that test; but, being imprisoned now and sick of daily torture, he said, "I will show you a miracle." In the presence of the Emperor he wrote some words upon a sheet of paper, folded it, tied it with a thread round his neck, and then bade them bring the executioner with his sharpest sword to behead him. His head fell, severed at once from the body. But what he had written was these words: "I give my head but not my religion." The superbly ironic miracle was a portent. Estranged once for all, the Sikhs under Govind Singh, and later on under different warrior leaders, were committed in defence of the faith to form their nation and to break the power.

Institution of the Pahul.

I pass over the years of Guru Govind Singh's preparation for conflict, and come to that most important event in the history of the Sikhs which is known as the Great Test, and to the organisation of the "Khalsa." Determined to evolve out of this religiously united people a nation of warriors, he called a huge meeting of the Sikhs on the first of Baisakh (April 12th), 1698. It was drawn from all parts of the Province, and it met in an extensive plain, in the midst of profuse verdure, in one of those beautiful valleys which lie at the foot of the lower range of the Himalayas. Out of a tent pitched in one corner appeared the Guru with a drawn sword in his hand, and demanded for the establishment of the kingdom of righteousness the head of one of his Sikhs to be sacrificed. A man instantly arose, and with folded hands said, "Yes, O Lord, I am at your service. Do with me as you please." This brave soul was Daya Singh, a Kshattriya by caste. The Guru led him inside the tent. A moment later he appeared again with the sword dripping blood. When he demanded another head the ordeal was of the severest; yet a second man, Dharma Singh, responded to the call. Three times more the Guru made his demand, and three more heroes offered themselves—Himmat Singh, Mohkar Singh, and Sahib Singh, all three of low caste. There were many others ready to sacrifice their lives for the true cause, but the Guru did not appear again. Soon afterwards the curtains of the tent were drawn back, and, to the great astonishment of the assembly, there stood revealed the five chosen ones, typical of that region of five rivers of which the Punjab was to be formed. Addressing the multitude, the Guru said: "Heaven is but a property of noble souls like these; nevertheless there is work for them yet in this world. I wished to find out, in the presence of a full meeting of my Sikhs, what each individual was capable of; and we have found that out."

This ordeal was followed by a great Durbar, in which the first ceremony of the Pahul baptism was performed. An iron vessel was brought, some water and sugar were put into it, and these were stirred with the point of the sword while the Japji and a composition of the sayings of Guru Govind Singh were recited. The Guru called this mixture *shirbatt*, as Amrita—ambrosia. Some of it was sprinkled on the heads of those first five, and the rest was drunk. Then he in turn had himself baptised by the five. In virtue of this ceremony they became members of an equal brotherhood; and they were invested with swords, and stood vowed to their faith as sons of the Guru. The spirit of their Guru had entered into them. By companies of five, all who offered themselves were afterwards inaugurated; they were hailed as Singhs, or lions, warriors or Kshattriyas without distinction of caste, a name which had been used by Hindu Kshattriyas or warrior caste alone; and thus was formed the Khalsa, or fighting commonwealth of the Sikh nation. In less than a fortnight 80,000 Sikhs had flocked around the Guru as Singh. Later on a few Mohammedans and a large number belonging to the low caste considered as "untouchable" amongst Hindus were also baptised. The fact that even under the circumstances a few Mohammedans accepted the religion is remarkable when arms were used for conversion to the faith of the rulers. His purpose and the pure creed of Guru Nanak were proclaimed in an eloquent exhortation; and, by way of marking a clear outward distinction from Mohammedans and Hindus alike, not only were certain customs and insignia forbidden to them, but as warriors they were enjoined to wear "the five K's"—namely, the *kes*, or uncut hair; the *kripan*, or dagger; the *kanga*, or comb; the *kuchh*, or short breeches ending at the knee; and the *kara*, or iron bangle. They were to worship neither idols nor the dead, no Hindu tomb and no grave, and abstain from the use of tobacco. Finally, they were to greet each other with a special salutation, meaning "The Khalsa is of God and His is the victory."

Govind Singh's Achievement.

This was the starting-point of the Sikh nation. Govind Singh had created a force which soon proved formidable, even against the might of Aurangzeb. In the course of more than thirty years, during which he was the spiritual head of the Sikhs, he commanded in many battles and won some signal victories, which led to the rise of the Khalsa as a commonwealth and a power, and were one cause of the fall of the Moghul Empire. Historians all agree upon his genius. He was the greatest teacher and reformer of his age, a great organiser and leader in war, and an ideal of self-sacrifice, self-denial, and modesty in his relations with the brotherhood he had created. It is said that a Sikh once brought to the Guru, as a gift, a pair of wristlets set with precious stones, worth a hundred thousand rupees. Govind Singh would not accept the offering. At the moment he was seated on the bank of a river, and on the Sikh insisting he put the jewels on, but a few minutes later dropped one of the wristlets into the stream. Anxious for its value, the devoted Sikh announced a reward of a thousand rupees for any man who should recover it. A diver came forward. Before entering the water this man asked the Guru to point out the exact spot where it had fallen; and thereupon Govind Singh, by way of doing so, cast in the other wristlet after it. As for the spirit of self-sacrifice, we have seen how it appeared in him under the test of his father. And what sacrifices could be greater than he suffered in the loss of his four sons? When that unhappy event reached his ears by which two of the younger were buried alive at Sirhind, not a single tear was seen in his eyes, and the only words he uttered were, "Thy will be done." This most cruel episode was never forgotten by the Sikhs; and Sirhind was for a long time the chief point of their warlike attacks, until it was finally conquered and destroyed. The original town still forms a part of Patiala State. The fact is a sufficient confutation of the vulgar fiction that the purpose of Sikh belligerency was plunder. They, too, exhibited the spirit of self-sacrifice. Govind Singh had so conspicuously imparted it to his followers that, with regard to certain Sikhs whose skin and flesh were torn by executioners under the orders, a Mohammedan writer says: "It is singular that these people not only behaved firmly during the execution, but they would dispute and wrangle with each other who should suffer first; and they made interest with the executioner to obtain the preference." In the battlefield every Sikh bore himself fearlessly, repeating the saying of the Guru—

> O Lord, give me only this blessing, that I may never go back from doing virtuous acts . . .
> And when I go into the field that I may be killed there, and my firm belief be in victory.

Such was the national spirit created by Guru Govind Singh, and yet of these followers he said—

> Verily I am but one adorned by them; otherwise there are millions of poor men like myself.

Besides all this, I have to complete his picture by a reference to fostering services to the Hindi and Punjabi languages. He was an excellent poet of Hindi as well as Persian. In Persian he wrote the famous letter in verse to Aurangzeb known as "Zuffer Nama." In Hindi there are a few books and a good many verses written by him. He was so fond of poetry that he had always with him a school of poets, who translated numerous Hindu Shastras and some Persian manuscripts into Hindi verse to make a literature of their own. The Granth of the tenth Guru contains all such poetical works. It is notable that music and poetry have been so intrinsic to the religion that these arts are a predominant feature of all the Sikh ruling courts.

The last of the Gurus died peacefully in 1708, in the midst of his devotions at Nadir in the territory of H.H. the Nizam, where later Maharaja Ranjit Singh erected the tomb, and H.H. the Nizam's Government assigned a sumptuous Jagir for the upkeep of the same. The value of his Pahul was to be recognised in due time by the British Government, when it was made compulsory upon all Sikhs entering the Indian army; and I desire at once to acknowledge that this recognition has been largely instrumental in maintaining the spirit of the nation.

Rise of the Khalsa.

On the death of Guru Govind Singh, the Khalsa was led by an intrepid warrior named Banda, who for a time made himself master of the region between the Sutlej and the Jumna. But it is chiefly important to note the rise of that organisation. Guru Govind had said: "The Khalsa arose from the Guru, and the Guru from the Khalsa." Again: "The Guru shall dwell with the Khalsa; and wherever there shall be five Sikhs gathered together there shall the Guru be also present." There came into existence a sort of a system of a cabinet or national council, which, having been founded by Guru Govind himself, with a quorum of five,

replaced his personal authority in it, and which sometimes elected a leader called the Jathaidar. When this met, the Khalsa had an opportunity of expressing their feeling as to current events; and the cabinet's decision was known as the Guru Mata. Sir Charles Malcolm says of the institution of this cabinet and the Guru Mata that: "It furnishes a fresh proof of the comprehensive and able mind of this bold reformer, who gave by its foundation that form of a federative republic to the commonwealth of the Sikhs . . . by giving them a personal share in the government and placing within the reach of every individual the attainment of rank and influence in the State." There is a significant story of the election of a Jathaidar, Kapur Singh, and the high appreciation for the sense of justice shedding a humane light upon a period of cruel trial. The national council being assembled, it was said: "We should elect such a man as will see all parties with the same eye." In a recent battle Kapur Singh, carrying a water-skin, had been seen giving drink to the wounded, and it had been noted with admiration that in doing so he did not distinguish between a Sikh and a Mohammedan. He was elected for this magnanimity. But it is to the second of such chosen leaders, Jassa Singh, with his contemporary Ala Singh, that the credit of actually founding the kingdom of the Punjab must be given. The Sikh commonwealth at this time was divided into twelve families, clans or *misls* as they were called, and Jassa Singh, belonging to one of these, held together a confederacy on the northern side of the River Sutlej; while Ala Singh stood in a similar relation to the *misls* of what are now known as the Phulkian States on the southern side. Jassa Singh, the founder of the ruling house of Kapurthala, now the premier ruling State on the trans-Sutlej side of the Punjab, commanded universal respect among the Sikhs; and even the family of Ala Singh considered it an honour to be baptised at his hands. His was a great achievement. Compared with the romance, the bloodshed and the heroism of that period, there is nothing in the history of Scotland before the Union that can be considered on the same scale, for Scotland had but only a single though an inveterate enemy, but the Punjab was the high road of every foreign invader and the first brunt of the onset fell upon the Sikhs.

The Kingdom Founded.

Jassa Singh's outstanding bravery and political skill founded the kingdom of the Khalsa at Lahore in 1753. And for the first time coin of Khalsa was struck in the mint of the Moghuls, bearing the inscription, "Coined by the grace of the Khalsa in the country of Ahmud, conquered by Jassa the Kallal"; and he was the first ruler to be called by the Sikhs their king. Thus the force created by the genius of Guru Govind Singh began to come into its own, and even the relentless energy of Nadir Shah and Ahmad Shah Durrani could not subdue it. It was at this time that the Golden Temple was rebuilt at Amritsar.

Ranjit Singh.

On the foundation laid by Jassa Singh, Ranjit Singh, the Lion of the Punjab—who began to rule at Lahore in 1799—built the complete sovereignty. The policy of Maharaja Ranjit Singh, who belonged to the Sukarchakia *misl*, is notable in these respects—that among the officials of his Court, high and low, he had both Hindus, Mohammedans and Sikhs; that in his armies there were officers and men of all ranks belonging to the three religions; and even Europeans. By the end of 1834 he had not left a trace of Afghan authority east of the Indus, and ruled over a kingdom with an area of some 145,000 square miles.

At the time of Ranjit Singh's accession only three *misls* commanded much influence. On the northern side of Sutlej two of them had founded independent States, namely, the kingdom of Lahore and Kapurthala, the latter ruled by Fateh Singh, a descendant of the great Jassa Singh and a chieftain of whom Sir Charles Metcalfe said that he was "the equal, if not the superior, of Ranjit Singh in rank and power." The third, on the southern side, had founded under Ala Singh the State of Patiala, together with the States of Nabha and Jindh, known as the Phulkian States. When Ranjit Singh was on the threshold of his career, in 1806, the East India Company became involved in the second Mahratta war, and these three States were perhaps the first in Northern India to make alliances with the Company. There you saw the effect of the prophecy uttered by Guru Tegh Bahadur. The result of these alliances, and of the rout of Jaswant Rao Holkar, the Mahratta chief, was to free the hands of Ranjit Singh for those campaigns in which, with the powerful aid of Fateh Singh, he wrested the provinces of Multan, Kashmir and Peshawar from the Afghans.

Annexation and the Mutiny.

After the death of Ranjit Singh a state of anarchy prevailed in the Kingdom of Lahore,

and constant troubles obliged the British administration to annex that kingdom, while the other States continued to exist independently. The policy of Lord Dalhousie by admitting them to the British Army as valorous friends, and the trust thus placed in them, enlisted the martial spirit of the Sikhs almost immediately on the side of the British. By some critics this policy was questioned; but in 1857 the Mutiny put it to a supreme test, and the Khalsa did not waver. The Kapurthala and Phulkian chiefs were the first leaders to take the field against the mutineers, and their example was followed throughout the Punjab. Sir Lepel Griffin acknowledges freely that they acted "on the very first alarm, and without waiting to see whether the omens were auspicious or hostile." The promptness and entire devotion of the Patiala and Kapurthala chiefs have, I believe, endeared their memory in particular not only to Englishmen, but to all Indians who appreciate the blessings of peace, prosperity, and freedom. They put all their resources, without reserve, at the disposal of the British authorities, and when the Punjab declared itself on the same side the issue ceased to be doubtful. To the mutineers the fall of Delhi was a death-blow. When you consider that eleven years only had passed since the annexation, and that this had been preceded by two wars, I do not think you will underestimate such a proof of attachment and spontaneous loyalty.

The Sikh Civilisation.

Let me sketch, briefly, the civilisation which had begun to shape itself among the Sikhs at this time. Sikhism is eminently a literary religion. As we have seen, the Sacred Book compiled by the fifth Guru, and supplemented by the ninth, contains hymns of singular beauty, the singing of which forms the most important part of our worship. They are mostly in Punjabi, though the hymns of Guru Nanak include a number in Rajasthani and Sindhi, and a few in Persian. The original manuscript is preserved at Kartarpur, in my own district. This Sacred Book, carried at the head of all Sikh regiments, is considered as a living Guru. Besides this sacred volume, the sayings and works of Guru Govind Singh, and the compositions of all his chief poets, are collected in another book, which is generally spoken of as the Granth of the tenth Guru. They include not only hymns, but regular compositions in the language of Hindi classical verse. A system of education introduced by the Gurus is noteworthy. In connection with religious centres called Dharmsalas, established in every town, and even in every village where the majority of the population were Sikhs, there was a learned teacher whose duty it was to impart secular as well as religious instruction. This system corresponded to what in modern times is called free primary education. There was also a system of tribunals, the Panchayats, deriving its name from the quorum of five or "Punch" fixed by the Guru for the National Cabinet, a system which the British Government has lately been disposed to revive. The functions of this tribunal were civil and judicial. But the greatest proof and test of our civilisation is its social effects throughout the Province. It is only in the Punjab that you may see to-day a free intercourse between Hindus and Mohammedans in eating and drinking, and that the social life is cosmopolitan. Whereas, indeed, even a Brahmin of one province will not eat with a Brahmin of another province, and elsewhere one man fears to be defiled by another's shadow.

Art.

Of our arts, the chief example is the Golden Temple. How shall I describe that glory of architecture? It stands four-square, reflected on all sides in the waters of the sacred pool, a shining splendour of gold and marble. A marble gate and bridge form its noble approaches. From the picture I show, you will see that the style is Mohammedan, with Hindu details, and that the high plinth is of marble, with a golden superstructure topped by minarets. In this temple only the Sacred Book is read, and the orisons for dawn and sundown are daily sung. As the light of each day breaks there are thousands of worshippers, from the poorest to the richest, waiting to hear the first verse when the Book is opened. The scene is wonderfully solemn and uplifting. Then consider the historic interest of the temple's surroundings. On the outer margin of the pool there are houses built by the *misls* and by other leading men of the past. Devotees come and sit between this façade of houses and the water, where a broad marble path goes round the "Pool of Immortality." The temple is radiant under the Indian sun. And when the pool is illuminated with floating lamps for the Dewali Festival, and you see it gleaming beneath a canopy of stars, it leaves one of those ineffaceable memories which all men cherish.

The Dominions.

Just a word to compare the Sikh dominions as a whole with the present Province of Punjab.

As I have said, the Sikh dominions extended from Delhi to the Khyber Pass, and from Multan to the Kara Koram Mountains. It included the States of Jammu and Kashmir, the district of Hazara, Kohat and Bannu, and also the district of Derajat. The whole cis-Sutlej side was under the rule of the descendants of Phul. On the northern, or trans-Sutlej side, a part of the Ludhiana, Jalandar, Ferozpur and Amritsar districts was under that of the Kapurthala house, descendants of Jassa Singh; while the rest was known as the Lahore Kingdom under Maharaja Ranjit Singh's government. As it now stands, the whole region is divided into three parts. Two, the Punjab proper and the North-west Frontier Province, are under British administration, while the third forms the State of Jammu and Kashmir.

States.

Within the States administered by the British Government, the Phulkian and Kapurthala houses still enjoy their ruling powers; and two more ruling States, though much smaller, are recognised besides, viz., Faridkot on the trans-Sutlej side and Kalsia on the other. The total area of these various ruling States is about ten thousand square miles, and their military strength is seven thousand with 152 guns. This, from the Mutiny down to the present world crisis, has always in time of need been put at the disposal of the Government, together with every other resource of these independent States.

Aristocracy.

Besides the ruling houses, there were at the time of the annexation a host of smaller chiefs or large landholders, Jagirdars, together with some nobles of Ranjit Singh's court. They now enjoy nearly the same privileges, forming the famous aristocracy of the Punjab. They are the social and political leaders of the Province, and have never failed to serve in times of war and peace alike. It was due to Sir Charles Aitchison, one of the ablest Governors the Punjab has ever had, that this nobility was brought together, along with the aristocracy of Hindu and Mohammedan subjects, to form a class whose influence being thus maintained should be increasingly useful in days to come. He founded at Lahore the "Chiefs' College," to impart education to the sons of this nobility and to fit them for the work that lay before them. The students of the college now occupy places of distinction in Government services and Councils, and prominent positions on public platforms. Recently we have formed the Punjab Chiefs' Association, the principal objects of which are to bring about a better feeling between the ruler and the ruled, and to safeguard the interests of the class in particular and of the Province in general. In answer to an address from this association, Lord Hardinge said the other day: "It is no small consolation to think that I can count for understanding and support upon your association . . . to co-operate in the furtherance of the policy of the Government."

Education.

I have already noted the interest taken by the Gurus in literary and educational propaganda. I have also mentioned the system of free primary education founded by the first Guru himself. Up to the time when the Lahore kingdom was established that system had not shown any results worth mention, except that the whole population was accustomed to the Gurmukhi character. Under Rangit Singh it was improved by starting schools here and there, including even a girls' school, which existed at the annexation, as remarked by Lord Lawrence. The time had now come to reap the seed thus sown. Alongside the Government and other educational institutions of the Punjab, the Government has enabled the Sikhs to develop an extensive system, though they constitute a minority of the population. We have a national residential college at Amritsar, affiliated to the Punjab University; colleges in each Sikh State; and over 100 high schools, the number of which is continually increasing. These schools, managed and taught by Sikhs, are under the control of a Sikh educational conference, which meets annually and which has always been able to rely upon receiving help from the Government. It is noteworthy that, save at some places in Mysore and Travancore, female education in India is greatest among the Sikhs. We have a very large residential school for girls at Ferozpur, with accommodation for at least 500 or 600 pupils, and more than twenty-four other Sikh girls' schools exist in the Province. It is hardly necessary to say that, but for State help, these developments would have been impossible to a small community like ours. At the same time our students share very fully in the benefits of the Veterinary College at Lahore, and the Agricultural College at Lyallpur.

Finance and Agriculture.

In the first place, it is difficult to get the exact figures of the revenue of those days, and, secondly,

the system of revenue being different it is so difficult to compare the past and present revenues of these provinces. There is, however, no question to the fact that the revenues have increased immensely. This augmented yield is due to enormous material benefits conferred on agriculture, for which source of wealth the Province is most famous. In the first place, irrigation by wells alone has increased by 60 per cent., if not more. The total number of wells is over 300,000, and new ones are being continually sunk. Besides these, there have been works of irrigation costing £14,000,000, and doubling the produce of the Punjab. There are some 18,000 miles of canals and distributing channels. The value of the cultivated land has increased threefold; and new land, brought under cultivation by colonisation schemes, has provided more than 100,000 peasants with fertile farms. These schemes tend to make the Province the granary of India. Significantly, it is in the Punjab that we have the headquarters of the longest railway line in India, the North West Railway managed by the Government.

Sikh Loyalty.

The story of Sikh loyalty to the Empire deserves to be written at greater length than for such an occasion as this. You will allow it to be one of the brightest chapters in Indian history. I remember hearing my father—who, with his brother, the then Maharaja of Kapurthala, led the Kapurthala forces in the Mutiny—describe the enthusiasm which prevailed throughout the Sikh world, every man filled with the zeal of the Khalsa; how eagerly they rallied and with what energy they fought. It left an indelible impression on my mind.

There was another great revival of fighting fervour in the second Afghan War, and you will recall, in connection with the Chitral Expedition later, that heroic defence made by a handful of Sikhs at Saragarhi. Some twenty men were surrounded in a small fortress by several thousand Afghans, against whom they had to guard a store of munitions. Their position was hopeless, but they did not surrender. Every man died at his post. The last of them, turning from the gate when he had fired his last cartridge, went into the store-room and blew up the fort, dying rather than leave it to the enemy. A memorial to these gallant heroes, built by the Government, now stands at Amritsar, and another at Ferozpur. I was at Simla when the present war broke out, with the Maharajas of Patiala and Kapurthala, and the other Maharajas and Rajas, and I can testify to the eager loyalty with which the great Sirdars and the rest of the nobility and gentry placed all their means, men and money, and their personal services at the disposal of the Government instantly. There was happily an equal enthusiasm throughout British India on this occasion; but I may be forgiven for speaking of my own people of all ranks, hurrying to their depots, anxious to strike a blow for the Empire they have learned to look upon as partly their own. It was not as if the permanent Sikh army of 30,000 men had merely been willing to do their duty as soldiers of the King-Emperor. From villages, towns and great cities came out even retired and old Sikhs eager to fight the enemy of their "beloved Sarkar." The independent ruling States furnished munificent and spontaneous help in money and men, and their forces are fighting side by side with the splendid volunteers of our whole Empire in Flanders and France, Egypt, Mesopotamia, and East Africa—all the theatres of war. Once more the warriors of the Khalsa have proved themselves, in the words of Sir Lepel Griffin, "Equal to any troops in the world, and superior to any with whom they are likely to come in contact." Sir Ian Hamilton's great and generous praise of the quality shown by the 14th Sikh Regiment in the Dardanelles is fresh in your minds. So it will be, I do not hesitate to say, as long as the spirit of Guru Govind Singh animates the Khalsa, and the prophecy of the ninth Guru is fulfilled by the British Raj in India. As in the days of old, when their own cause was alone at stake, each and every Sikh will be at all times ready to leave the plough and take the sword in defence of what is now the common heritage of many peoples, and the glory of them all.

[The discussion on the paper will be published next week.]

HEMP SUPPLIES AVAILABLE.

An interesting and useful *résumé* regarding the sources of hemp supply at present available has been prepared by Professor L. H. Dewey, fibre expert to the United States Department of Agriculture. In this *résumé* Professor Dewey deals only with the true hemp, or soft fibre, such as is produced in Kentucky, and omits all reference to abaca, the so-called "manila hemp"—a hard fibre obtained from the leaf-stems of a banana-like plant in the Philippines; henequen—a hard fibre obtained from the leaves of an agave in Yucatan and Cuba; and true sisal—a hard fibre from the leaves of another agave in East Africa, the Bahamas, and Hawaii. Abaca, henequen and sisal are used

for binder twine, rope, cables and hawsers. Hemp is a fibre of very different character, not suitable for binder twine or for coarse cordage, and is used chiefly for "commercial" tying twines, carpet warps, and tarred cordage of small diameter. Being prepared and spun on different machinery and used for such different purposes, it competes only in a very indirect manner with the hard fibres.

The price of henequen has increased owing to political disturbances and a heavy export tax in Yucatan; the price of sisal has risen owing to the supplies from German East Africa and Java being practically cut off by the European war; and the price of abaca has advanced owing to typhoons in the Philippines and difficulties in ocean transportation, but the higher quotations for these hard fibres do not directly affect the price of hemp.

Professor Dewey points out that the true hemp plant, *Cannabis sativa*, is cultivated commercially for fibre production in Kentucky, Ohio, Indiana, Wisconsin, and California, and in China, Manchuria, Japan, Northern India, Turkey, Serbia, Rumania, Russia, Austria-Hungary, Italy, France, Belgium, Germany, Sweden and Chile. The principal countries producing hemp for export in recent years are Russia, Italy and Austria-Hungary. The supplies from these countries are now practically cut off, and the prices currently quoted for hemp fibre are abnormally high.

The importations of hemp into the United States in recent years have ranged from 5,000 to 8,000 tons annually, valued at £200,000 to £300,000 at the point of shipment. With these importations stopped and a reduced crop in Kentucky last year, the hemp-spinning mills—about twenty in number—in the United States are threatened with a hemp famine.

The estimated production of hemp fibre in the United States from the 1914 crop, of which at least one-fifth remains to be broken out, is as follows:—

State.	Area.	Average Yield per Acre.	Estimated Total Yield.
	Acres.	lb.	lb.
Kentucky . .	2,500	600	1,500,000
Ohio . . .	500	1,000	500,000
Indiana . . .	1,000	900	900,000
Wisconsin . .	350	1,000	350,000
Michigan . .	40	750	30,000
California . .	600	1,200	720,000
Total . .	4,990	802	4,000,000

The statement of acreage and estimated production does not include 1,500 acres in Indiana and Ohio sown with imported seed, producing a crop of such inferior quality that most of it was not harvested. The acreage in Kentucky was below the normal, and the severe drought in that State reduced the yield. There is some hemp, still unbroken, left over from the 1913 crop, but the total of all the fibre available until the crop of 1915 is ready for market is less than 2,500 tons, or about one-fourth of the normal supplies required by American spinners. Much of this is already sold or under contract.

Flax is the only other fibre of commerce similar to hemp in essential properties, but flax is even more difficult to secure than hemp at the present time. Indian jute, sunn, and chingma (China jute) may be substituted for hemp, but they are all weaker and very much less durable than that product. There are no satisfactory substitutes available.

An investigation has been made through the American Consular Service as to the supplies of hemp in China and other countries where it is produced but heretofore has not been exported to the United States. Chile, the only country in the Southern Hemisphere cultivating fibre hemp, does not produce enough for home consumption. It seems impossible to secure supplies from Serbia, Rumania, or from the Damascus region of Turkey. The spinning-mills in Japan consume practically all of the 10,000 tons of hemp and jute produced annually in that country and more than 15,000 tons additional imported from China and India. Excellent hemp is produced in Japan, the best and finest being that of the Tochigi district, while that of Hiroshima is more nearly like Kentucky hemp.

The production of hemp in China, the original home of the hemp plant, is probably greater than that of any other country except Russia, and the new Republic seems to offer the only promising sources of supply. Unfortunately the name "hemp," carelessly employed in the United States to indicate nearly all long fibres, is used in a similar manner by English-speaking people in China, and the Chinese name "ma" is used in the same unfortunate way. This confusion of terms causes some uncertainty, for the statements made in the reports submitted by Consuls include with hou-ma or Hsien-ma (hemp), ching-ma (China jute) in the north, huang-ma (India jute) and tung-ma (Sterculia fibre) in the south, and ch'u-ma or tsu-ma (ramie) in many localities. In ordering hemp from China, therefore, it is necessary to specify distinctly just what kind of fibre is desired.

The American Consul-General at Tientsin states that there is an abundance of fibres available for shipment from that port. The best is the hemp from the Kalgan district. The next best, from the Shun-te-fu district, is somewhat coarser. Ching-ma, known in the fibre markets of the United Kingdom as Tientsin jute, and ramie, from the Province of Hupei, are also sold in Tientsin.

The American Vice-Consul at Newchwang reports that two fibres, hemp (called Hsien-ma) and ching-ma, are exported from that port. The shipment of these fibres from Newchwang in 1914 amounted to 882,000 lb. This all went to other

parts of China, but with favourable market conditions some of it could probably be secured to meet a foreign demand.

The American Consul at Chungking, in the Province of Szechwan, reports that about 4,500,000 lb. of hou-ma (hemp) were shipped from that Province in 1914 to ports in the Yangtze Valley.

Samples of the fibres were received with the reports from the Consular officers, and were found to be all well cleaned, the hemp samples having excellent strength. The fibre is stiffer than dew-retted Kentucky hemp, and very different in appearance and feel from water-retted Italian hemp. The Kalgan, Shun-te-fu, and Hsien-ma samples, all true hemp, are very light coloured, suggesting some of the best grades of Russian or Californian hemp. The strands are in ribbons one thirty-second to one-fourth of an inch wide.

Ching-ma (China jute) is lustrous, yellow-white in colour, ribbon-like but fuzzy in texture, stronger than India jute, but more difficult to prepare for spinning because of its ribbon-like strands with fibres apparently interlacing towards the base. This fibre may be obtained in greatest abundance and at a relatively low price, but it is weaker and much less durable than hemp.

INTERNATIONAL INSTITUTE OF AGRICULTURE.

The June number of the *Bulletin of Agricultural and Commercial Statistics*, published by the International Institute of Agriculture, commences with information as to areas sown, condition of crops and yield in the Northern Hemisphere.

As regards the areas under cereal crops, amongst the chief new matter published in the present *Bulletin* may be noted the data from Spain (wheat 4,155,512 hectares, or 102·3 per cent. of the area in the preceding year and 107·6 per cent. of the five years' average 1909 to 1913, barley 1,414,454 hectares, or respectively 92·3 per cent. and 99·6 per cent.), from France (wheat 5,205,620 hectares, or 91 per cent. of the area of the preceding year and 80·4 per cent. of the five years' average 1909 to 1913, oats 3,044,760 hectares, or respectively 90·2 per cent. and 76·6 per cent.), from Canada (wheat 4,650,583 hectares, or 88·5 per cent. of the area in the preceding year and 109·5 per cent. of the five years' average 1909 to 1913, oats 4,249,140 hectares, or respectively 92·4 per cent. and 117·5 per cent.) and from the United States (spring wheat 7,224,121 hectares, or 91·8 per cent. of the area in the preceding year, and 95·3 per cent. of the five years' average 1909 to 1913, barley 3,139,180 hectares, or respectively 104·9 per cent. and 101·8 per cent., oats 16,430,009 hectares, or respectively 99·6 per cent. and 108·7 per cent.).

Some forecasts appear as to the wheat crop of 1916. In the United States the winter wheat crop is estimated at 127,611,469 quintals (71·6 per cent. of that of the preceding year, and 106·3 per cent. of the five years' average 1909 to 1913), and the spring wheat crop at 67,044,929 quintals (69·1 per cent. of that of the preceding year, and 100·4 per cent. of the five years' average). British India has reaped 86,546,883 quintals of wheat, or 82·9 per cent. of the yield of 1915 and 88·6 per cent. of the five years' average.

The forecast from Japan is for 6,653,000 quintals of wheat, or 94·8 per cent. of the crops of 1915, and 101·2 per cent. of the five years' average. That from Switzerland is for 1,172,000 quintals, with respective percentages of 108·8 per cent. and 129·9 per cent.

The United States estimate of the rye crop is for 11,091,093 quintals (88·8 per cent. and 125·1 per cent.), of the barley crop for 41,208,039 quintals (79·9 per cent. and 104·1 per cent.), and for 182,091,996 quintals of oats (81·4 per cent. and 110·9 per cent.). The Japanese forecast of barley is for 21,733,000 quintals (99·0 per cent. and 102·0 per cent.).

The crop conditions are generally satisfactory in France, Great Britain, Italy, Luxemburg, Sweden and Egypt, but less so in Hungary and Switzerland, while the season is said to be very late in Ireland, in the Netherlands and in Canada.

In the *Bulletin* information is added regarding crop conditions for flax, potatoes, sugar beet, tobacco, hops, hemp, rapeseed, cotton, vines and olive trees, and the development of the silkworm industry in the Northern Hemisphere, as well as the preparations in the Southern Hemisphere for the season of 1916–17.

The agricultural section of the *Bulletin* terminates with supplementary information on the yields of 1915 in Germany, Spain, Italy, and the United States, together with those of 1915–16 in Paraguay.

The commercial section of the *Bulletin* contains the usual tables of imports and exports, of stocks, and of prices for cereals and cotton in the principal markets. It also includes information on the current rates of ocean freight for cereals and cotton on the more important routes.

GENERAL NOTES.

GROWTH OF PETROLEUM-REFINING INDUSTRY.—The value of the annual production of the petroleum-refining industry of the country, according to the preliminary report by the United States Bureau of the Census, increased 67·2 per cent. between 1909 and 1914. The total cost of the crude petroleum increased 64 per cent. between those years. The production of naphthas and lighter products, chiefly gasoline, increased from 10,806,550 barrels in 1909 to 29,200,764 barrels in 1914, while the value increased from £8,286,000 to £25,400,000. The output of fuel oils increased from 34,034,577 barrels, valued at £7,596,000, to 74,669,821 barrels, valued at £17,504,000. Illuminating oils show an increase in quantity from 33,495,798 barrels, valued at £19,697,000, to

38,705,496 barrels, valued at £20,168,000, or an increase of 11·7 per cent. in quantity, and of 2·4 per cent. in value. On the other hand, lubricating oils show a decrease in quantity, with an increase in value, from 10,745,885 barrels, valued at £8,101,000, to 10,348,521 barrels, valued at £11,628,000. All other products, including residuum or tar, greases, paraffin, wax, asphalt, and subsidiary and by-products, increased in value from £5,694,000 to £7,876,000, or by 38·2 per cent. The gasoline product of the petroleum refineries does not include casing-head gasoline, condensed from natural gas at the gas wells. The total gasoline production, including casing-head gasoline, was 24,711,565 barrels of 50 gallons, or 1,235,578,250 gallons.

NICE AND THE FOOD SUPPLY OF SWITZERLAND.—Since the outbreak of the war considerable delay has been experienced in the discharge of ships, bringing foodstuffs for Switzerland, at Marseilles and Cette. To cope with the congestion problem, which was becoming serious, this traffic has been diverted to Nice, notwithstanding its 225 kilometres (140 English miles) greater distance by rail to the Swiss frontier at Bellegarde, 21 miles only from Geneva. Nice is 712 kilometres (442 miles) from the frontier station, as compared with 487 kilometres (302 miles) from Marseilles. It is anticipated that the cost of carriage by rail will be fully compensated by the reduction of demurrage charges. The port of Nice is well equipped with electric cranes and other appliances for discharging cargoes direct into the railway trucks without delay. There is ample quay space. The first vessel, the s.s. "Ness," bringing 4,400 tons of rice from Rangoon, arrived in this port a few days ago (May 7th), and several others are expected shortly.

TESTS FOR GUM ARABIC.—A study of many of the published tests for gum arabic, with descriptions of attempts to find others than the few that proved to be reliable, has been published by the United States Bureau of Standards. It was found that basic lead acetate gave the most characteristic reaction, while mixtures of copper sulphate and sodium hydroxide and of neutral ferric chloride and alcohol are of value as confirmatory tests. Dextrin and gum ghatti were subjected to the same tests. A summary of the more important methods that have been proposed for the quantitative estimation of gum arabic is next given, followed by a description of the steps that led the investigators at the Bureau to the use of alcoholic copper acetate-ammonia solution for this determination. Technologic Paper No. 67, "Some qualitative tests for gum arabic and its quantitative determination," may be obtained by interested persons from the United States Bureau of Standards, Washington, D.C.

London: Printed by WILLIAM CLOWES & SONS, LTD., Duke Street, Stamford Street, S.E., and published for the Royal Society of Arts by G. BELL & SONS, LTD., York House, Portugal Street, W.C., in the Parish of St. Clement Danes, in the City of Westminster.—July 21, 1916.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICES.

EXAMINATIONS.

It has been found necessary to make a small increase in the Examination fees by adding 1*s*. for each subject in the Advanced Stage, and 6*d*. in the Intermediate and Elementary Stages.

The fees in future, therefore, will be as follows: Stage I., 2*s*. 6*d*. for one subject, and 1*s*. 6*d*. for each additional subject taken by the same candidate; Stage II., 3*s*.; and Stage III., 3*s*. 6*d*. for each subject.

The results of the Elementary (Stage I.) Examinations, held in April, were sent to the centres concerned on the 20th inst. This completes the issue of the results of the first division of the Examinations, those for the Advanced and Intermediate Stages having been sent out in June.

It is hoped to send out the results of the Advanced (Stage III.) Examinations, held in May and June, about the end of this month, and those of the Intermediate and Elementary Stages, held at the same time, during August.

The publication of the results is this year considerably delayed owing to the war, as not only is the Society's staff considerably depleted, but the Examiners have also lost the services of many assistants, who have joined H.M. Forces.

INDIAN SECTION COMMITTEE.

A meeting of the Committee of the Indian Section was held on Friday, the 21st inst. Present:—

Sir William Duke, K.C.S.I., K.C.I.E. (Chairman of the Committee); Sir Charles Stuart Bayley, G.C.IE., K.C.S.I.; Thomas Jewell Bennett, C.I.E.; William Coldstream, B.A., I.C.S. (retired); Sir Frederic W. R. Fryer, K.C.S.I.; Sir Frederic S. P. Lely, K.C.I.E., C.S.I.; Sir John Ontario Miller, K.C.S.I.; Sir Frederick Alexander Robertson, LL.D.; Colonel Charles Edward Yate, C.S.I., C.M.G., M.P.; and S. Digby, C.I.E., Secretary of the Section.

PROCEEDINGS OF THE SOCIETY.

INDIAN SECTION.

REPORT OF THE DISCUSSION ON THE PAPER ON

THE SIKHS.

By Sirdar Daljit Singh, C.S.I.,

Member of the Council of the Secretary of State for India.

(*Continued from p.* 631 *of the* Journal *of July 21st*, 1916.)

The Chairman (the Right Hon. Austen Chamberlain, M.P.) said the audience had had the opportunity of listening to an admirable paper on the history of a religion and a people which was full of interest for any thinking man. He was sure all had been struck by the nobility and beauty of the teaching of the founder of Sikhism, and had followed with interest the development of that teaching under his successors, and the gradual establishment of the great warlike race which was known at the present day. In the few observations he proposed to make he intended to dwell upon their services to the Empire in the war, because that was the subject which was uppermost in all minds, and it was well to remember the fine work done by the Sikh regiments. At the same time he did not wish it to be supposed that in speaking about the Sikhs he forgot the work done by other Indian soldiers of the King-Emperor. For the first time the Indian army had taken its place in a great European war by the side of armies coming from all the other Dominions of His Majesty. The Indian Army had served not only in France, but in Egypt, Gallipoli, East and West Africa, Aden and Mesopotamia. Wherever work had to be done and stout hearts were needed, India had sent her sons to play their part with the men from other portions of the Empire in the defence of their Sovereign's Crown, and of the liberties of the Empire to which they belonged. He was recently present at Buckingham Palace when His Majesty the King-Emperor received some Indian soldiers from one of the hospitals who desired to present an address to him. Among them was an officer who, since the war began, had fought at Aden,

on the Suez Canal, and in Gallipoli, and, after being invalided home suffering from illness, had gone to France and fought there; and, at the time he saw him, was on the point of leaving for India. He asked the officer if he had any wish, and he replied that he desired not to be sent home to India but to Mesopotamia, so that then he would have fought in all the theatres of war. That spirit was characteristic of the army to which he belonged. In the many theatres in which they had been engaged they had reaped a full share of the honours that were earned. He found that among the ranks of the Indian army over 1,300 decorations had been conferred for services in the war, of which nearly 400 had been won by Sikhs. Among the decorations Victoria Crosses had been won by seven of various ranks, one of the recipients being a Sikh; the Military Cross by twenty-six, of whom six were Sikhs; the Indian Order of Merit of the First Class by six, of whom two were Sikhs; and the Indian Order of Merit of the Second Class by 416, of whom 119 were Sikhs. He asked the audience to bear with him for a few moments while he narrated two instances which gave some idea of the services by which such distinctions had been earned. The first case was that of the 14th King George's Own Sikhs in Gallipoli, as told to him by Major-General Sir Henry Cox, who commanded the 29th Indian Brigade at the time. The 14th Sikhs went into action on the left flank of the famous 29th Division, and attacked and carried the Turkish trenches in front of them. There were fourteen British officers, eighteen Indian officers, and about 500 of Indian ranks when they started. Unsupported they held on to the ground they had taken for twenty-four hours, and when they were withdrawn they came out with only two British officers, five Indian officers and about 120 of the Indian ranks. The ground was retaken a few days later, and everywhere a Sikh was found on the top of a Turk, and not a man's face was looking the wrong way. The second incident, part of the story connected with which had already been published, occurred in France, and was as follows: On the night of May 17th a company of the 15th Sikhs under Captain K. Hyde-Cates, relieved a portion of the 1st Battalion Highland Light Infantry in a section of a trench known as the "Glory Hole" near the *Ferme du Bois* on the right of the Indian Army Corps front. Furious fighting had been in progress there for some time, the position at the moment of relief being that we had taken and occupied a section of the German trench, a portion of the same trench on our left being still held by the enemy, who had succeeded in erecting a barricade between themselves and our men. In the early morning Captain Cates observed that attempts were being made to reinforce the enemy in the trench. Numbers of Germans were seen rushing towards the further extremity of the enemy's trench. Rapid fire was brought to bear on them as they crossed the open, but in the dim light the effect could not be judged. When day broke it was ascertained that the German trench was packed with men, with the evident intention of attacking us. A short time afterwards the attack began by heavy bombarding, to which the 15th replied vigorously and succeeded in holding their own until noon, when the position became critical, as all our dry bombs had been expended and those that had become wet from rain were found to be useless. It was then resolved to attempt to relieve the situation by sending up a bombing party from the reserve trenches. The desperate nature of this undertaking may be gauged from the fact that two previous attempts had been made by the Highland Light Infantry. On both occasions they failed; the officers in command being killed and the parties having suffered very severely. However, the position was desperate, and Lieutenant Smyth, a young officer who, in spite of his years—he was only twenty-one—had already been brought to notice for his gallantry, was ordered to take command of the party. Volunteers were called for and were immediately forthcoming. The alacrity with which the demand was responded to spoke volumes for the spirit of the regiment, for each man felt sure that he was proceeding to almost certain death. Lieutenant Smyth and his little party of ten men started at 2 p.m. to cover the 250 yards which intervened between them and our trench, taking with them two boxes of ninety-six bombs. The ground to be covered was absolutely open, devoid of all natural cover. The only possible shelter from the frightful fire which met the party as soon as they were over our parapet was an old broken-down trench which, at the best of times, was hardly knee-deep, but now, in places, was filled almost to the top with the dead bodies of Highland Light Infantry, Worcesters, Indians, and Germans. Truly it was an undertaking to appal the stoutest heart. Dropping over our parapet, they wriggled their way through the mud, pulling and pushing the boxes with them, until they reached the scanty shelter of the old trench, where they commenced a progress which, for sheer horrors, can seldom have been surpassed. Pagris had been attached to the front of the boxes. By means of these the men in front pulled the boxes along over and through the dead bodies, while those in the rear pushed with all their might, the whole party lying flat. At any minute the bombs might have exploded. The whole ground was hissing with the deluge of rifle and machine-gun fire, while the air above them was white with the puffs of shrapnel. To the anxious watchers in the rear it seemed impossible that a single man should win through. After they had accomplished a mere twenty yards of their deadly journey, Sepoy Fatteh

Singh rolled over wounded, followed in the next eighty yards by three sepoys—Sucha Singh, Ujagar Singh, and Sunder Singh. This left only Lieutenant Smyth and six men to get the two boxes along. Under ordinary circumstances four men are required to handle a box of bombs. They crawled on and on until, just before they reached the end of the trench, the party had dwindled to two—Lieutenant Smyth and Sepoy Lal Singh. Of the remainder of the band of heroes, Sepoys Sarain Singh and Sapooram Singh had been killed, Ganda Singh, Harnam Singh, and Naik Mangal Singh being wounded. The second box of bombs had, therefore, to be abandoned, and to haul even one box along in the face of such difficulties appeared an impossible task. Still pulling and hauling, Lieutenant Smyth and Lal Singh emerged, wriggling painfully along into the open, where they were met with an increased blast of fire. Miraculously surviving this, they crawled on only to be confronted suddenly by a small stream which was too deep to wade. Across it lay the direct line to safety. The ordinary man, under such circumstances, would probably have taken it, but these were no ordinary men. They crawled on and on, in full view of an enemy now at close quarters, until they came to a point in the stream which was just fordable. Across this they struggled with their valuable burden, and in a few yards they were amongst their friends in our trench, both untouched, although their clothes were perforated with bullet holes. Sad to relate shortly after reaching the trench the gallant Sepoy Lal Singh was killed. For his most conspicuous bravery Lieutenant Smyth has now been awarded the Victoria Cross and each of the brave men with him the Indian Distinguished Service Medal. He offered no apology for the time he had occupied in reading the account of the two instances he had quoted—two only, out of many —which showed how Sikh soldiers had fought. He was sure those present would join with him in expressing their admiration for such deeds, and for the men who performed them.

Sir Louis W. Dane, G.C.I.E., C.S.I., said that nearly the whole of his service in India was passed in Sikh districts, and he had had the honour of being Lieutenant-Governor of the Sikh Province of the Punjab. Whatever success he had achieved in life was due to the Sikhs, and the least he could do was to offer his poor tribute to their magnificent history as adherents of a creed, as a nation, and as men. Mr. Chamberlain had said something of what the rank and file of the Sikh regiments had done in the present war, and the author had referred to what they had done in previous wars. He desired to point out the conspicuous service the Sikh chiefs, as distinct from the rank and file, had rendered to this country in a time of most signal difficulty. The map of the Punjab showed that the line of communications between Umballa and Delhi was practically entirely through the territories of the great Sikh chiefs, and if those chiefs had not stood by this country during the Mutiny he had very little hesitation in saying that it would have been absolutely impossible for the British troops to have retained their position upon the ridge and to have taken Delhi. Some people did not quite appreciate the difference between Sikhs and Singhs. They saw them with shaved beards, and asked how such persons could be Sikhs. Their idea of a Sikh was a tall, stately man with all his hair and a very fine martial carriage. The fact of the matter was that until a Sikh had taken the *pahul* he did not become a Singh. It was not obligatory upon him to let all his hair grow. Although he had very many good friends among Sikhs who had not taken the *pahul* and who shaved, it was his experience that those who had taken the *pahul*, or Kesdhari Sikhs, were more successful in their careers than the Sahjdhari Sikhs, who cut their hair. He did not know why that should be so, unless it was that, like Samson, the virtue resided in their hair, or because the precepts of their religion prevented them from smoking. In the central Punjab it was frequently found that in the same village, or in adjacent villages, there were men of the same stock, some of whom were Mohammedans, some of whom were Hindus or Sikhs, who shaved, and some of whom were Singhs who did not cut their hair at all. Of those three classes it was invariably the case that the section which was most prosperous and successful was the Singh section. They made a good deal of money by serving in the Army and under the Government in various offices, but that of itself was not sufficient to explain the circumstance. He left it to the ethnologist to decide why it was that men descended from the same common ancestors under exactly similar economic conditions showed such varied results in practice. The Mohammedans often said that the reason they did not succeed was because they smoked too much. They said they could not get up in the morning and go on with the ploughing until they had spent half an hour at the hookah; and every hour or hour and a half during the day they did the same. He did not wish to say anything against smokers, but he was inclined to think there was a good deal in the suggestion. On the other hand, while the Singhs did not smoke, they took a little spirit occasionally. All Singhs over thirty or forty years of age usually took a decoction of poppy seeds in water, or even a small pill of opium, but it did not seem to do them any particular harm. The result remained that the Singhs were invariably successful agriculturists and exceedingly prosperous. It was much to be regretted that the Sikhs had to leave the Punjab because, like the Irish, good careers were not open to them in their own country. When they went abroad they sometimes imbibed modern

ideas which were not thoroughly well digested, and a good deal of trouble had arisen from that fact in the past. He believed the remedy for that state of affairs was to endeavour to provide for the non-agriculturist class of Sikhs, to whom the wayfarers largely belonged, a good career in their own country. Anything that could be done in the way of introducing more capital into the Punjab for the greater development of the arts and industries in that Province, whereby the Sikh workmen would be able to remain at home and earn a good living, would be a great thing for the nation of the Sikhs and also for the British Empire.

General Sir O'Moore Creagh, V.C., G.C.B., G.C.S.I., said that this was an unique occasion because they had heard for the first time in London a paper by a highly-educated Indian nobleman whose education had been based on Oriental tradition. Such a basis of education alone enabled Indians to keep their position among their people and the chiefs, and also to be leaders among them. That was not the case with those people whose English education was based on ideas generated in the West. The views obtained by the latter were often apt to be ill-digested and unorthodox, and for that reason were not popular among Indians generally. He believed that if it was desired to obtain the views of Indians they must be forthcoming from the chiefs, nobles and gentry, who were the real leaders of the people and had a great stake in their country. None of the gallant deeds which had been narrated, performed by Sikhs in the present war, had been heard by him with astonishment, because he had spent forty-five years of his life in peace and war among the Sikhs and knew the loyalty and gallantry of this brave people. The Sirdar had mentioned a very remarkable fact, that, in spite of the two wars that took place between the Sikhs and the British, only eleven years afterwards they assisted the British Government against the mutineers in India. The conclusion he had come to was that the Sikhs assisted the Government in the Mutiny because of the friendships which existed between the first British officers who were sent to rule the Punjab and the chiefs, gentry and priesthood. Through a long course of history, friendships in the East had exercised a great and most important influence, and he could not too strongly emphasise the immense importance, as well as the pleasure it was to themselves, of all British officers who served in India making friends with the nobility, gentry and priesthood of the country. He specially mentioned the priesthood, because in a country like India, unless one knew the thoughts and aspirations of the priesthood, very little could be done in leading the people towards modern methods of civilisation. He had known Sikh soldiers from his earliest days, and was thoroughly acquainted with the friendly relations that had always existed between the family of Sirdar Daljit Singh and British officers. The Sirdar's lamented brother did everything he possibly could to alleviate the somewhat dull conditions of the British soldiers in the Punjab. Just before his death he endeavoured, with the aid of the Sikh Chiefs' Association in the Punjab, to get the great landowners and noblemen to open some of their forests for the soldiers to shoot, fish and sport in. That was a most noble idea, because it benefited the British soldier's health and trained him for war; a good sportsman was always a good soldier. He held his own ideas on the subject referred to by Sir Louis Dane of the Sikhs who cut their hair and those who did not. Those who cut their hair were not attentive to their religion, while the others were. Only such as did not cut their hair were enlisted in the army. Unless a soldier or a cultivator, or any other class of man, was attentive to his religion he was no good. Many troubles were caused by want of knowledge of the religions of India.

General Sir Edmund Barrow, G.C.B., said that twenty years ago English people imagined that there were no soldiers in the Indian army other than Sikhs—a fact which was very much to the credit of the Sikhs, because they were such fine soldiers that every Indian who was worth anything was always dubbed a Sikh. The Sikh population of India was only $2\frac{1}{2}$ million, or $\frac{1}{126}$ of the total population; nevertheless, they contributed one-fifth of the whole of the men in the Indian army. That alone was a sufficient tribute to the value of the Sikh element to the British Empire.

Sir Frederick A. Robertson, LL.D., said that, having spent thirty-five years in the Punjab and marched through every Sikh district in that Province, and having also an enormous number of friends amongst all classes of Sikhs, he could speak with some outside knowledge of the subject as compared with the inside knowledge possessed by the author. Coming in contact with them as an administrative officer, he saw the best side of them. It was afterwards his fortune to serve in India in a different capacity, and he then saw something of the other side. Speaking as an intimate friend of Sikhs, he thought it was as well to give a word of warning about one or two dangers the Sikh seemed to him to be running. The first was that he sometimes had a little too much to drink; and there was a danger of that becoming too common a habit. The drink came largely from the same source as some of the drink produced in Ireland: it was not made in any Government still. When the Sikh indulged in that little amusement he became a very dangerous creature. The other danger

was a curious result of legislation which had been passed. The ordinary moneylender had been prevented in the Punjab from acquiring land; only men of the agricultural classes could buy land. As a result, the Sikh, who was essentially an agriculturist and a very careful person, was in some danger of getting the reputation of being a land-grabber, because the position of moneylender was occupied by Sikhs who were ready to buy up the land of other agriculturists. Dealing with the various characteristics of the Sikhs, the first thing that struck anyone in marching through a Sikh district and seeing their agricultural methods was their extraordinary patience and attention to work. The Punjab had a doubtful climate, and the difficulties connected with agriculture were great; but he had never known a Sikh fail to face those difficulties with the greatest courage and determination, and he generally overcame them. He was absolutely the ideal agriculturist. He remembered that at a big Highland dinner at Lahore, the late Sir George White made a speech in which he compared the characteristics of the Sikh to those of the Highlanders of Scotland. He did not think that parallel was altogether a good one. Personally he would be more inclined to compare the Sikh to the Lowland Scot. He had the same determination, the same power of looking after his money, and the same power of facing good and bad fortune, which the Lowland Scot possessed. In one important respect the Sikhs resembled the Highlanders—and it had been of the greatest value to the Empire—namely, that when the fight was over they were the best of friends. No two nations every fought each other more strenuously than the English and the Scotch and the British and the Sikhs, and now they were the very best of friends.

Sir George Birdwood, K.C.I.E., C.S.I., in moving a vote of thanks to Sirdar Daljit Singh, said he had the greatest pleasure in so doing; and not only because he was deeply interested in the subject of it, through the fact of the translator into English of the *Grantha* [*i.e.* Sacred "Book"] of the Sikhs, Ernest Trumpp, having been a great friend of his father, and done much of the translation of "the Book" in his father's house, both in Karrachee and at Aden, but also because of the excellence of the paper, and of the high esteem in which the author of it was held by everyone who had known him in India. He would only ask the Sirdar Sahib, in view of the phenomenal ignorance of the "stay-at-home" English, in revising his paper for publication, to add, either as a footnote or immediately after the first paragraph, a chronological table of the succession of "the Ten-Gurus" [literally, "Weighty"-men, *i.e.* Priests] of the Sikhs, adding the two supernumerary ones included in the list by some; and, if after every Indian word unfamiliar to the "stay-at-home" English, the Sirdar Sahib would give its radical and derivative meanings, it would add greatly to their intelligent assimilation of the invaluable information and wisdom treasured up in the paper. For two or three instances: Sikh was from *sikna*, "to learn," through *sishya* a "student," and hence a "Disciple"; Khalsa meant "pure," "select," "elect," and hence "the Sikh Theocracy", *sharbat* meant literally "a draught," and in the *pahul*, or rite of initiation of the Nanak-Shahi, or Sikhs, it was a mixture of sugar and water, and therefore the name of *Amrita* [*i.e.* "Deathless"], although as a word equivalent to the Greek word "Ambrosia," the mixture it denoted was a "Nectar" ["Better"-drink?] and not an Ambrosia, or "food of the gods"; and so on with a dozen other cryptic words. The designation "Muhammadan" [from Muhammad, "the Praised," "the Prophet of God"], in classical English "Mahomet," was most offensive to Muslims [*i.e.* "Believers"]; indeed, was regarded by them as blasphemous and should never be used of them. But the great lesson to be learned from the history of the Sikhs was that their success as a secular power was based on the force of their spiritual convictions and enthusiasm, exactly as in the case of the Saracen Muslims; and that the secret of their decay, as of that of the Saracens, lay in the fact of their having admitted "Believers" of the inferior races of mankind to a social as well as spiritual equality with themselves. This was a natural enough, almost an unavoidable error, and committed long before then by the primeval Aryan invaders of India, and again later by the Spaniards in America; the evil of it in both these cases having been aggravated by the depressing effect of the heat of all countries lying within the north and south tropical zone. This double danger was the greatest menace of the future to the United States of America, where both the mulattos and the creoles were increasing in numbers. It should never be forgotten that it was not the Rome of the ancient Romans that was overthrown by the virile barbarians, but the Rome of African and Syrian Roman mulattos and creoles.

Mr. Mirza Abbas Ali Baig, C.S.I., in seconding the motion, said that the Chairman's stirring and appreciative words would convey a cheering and inspiring message to all Indian soldiers, who were now fighting the battles of the Empire on three continents, as well as to the people of India.

The resolution was carried unanimously, and briefly acknowledged by Sirdar Daljit Singh.

Sir Krishna Gupta, K.C.S.I., in thanking the Chairman, on behalf of the Society, for presiding, said Mr. Chamberlain had done a

great service to India by recalling the gallant deeds the men of the Indian army had performed in many theatres of the present worldwide war. There was some risk of those services being overlooked and forgotten in view of the clamorous demands made in the same direction by the younger daughters of the Empire, and, as an Indian, he was, therefore, most grateful to Mr. Chamberlain for bringing the services of the Indian army so prominently to the notice of the British public.

THE HISTORY OF THE SAFETY-LAMP.*

The earliest references to the nature of firedamp appear to occur in the latter part of the seventeenth century. From these it is evident that the risk of its ignition and explosion was known, and it was recognised that ventilation (to keep the air very "quick") was a means of prevention of these dangers. The recognition of the presence of firedamp by means of the candle-flame was also known. No remedy other than ventilation appears to have been suggested until about 1730 or 1750, when the flint-and-steel mill was invented. This invention is attributed to Mr. Carlisle Spedding, of Whitehaven. The use of flint and steel in the presence of firedamp is mentioned by Sir James Lowther in 1733, and Mr. John Buddle in 1813 gave a full description of the flint-and-steel mill. This instrument, however, did not give immunity from explosion. An explosion at Wallsend in 1785 was stated by Mr. Buddle to have been traced to the use of the steel mill, and he also affirmed that, although he had never witnessed an explosion from the sparks emitted by the instrument, yet "the inflammable air has frequently fired at the sparks of the steel mills, but only when they are played near the place where the hydrogen gas is discharged." Matthias Dunn also asserted that explosions were originated by the flint-and-steel mill. Other attempts to avoid the use of naked lights in presence of firedamp were made, and Von Humboldt describes a lamp invented by him in which the flame was supplied with air from an air-reservoir. The use of phosphoric lights, fish in a state of incipient putrescence, Amadou (or fungus tinder), and other schemes were suggested, whilst sunlight was directed down the shaft by mirrors, and proposals were made at a later date to reflect the light into the workings.

Some progress was also made in respect of the knowledge of the properties and composition of firedamp. Some investigators recognised its similarity to hydrogen gas, and were aware that it was heavier than hydrogen, but lighter than air; and although Volta pointed out the differences between firedamp and hydrogen as early as 1776, and Berthollet proved that it contained both carbon and hydrogen in its composition, still firedamp continued to be spoken of as "hydrogen." In 1805 Dr. William Henry distinguished between marsh-gas and olefiant gas. The occurrence of firedamp in coal-mines was, however, not understood at this date, and in many instances its presence was attributed to the decomposition of water by iron pyrites, or to the decomposition of water by the coal with separation of the hydrogen.

The years 1812 and 1813 were important in the history of the safety-lamp. On May 25th, 1812, an explosion occurred at the Felling Colliery. In consequence of this explosion, the Rev. John Hodgson, the incumbent of Jarrow and Heworth, and Mr. James John Wilkinson took steps which eventually resulted in the formation on October 1st, 1813, of the "Society in Sunderland for Preventing Accidents in Coal Mines." This Society had, as Patron, His Grace the Duke of Northumberland; there were sixteen Vice-Presidents, with Sir Ralph Milbanke, Bt., as President, and Mr. W. Burn as Secretary. In addition, there was a permanent committee of twenty-eight, among whom were the Rev. Robert Gray, the Rev. John Hodgson, William Reid Clanny, James John Wilkinson, John Buddle, and Matthias Dunn. This Society was most assiduous in its endeavours to promote the objects for which it was formed, and it was due to its efforts that the safety-lamp was introduced at this period. Among those who, at the time when the Society was formed, were actively engaged in endeavouring to discover some safe means of lighting coal-mines were William Reid Clanny and George Stephenson, and the Society, apparently influenced by Mr. Buddle's expressed opinion that nothing further could be done to prevent explosion by the application of mechanical agencies, that the only remedy lay in the discovery of some chemical method for rendering firedamp harmless as it was discharged, and that it had to look to scientific men for assistance in providing "a cheap and effectual remedy," eventually determined to apply to Sir Humphry Davy for assistance.

The work accomplished by the Society in connection with the movement of the safety-lamp entitles it to be gratefully remembered by all interested in coal-mining.

Dr. Clanny.—William Reid Clanny was born in 1776 at Bangor, County Down, Ireland. He entered the medical profession, and eventually settled down in practice at Bishop Wearmouth, near Sunderland. In 1810 his attention was drawn to the subject of explosion of firedamp in collieries. He invented a number of lamps, among which is the well-known Clanny lamp. On May 23rd, 1813, he contributed a paper on his newly-invented lamp to the Royal Society.

Clanny's first lamp (the "Blast" lamp) consisted of a lantern with cisterns of water above and

* Abstract of a paper on "The History of the Safety-Lamp," by Professor F. W. Hardwick, M.A., and Professor L. T. O'Shea, M.Sc., read at the meeting of the Institution of Mining Engineers, held in the Rooms of the Geological Society, Burlington House, on Thursday, June 8th. Published by permission of the Institution.

below the light. Air was forced in by means of a bellows, so that it bubbled through the water in the lower cistern whilst the products of combustion escaped through a chimney at the top, the open end of which was narrowed and bent over so as to dip beneath the surface of the water in the upper cistern. This lamp was tested on the surface on October 16th, 1815, and underground on November 20th, 1815. The construction of the lamp was subsequently modified: the water cisterns were abandoned, the oil in the oil-vessel was used to seal the inlet of the air, and the outlet consisted of a vertical chimney that tapered to a fine point.

His second lamp was exhibited to the Sunderland Society in December, 1816, was described before the Royal Society of Arts on April 2nd, 1817, and was known as the "Steam" lamp.* Air passed in through a tube in the bottom of the lamp, and was conducted through an extension of the tube to a point high up in the lamp. Above the oil-vessel and flame, and situated about the middle of the lamp, was a water reservoir. The water in the reservoir was boiled by the heat from the oil-flame. The air was conducted below the oil-vessel by two tubes, and then passed up the sides of the cistern, where it mixed with steam from the boiling water and finally escaped through the chimney.

A third lamp was the "Gaslight" lamp, which was stated to have been designed to burn firedamp in lieu of oil in an atmosphere charged with gas. It was similar in construction to the Steam lamp.

These early examples of Clanny's lamps show the important part that Clanny took in his attempt to reduce the dangers arising from the use of naked lights, and in 1843 the South Shields Committee for Investigating the Causes of Accidents in Coal Mines expressed their opinion of the value of his labours as follows:—

"Dr. Clanny, in this country, appears to have been the first man of science that conceived it possible to enter into a contest with this destructive element [firedamp], and, sustained by his unwearied philanthropy, has never ceased for thirty years to devote his talents and exertions to mitigate the horrors consequent upon its explosion. A life so spent, it is to be hoped, will not be allowed to pass without some mark of respect from his country, or of gratitude from those he has laboured so much to benefit."

George Stephenson.—George Stephenson, born on June 9th, 1781, at Wylam, near Newcastle-upon-Tyne, was, at the age of fourteen, appointed assistant fireman at Dewley Burn Colliery, and enginewright at Killingworth Colliery in 1812.

The idea of his first lamp ("The Tube and Slider" lamp) was conceived from experiments made on blowers that he met with in the Killingworth Pit. He found that the "burnt air" from five or six candles held to windward of an ignited blower would extinguish the flame. Further, that when firedamp was ignited, an appreciable time was necessary for the flame to travel from one point to another, and his idea was that if the upper part of a lamp could be charged with burnt air, whilst the firedamp was admitted below in small quantity and burnt as it came in, then the burnt air would prevent the explosion from travelling upwards, and the velocity of the entering current would prevent it from passing downwards. In the "Tube and Slider" lamp air was admitted through a tube ½ inch in diameter, and passed from the centre of the bottom of the lamp to the centre of the wick; the bottom of the tube could be wholly or partly closed by a valve or shutter, and so the admission of air regulated. This lamp was tested on October 1st, 1815, at Killingworth Colliery. Subsequently Stephenson undertook some experiments on firedamp and tubes which decided him to substitute three tubes for the single air-inlet tube, and he constructed his second, or "Tube" lamp, in which the air was admitted through three tubes, 3½ inches long and $\frac{3}{32}$ inch in diameter; the air passed from the bottom of the lamp through the oil-vessel, the upper ends of the tubes being inclined towards the wick. This lamp was tried at Killingworth Colliery on November 4th, 1815. Subsequently Stephenson decided that to admit air into the lamp through capillary tubes would be a better method, but afterwards he decided to adopt smaller holes drilled in a plate, and constructed his third lamp, into which air was admitted through holes in the side of the oil-vessel, then through small holes from $\frac{3}{28}$ to $\frac{1}{32}$ inch in diameter into a space between two plates, whence the air issued to the flame through a set of holes $\frac{1}{12}$ to $\frac{1}{13}$ inch in diameter punched in a metal ring. This lamp was tried underground on November 30th, 1815. In the final form of Stephenson's lamp, the punched plate was replaced by a gauze cylinder, which surrounded the glass cylinder; air was admitted through small holes in the ring to which the standards are fixed or in a flange just above the ring. It has not been possible to ascertain the date when the wire gauze was substituted for the punched plate.

Sir Humphry Davy.—Sir Humphry Davy was born near Penzance on December 17th, 1778. He was educated at the Penzance Grammar School, and was eventually apprenticed to Mr. J. B. Borlase, a surgeon and apothecary. He devoted his attention chiefly to chemistry, and in 1798 was appointed Superintendent in the laboratory of the Pneumatic Institute at Bristol, where he investigated the properties of various gases, among them carburetted hydrogen. In 1801 he joined the Royal Institution

* Dr. Clanny brought two forms of his lamp before the Society; for the one above described he received a silver medal in 1816, and for the second (the Steam lamp) a gold medal in 1817. By an unfortunate error the dates are wrongly given in the "History of the Society," p. 254, as 1815 and 1816. Further information about Clanny's lamps will be found in the full text of the paper when it is published. Professor Hardwick has kindly furnished the Secretary with some notes and has thereby enabled him to add the references contained in the footnotes on this and subsequent pages.—H. T. W.

as Assistant Lecturer in Chemistry, Director of the Laboratory, and Assistant Editor of the Journals of the Institution, and on May 31st, 1802, was appointed Professor. He was elected a Fellow of the Royal Society in 1803, was Secretary of that Society from 1807 to 1812, and was elected President on November 30th, 1820. He was knighted in 1812 and created a Baronet in 1818. On resigning his Professorship at the Royal Institution, he was elected Honorary Professor of Chemistry. He died at Geneva on May 29th, 1829.

It was in August, 1815, that Davy met the Sunderland Committee, and after learning the conditions under which coal was mined and paying visits to the Hebburn and Wallsend collieries, he returned to London and commenced his investigations into the nature of firedamp, which eventually led to the invention of his lamp. On November 9th, 1815, he read a paper before the Royal Society "On the Fire Damp of Coal Mines and on Methods of Lighting the Mines so as to prevent Explosion." In this he gave an account of his investigations into the explosive properties of firedamp and the passage of flames through glass and metallic tubes. In his paper he stated :—

"It is evident that to prevent explosions in mines it is only necessary to use air-tight lanterns, supplied with air from tubes or canals of small diameter, or from apertures covered with wire gauze placed below the flame, through which explosions cannot be communicated, and having a chimney at the upper part on a similar system to carry off the foul air; and common lanterns may be easily adapted to the purpose, by being made air-tight in the door and sides, by being furnished with the chimney, and the system of safety apertures below and above."

In the paper three lamps are described: they appear to have been lanterns of tin plate with four glass plates in the side. In the first lamp air entered below the flame through a number of tubes $\frac{1}{8}$ inch in diameter and $1\frac{1}{2}$ inches long, and the products of combustion escaped through a chimney composed of two open cones protected by a plate containing many small apertures. In the second lamp both inlet and outlet were protected by "safety canals" consisting of concentric metallic cylinders, one within the other, and separated from one another by annular spaces from $\frac{1}{24}$ to $\frac{1}{40}$ inch wide and $1\frac{7}{10}$ inches long. The inlet and outlet of the third lamp were protected by brass-wire gauze $\frac{1}{200}$ inch thick having apertures not more than $\frac{1}{120}$ inch. A little more than a month later, namely on January 1st, 1816, Davy announced to Dr. Gray his important discovery of the use of the gauze cylinder, and communicated his discovery to the Royal Society in a paper on January 11th, 1816. In this paper he describes his invention as follows :—

"This invention consists in covering or surrounding the flame of a lamp or candle by a wire sieve; the coarsest that I have tried with perfect safety contained 625 apertures in a square inch and the wire was $\frac{1}{70}$ of an inch in thickness, the finest 6,400 apertures in a square inch and the wire was $\frac{1}{250}$ of an inch in thickness."

The first Davy lamps seem to have been tried at Hebburn Colliery on January the 9th and 17th, 1816. Davy recommended the use of iron-wire gauze composed of wire from $\frac{1}{40}$ to $\frac{1}{60}$ of an inch in diameter and uncovered with any easily combustible metal; that in proportion as the inflammability of the gas increases the apertures should be smaller and the radiating surface greater; and that several gauzes superposed might be necessary for continuous explosive mixtures. He pointed out that no aperture should be allowed in the lamp and the precaution of supplying a short gauze cap over the top of the main gauze cylinder. He also gave dimensions for the cubic contents of the lamp, recommending that the lamp should be from 8 to 10 inches high, and from 2 to $2\frac{1}{2}$ inches in diameter. Davy appeared to be aware of the limitations to the safety of his lamp, especially in currents of explosive gas, and recommended the use of twilled gauze or the protection of the gauze by a glass cylinder above the flame or a tin screen outside the gauze. On September 6th, 1816, he visited Wallsend Colliery and performed experiments with his lamps, and in pointing out the lessons to be learnt, said :—

"Now, gentlemen, you see the nature of the danger to which you are exposed in using the lamp, and I caution you to guard against it in the manner I have shown you. This is to show the only case in which the lamp will explode, and I caution you and warn you not to use it in any such case when you can avoid it, without using the shield."

There is little doubt that Clanny considered himself the inventor of the first safe lamp, and a regrettable controversy arose towards the end of 1816 as to whether Stephenson or Davy was to be regarded as the first inventor of the safety-lamp. It is not necessary to go into the details of the controversy, but in regard to the merits of these two inventors Stephenson deserves great credit for his work. Unacquainted with the principles of chemistry, and devoid of proper apparatus for experimentation, he was yet able to produce a lamp which seems to have been safe under the conditions for which it was designed. But to Davy's work the mining community is indebted for the safety-lamp as it exists to-day; not only did he invent a lamp which was within limits safe, but he laid down the principles of safety which have been followed and confirmed by subsequent investigators.

About the same time lamps were devised by Chèvremont; John Murray, Lecturer on Chemistry at Hull; Dr. John Murray; and R. W. Brandling. All these were similar, and consisted of enclosed lamps connected with long tubes through which air free from firedamp could be brought from a distance.

Period 1816 to 1835.—The Davy and Stephenson

lamps came into use shortly after their invention, and in 1818 the Davy was used in the North of England, Whitehaven, and Wales. It was also introduced into France, Belgium, and Germany. It was during this period that distrust arose as to the safety of the Davy lamp when exposed to currents of explosive mixtures other than those moving with low velocities. Davy had foreseen the danger, and had suggested precautions that should be taken. There appears to have been a feeling of disappointment that since the introduction of the safety-lamps mortality due to accidents from firedamp had increased. In 1835 a Select Committee on Accidents in Mines was appointed. The Committee issued its report on September 4th of the same year, in which they stated that "ignorance and a false reliance" on the merits of the Davy safety-lamps "in cases attended with unwarranted risks have led to disastrous consequences"; but a more extended use of the safety-lamp was recommended —"in some mines, now lighted by the ordinary means, the use of the lamp ought to be compelled by the owners." Among the lamps brought to the notice of the Committee that of Upton & Roberts* is commended. This lamp consisted of a gauze chimney of the Davy type enclosed in a glass cylinder; above the glass and fitting closely on to it was a metal chimney with perforated top. The air entered the lamp through horizontal holes just above the oil-vessel, and passed through a double layer of gauze into a cone, by which it was directed on to the flame.

During this period Clanny brought out his fourth or "New" lamp. It was a Davy lamp fitted with a telescopic extinguisher in three sections. When pushed up, it was held in its place by a thin brass wire and exposed two-thirds of the gauze cylinder. In an inflammable atmosphere the wire fused and let down the shield, leaving only a small scrap of gauze exposed. The flame of the burning gas was extinguished, but a small oil-flame continued to burn. Other lamps introduced during this period were a Mueseler lamp similar to the Upton & Roberts, lamps by John Martin, John Newman, John Dillon, and the "Refrigerating" lamp of Wood, all of which are briefly described in the paper.

Period 1836 to 1843.—During this period two important investigations into safety-lamps were carried out, namely:—

(1) By the Belgian Commission, appointed on April 13th, 1836; and

(2) By the South Shields Committee, appointed shortly after the explosion at St. Hilda Colliery, which occurred on June 28th, 1839.

* In 1826 a silver medal was awarded by the Society of Arts to J. Roberts for a safety lamp, and in 1830 a second silver medal to J. Roberts (the addresses are different) for a reflector for safety lamps. Mr. Hardwick considers it certain that the recipient of the first medal was identical with John Roberts, Upton's partner, but does not think that the lamp rewarded was the same as the one mentioned in the text. This, he believes, could not have been invented before 1831, though the date is often given as 1827.—H. T. W.

Both Committees tested safety-lamps from the point of view of safety, and issued reports.

The Belgian Commission issued three reports: the first on April 25th, 1840, the second on August 31st, 1840, and the third on August 30th, 1841.

Among the lamps brought before the Commission and tested were the Davy, two lamps designed by Mueseler, the Cambrésy, the Dumesnil, and the Upton & Roberts. In the first report the opinion was expressed that the Davy lamp left much to be desired as regards safety, but that no lamp had been found to take its place except the Dumesnil. In the second report the Commission recommended that the Dumesnil, the Lemielle, and the now well-known chimney lamp of Mueseler be permitted for use, provided that their construction and dimensions were the same as the examples placed in the bureau of the Ingénieurs des Mines. The third report deals with trials made with the Mueseler lamps in practical working, and confirms the favourable opinion already expressed.

The South Shields Committee tested the following lamps:—the Davy, Stephenson, Clanny (the fourth, fifth, and probably sixth lamps), the Upton & Roberts, and the lamps of Henry Smith, Wm. Martin, and Richard Ayre. The Committee issued their report in 1843, and came to the following conclusions:—

"No mere safety-lamp, however ingenious in its construction, is able to secure fiery mines from explosions; and that a reliance on lamps alone is a fatal error, conducive to those dreadful calamities which they are intended to prevent . . . The naked Davy is, without a complete shield, a most dangerous instrument.

"The best description of lamp to be employed is that on the principle of the Improved Clanny and the Mueseler lamps, the latter with a continuous gauze cylinder."

In 1840 Dr. G. Bischof, Professor of Chemistry in the University of Bonn, conducted tests on the Davy lamp, and obtained results which agreed with those of Davy.

The lamps tested by the Commissions are shortly described in the paper.

It was during this period that Clanny produced two more lamps (his fifth and sixth) and that Mueseler invented his lamp with the chimney. Clanny's fifth lamp consisted of a internal gauze cylinder, completely surrounded by an impervious metallic shield having glass and lenses in its side and only open at the highest part of the gauze cylinder for about 1½ inches from the top. There was a ½-inch air-space between the cylinder and the gauze, and air could only enter the lamp after passing over the top of the shield. The lamp was subsequently modified by surrounding the portion opposite the flame with a "thick globular" shield of glass. The sixth lamp was constructed on the plan of the well-known Clanny, namely, with a glass cylinder surrounding the flame and a gauze

cylinder doubled at the top fitted closely on to the glass.*

The Mueseler lamp tested by the Belgian Committee introduced the chimney inside the gauze, and was similar in construction to the unbonneted Mueseler of to-day. The air was taken in above the glass cylinder, and had to pass through a horizontal gauze fitted between the top of the cylinder and the chimney. The unprotected glass cylinder surrounding the flame was considered to reduce the safety of the lamps.

Period 1841 to 1866.—During this period three Select Committees were appointed in England between 1849 and 1854 to inquire into accidents in mines. In the reports of Committees appointed in 1849 and 1852 the Davy lamp was criticised on the score of giving defective light and want of security in a strong explosive current. The third Committee pointed out that opinions as to its security varied, but the majority were in its favour.

Inventors appear to have been active in this period, for a considerable number of lamps of both types were introduced. These lamps are referred to in the paper. It is only necessary here to mention the "Jack" lamp, a shielded Davy in which the gauze was protected by a glass cylinder that extended from a short distance above the bottom of the gauze to the bottom of short gauze-cap or smoke-cap. The "Tin-can" Davy was introduced in 1866, and consisted of a Davy lamp closed in a tin casing with a glass window. In order to improve the light given by the Davy, the "Reflecting" lamp was introduced, polished gauze being used and a polished cone being placed below the flame to reflect the light. Two gauze cylinders were used, the inner one "being placed at such a distance from the outer that the firedamp enclosed between the cylinders (if the flame passes the first) explodes and may extinguish itself."

Period 1867 to 1879.—During this period several investigations on safety-lamps were conducted, the chief of which were those of the North of England Institute of Mining and Mechanical Engineers; of the Belgian Government; of the Société de l'Industrie Minérale in France, and of Messrs. Smethurst and Ashworth. Several new lamps were introduced, but the only new type of lamp was the Gray. The tendency appeared to be to attain a high degree of safety by increasing the complexity of construction. The results of the various investigations showed the insecurity of the Davy in currents exceeding seven to eight feet per second, and in the report of the French experiments the use of the Shield (*écran*) is advocated. The Belgian Commission appears to have reported in 1873, and as a result the use of the Mueseler type of lamp was made obligatory in fiery mines. The experiments of Messrs. Smethurst and Ashworth confirmed Davy's results on restricting the diameter of the gauze cylinder.

Period 1880 to 1887.—This period was one of great activity in the investigation of safety in mines. The following Commissions were appointed:—The French Firedamp Commission of 1878-1882; The Prussian Firedamp Commission of 1880-87; The Saxon Firedamp Commission of 1880; and the British Royal Commission of 1879-1886. In addition, experiments were carried out by the Midland Institute of Mining, Civil, and Mechanical Engineers in 1884; by Mr. A. R. Sawyer in 1884-1885; and by the Mining Institute of Scotland in 1886. The reports of these Commissions contributed materially to the growth of knowledge on the subject. The principal results are given in the paper. The importance of the shield or bonnet in increasing the safety was frequently insisted on, but its use was in some cases objected to, as it concealed the gauze from inspection. A very large number of lamps were designed and submitted to tests. It is only possible to mention one of them here, namely, the Marsaut lamp. The first lamp introduced by Marsaut was a bonneted Boty or Clanny, with a chimney, derived from the Mueseler by suppression of the gauze diaphragm. On experimenting with his lamp by raising it into a glass bell containing illuminating-gas and then lowering and stopping it opposite to the edge of the bell (in order to cause an internal explosion at the height at which the gas was mixed with air in suitable proportions), ignition of the gas in the bell took place at nearly every trial. This phenomenon, known as "l'effet Marsaut," occurred with several other lamps when similarly tested. As a result of these experiments, Marsaut was led to construct the well-known Marsaut lamp. The gauze diaphragm and Mueseler chimney were replaced by an interior gauze. The large surface of this additional gauze offered means for the better cooling and escape of the gases. The gauzes were protected by a bonnet, with holes at the bottom for the admission of air, which was taken in over the glass and had to pass through both gauzes and holes at the top for the escape of the products of combustion. This lamp did not show "l'effet Marsaut."

Period 1888 to 1913.—The most striking features of this period are the large number of official stations erected for testing safety-lamps and the improvement in apparatus used. Stations have been installed in Great Britain, at Eskmeals, in France and in Belgium, and in Westphalia, Silesia, and Saxony in Germany, whilst the Austrian station at Mährisch-Ostrau used by the Commission of 1881 to 1891 appears to have been maintained; experiments were also carried out at Karwin.

* On March 25th, 1846, a paper by Dr. Clanny on his safety lamp was read before the Society of Arts, in which the lamp was fully described, and a specimen exhibited. The lamp was referred to the Committee of Chemistry, which discussed the paper and received evidence from a number of persons as to the efficiency of the lamp. The Committee resolved: "That Dr. Clanny's lamp will give a superior light to the wire gauze lamp in common use in coal mines, and might be equally safe, but they cannot recommend to the Society to take upon themselves the responsibility of recommending a new safety lamp, as they are not aware of any evidence of an explosion having occurred where the wire gauze lamp has been used with ordinary care."—H. T. W.

Considerable improvements have been made in the construction of lamps so as to secure strength in the various parts and to facilitate the operations of cleaning and assembling the lamps. Much attention has been given to the question of locking arrangements, and magnetic locks have come largely into use. Arrangements for lighting lamps by electric means after they have been assembled have been largely adopted, and in Great Britain, France and Belgium the efficacy of the bonnet has been fully recognised. In France, Belgium, and Germany the use of internal relighters is very generally approved, but not so in Great Britain. The question of illuminants has also received much attention, and even acetylene lamps have been introduced. Among the more important lamps of this period may be mentioned the Howat "Deflector" lamp, the Ashworth-Hepplewhite-Gray, the Thorneburry, the Fumat, the Body-Firket, the Wolf, and the Hailwood "Combustion-tube" lamp. As the result of recent experiments, there has been a tendency to restrict the use of lamps by legislation to "permitted" lamps. This has been done in Great Britain, France, and Belgium. A number of the modern lamps are described in the paper, but it would appear unnecessary to do so here, as their construction is more or less familiar.

The authors have brought their paper to a close at the end of the year 1913 because they consider the history of the safety-lamp as commencing in 1813, although the Davy lamp was not invented until towards the close of 1815. Another reason which decided them to adopt this course has been the difficulty of writing about contemporary events, for since the outbreak of the great European war in August, 1914, the course of events has not been normal, and possibly the development of the safety-lamp has been in consequence arrested.

ENGINEERING NOTES.

Twenty Millions for a City and Suburban Railway in Australia.—We have just received from Mr. Joseph Davis, M.Inst.C.E., Director of Public Works, New South Wales, a very comprehensive and carefully-studied report concerning the proposed city and suburban railways for Sydney, viz., the electrification of the inner zone of existing suburban railways to Parramatta, Hornsby, Sutherland, and Bankstown; the construction of the City Electric Railway, and electric railways to the eastern, western, and northern suburbs; the construction of two long-span cantilever bridges across the harbour of 1,600 ft. and 1,350 ft. centre spans respectively; the electrification of the outer zone suburban railways to Penrith, Campbelltown Waterfall, the Hawkesbury River, and various other small branches in the suburban area; and the construction of underground tramways. The cost of these works, which have been approved, will be approximately twenty million pounds sterling, exclusive of land purchase, which will be a very large item, and they will be carried out in the order indicated above. The subject was referred to in "Engineering Notes" of January 8th and February 5th, 1915, but we now have detailed information which shows the project to be a most ambitious one, entailing, in the neighbourhood of the city of Sydney and suburbs alone, an expenditure on railways and tramways which is probably unrivalled compared with any town of its size in the world.

Radio-Telephony.—The *Engineer* says, on this subject, the transmission of speech without wires is a problem with which scientists and electricians have been dealing in one way and another for a good many years, though it is doubtful if anyone imagined until quite recently that radio-telephony could be efficiently established across the Atlantic. Speech, however, has actually been transmitted between the giant station at Arlington, near Washington, and the Eiffel Tower. The achievement is all the more remarkable when it is remembered that not a word, or even a sound suggestive of a word, has ever been transmitted through an Atlantic cable, nor is there reason to think that this will be possible whilst present methods are in vogue. Working jointly, the American Telephone and Telegraph Company are said to have obtained results little short of marvellous considering the distance involved. To American engineers the credit for this achievement belongs, but it must not be imagined that wireless experts in this country have done nothing in this particular field. As far back as 1913, Mr. Round, of the Marconi Company, carried on conversation without wires between Marconi House and Berlin. In fact, such excellent progress was being made that had it not been for the intervention of the war the Marconi transatlantic stations would in all probability now be in wireless telephonic communication. Next to nothing of a technical character concerning the tests between Arlington and Paris has been published, although there is reason to believe that the methods adopted are very similar to those employed in the latest experiments conducted by Mr. Round. It is doubtful if radio-telephony will ever supersede the present wire system for short distances over land, but it will undoubtedly be of immense value where the wire telephone is impracticable. The development of radio-telephonic apparatus has been a slow and laborious process, involving much perseverance and expense. At times any real measure of success appeared hopeless, except for short ranges of transmission. But now that speech has been transmitted between Paris and Washington the outlook is altogether different, and there is every reason to believe that sooner or later radio-telephony will establish itself

permanently as a means of communication throughout the world. The *Times*, in connection with the above, says the national meeting of the American Institute of Electrical Engineers held in June involved simultaneous sessions in San Francisco, Chicago, Atlanta, Philadelphia, Boston, Salt Lake City, Denver, and New York, all these being connected together by the long-distance telephone circuits of the American Telephone and Telegraph Company. Over 5,000 members and guests were present, there being 500 at Atlanta, 700 at San Francisco, 900 at Boston, 850 at Philadelphia, 1,000 at Chicago, and 1,100 at New York; while fifty members at Denver and forty at Salt Lake City listened to the proceedings but were not connected so as to take part. The meeting began in New York at the scheduled time, and from that point the roll of the cities was called, the section officers presiding in the other cities responding with a statement of the attendance at each place. Mr. H. W. Buck, the president-elect, made a short speech of acceptance to the members gathered in the different cities. As regards the reports made at the meeting, the officers presenting them were not all at New York, and in a number of cases motions made in one city were seconded in another and discussed by several members in still other places. After the business was transacted each section held a strictly local session with an address by some prominent speaker. At the end of the local sessions the long-distance lines were again brought into use. The meeting was addressed by Dr. M. Pupin, speaking from New York, and closed with a general greeting to the members from the secretary, also in New York.

Hydro-Electric Power in Tasmania.—Great Lake, hitherto chiefly the resort of anglers, has been utilised to furnish water power for the generation of electricity for distribution to Hobart and throughout Tasmania. The project, which is now practically complete, will provide 26,000 h.p. at the turbine shafts for twelve hours a day, or 39,000 h.p. for eight hours a day, and it is believed that the amount can eventually be increased to 70,000 h.p., according to the report published by the *Board of Trade Journal*. According to the account of an interview between the British Trade Commissioner for Australia and the general manager of the Hydro-Electric Department of the Tasmanian Government, the latter had at the time already made arrangements for the sale of about 9,000 h.p., and was carrying out a publicity campaign with the object of bringing the scheme to the notice of Australian merchants and others desirous of obtaining light and power. Works for the manufacture of calcium carbide were projected, and apparently United Kingdom interests were investigating the possibility of installing woollen mills. The general manager considered that there will be an increased demand in Tasmania for electrical fittings and appliances, and he suggested that the time is ripe for more active steps to be taken by United Kingdom manufacturers for bringing this class of goods to the notice of consumers. Hydro-electrical instalment was effected a dozen years ago, in the case of lighting the town of Launceston, the second in importance to Hobart, the capital of Tasmania. This water is drawn from local sources, not from the Great Lake as in the present case.

Humphrey Gas Pumps.—The best-known type of Humphrey gas pump is that in which a long column of water is caused to oscillate to and fro in a play pipe by the explosion of combustible gases acting direct on the water. This type, while adapted for dealing with large quantities of water, as at Chingford reservoir, is not so suitable for smaller installations. The Humphrey Pump Company have therefore brought out a two-cycle direct-acting internal-combustion pump based on the same principle as the water-column pump, but introducing a piston between the gases and the water. The *Times* remarks, in reference to the foregoing, the pump in appearance is very similar to an ordinary vertical direct-acting steam pump, the combustion cylinder being at the top and the water cylinder underneath. The method of operation is as follows: Assuming the piston in the internal-combustion cylinder to be at the bottom of the stroke with a compressed charge below it, on ignition this piston is driven upwards carrying with it a cast-iron weight, which is fixed to the top end of the piston rod. Side rods are also fixed to the weight and secured at the other end to a crosshead carrying the end of the pump rod; on one of these side rods is fixed a cam which opens the exhaust valve when the piston has attained a certain height. The exhaust valve being open, the pressure underneath the piston falls to that of the atmosphere. The upward motion of the piston, however, continues in virtue of the momentum already acquired, and a little later the piston passes the ports in the cylinder, these ports communicating with an annular space chamber surrounding the upper part of the cylinder. Into this chamber the upward motion of the piston had previously compressed a charge of air and gas. This charge now escapes through the ports into the cylinder below the piston. At or near this part of the stroke the energy imparted by the charge has been entirely expended (1) in raising water, and (2) in lifting the weights, and the piston comes to rest. The piston now returns and compresses the new charge into the clearance space; and at the end of the stroke this charge is fired, and a new cycle begins. During the down stroke a new charge has been drawn in above the piston through a

non-return gas valve. An air-cushion is provided between the weight and top cylinder cover to prevent accident in event of exhaust valve leaking or breaking. To start the pump the piston is raised by a barring lever and a charge allowed to accumulate beneath it. The lever is then tripped, allowing the piston to fall, compress, and fire the charge. In the larger sizes a screw with ratchet attachment is used in place of the barring lever. It will be obvious that all the work is done on the upward stroke, and that the water in the pump is circulated only on the downward motion. The pumps will work on town gas, producer gas, or petrol. Compactness and lightness are the objects aimed at in the design. The smallest size (3 in.) made at present weighs only 350 lb., and can deliver 3,000 gallons an hour at 33 ft. head, with a fuel consumption of 20 cubic of gas, or ⅜ pint of petrol an hour.

OBITUARY.

Sir Robert Gray Cornish Mowbray, Bt.—Sir Robert Mowbray died on the 23rd inst. at Mortimer, Berkshire. He was born in 1850, and was educated at Eton and Balliol. He was elected a Fellow of All Souls in 1873. In 1876 he was called to the Bar at the Inner Temple. From 1886 to 1895 he sat in Parliament as member for the Prestwich Division of South-East Lancashire, and he represented the Brixton Division of Lambeth from 1900 to 1906. He served on several Royal Commissions, and as Parliamentary Private Secretary to Mr. Goschen, when he was Chancellor of the Exchequer, from 1887 to 1892. In 1900 Sir Robert was elected a life member of the Society, he having served as Prime Warden of the Goldsmiths' Company in the previous year, and being nominated by the Court of that Company under the annual subscription given to the Society. In 1903 he presided at a meeting of the Indian Section, when a paper on the Indian Census was read by Sir J. A. Baines, C.S.I.

NOTES ON BOOKS.

Robert Adam and his Brothers. By John Swarbrick. London: B. T. Batsford. N.D.

To all dwellers in the Adelphi anything connected with the life of Robert Adam must be of extreme interest, and the Society of Arts is quite the oldest inhabitant of the district, while it occupies what has always been its most important building.

Considering that Robert Adam died only a century and a quarter ago, and considering also the great reputation which he possessed in his lifetime, a reputation which has endured up to the present date, it is remarkable that not more is known about the man himself. We know something of his family, of his education and early friendships. We know how he visited Italy, and of the careful study he made of Diocletian's Palace in Dalmatia, so that when he returned to England, a man not much over thirty, he brought with him such a reputation that he was appointed architect to the King. We know, too, that he was popular and well known in society, and that he enjoyed the benefit of high patronage; while, as the late Mr. Cosmo Monkhouse points out in the "Dictionary of National Biography," his social position was attested by the fact that when he was buried in Westminster Abbey his pall-bearers included a duke, two earls and a viscount. But, after all, of his personal history we know really very little, and there is not very much about him in contemporary literature. Horace Walpole speaks of him, not with much approval. Fanny Burney met him, and recorded the fact in her diary; and there are, of course, other references, but they are not very numerous.

With regard to his works, it is quite another matter. It has been said of Robert Adam that he worked in the fashion of the elder Dumas, having a number of assistants, or according to the modern professional slang "ghosts," who were under his direction and carried out his ideas. Not only had he the assistance of his brothers, especially James and William—though the latter is believed to have managed mainly the business side of the brotherhood—but he brought over a number of Italian artists, who helped him, and besides these he appears to have employed a little army of subordinates. No one man could have done in a lifetime of sixty years the work which Adam left behind him, unless he had been able to depute the execution of a very large part of it to others.

And his works were as various as they were abundant. He was apparently most proud of the country houses which he built, and he had his full share in the construction of the numerous country mansions which provided so much employment for the architects of the eighteenth century; Fergusson says that in that century there were 200 erected. But he left his mark both on London and on Edinburgh. In the former city there are numerous houses which he built, modified, or decorated; and it is in London that his most remarkable, if not his greatest, work is to be found—the Adelphi, a private speculation of his own, which nowadays would certainly have been undertaken by the municipality.

Most of these buildings still remain to testify to Adam's genius, versatility and industry. But besides the buildings themselves there are copious literary records of them. The "Works in Architecture" was published in numbers from 1773. The various parts made two volumes, published in 1778 and 1779, and a third volume was published much later, in 1822. These are magnificent books of large folio size, full of fine engravings by Francesco Bartolozzi,

Antonio Zucchi, Domenico Cunego, Giovanni Vitalba, Benedetto Pastorini, Thomas Vivarez, Francis Jukes, James Caldwall, Edward Rooker, Thomas White, Robert Blyth, and others.*

Amongst the engravings we find the elevation of the front of the Society's House, which served as the frontispiece to Volume VIII. of the *Transactions*, and was reprinted from the original plate as the frontispiece to the recent History of the Society. But it is on a much larger scale, filling up the whole of the great folio page. Then there are the fifty-two large folio volumes of designs in the Soane Museum, including in all some 8,000 drawings and sketches.

The writer, therefore, of any fresh book on Adam's work has abundant material, and of it Mr. Swarbrick has availed himself fully and with considerable judgment. He has also added a number of original photographs of some of Adam's buildings and interiors, as well as reproductions of portraits of Robert and James. These are all produced in the manner for which Mr. Batsford has made a reputation, so that the volume is a very beautiful one, and a fine example of the best class of modern illustrated book. At the same time it is impossible to avoid a feeling of regret in comparing the splendid original engravings on thick linen paper with the modern work, fine as it is, on paper which must of necessity consist to a large extent of some mineral matter capable of providing an absolutely smooth and polished surface. One wonders how in another hundred years Mr. Batsford's beautiful book will compare with its predecessor of the end of the eighteenth century. Each age, however, must produce its own work in its own way, and modern reproductive processes are not capable of anything much better than that which Mr. Batsford and his author have given us.

If there is not a great deal which is new, it is because there is not very much that is new to be provided. The work of Adam (for it really was the work of Robert) is, of course, perfectly well known, and has been very fully discussed. There is room for an abundance of difference of opinion about it. There can, however, be no doubt whatever of the enormous influence that it had, not perhaps so much on architecture proper, but unquestionably on decorative art of every sort, not only architectural. After all, Robert Adam was a decorator and a designer rather than an architect (spite of all his houses), and it is because of his decorative work that his fame is still alive. He influenced his contemporaries as well as his successors, and he founded a school of permanent value. It is not merely a vagary of fashion that, after being decried and depreciated by the artists of the Gothic school, the Adam's style is now coming to the front again, and receiving its full measure of appreciation.

As was naturally to be expected, it is to the works of Adam that Mr. Swarbrick has devoted all his attention, for though the book professes to deal with the lives and work of the brothers, as well as with their influence on English decoration and furniture, there is practically no addition to our knowledge of the men themselves.

One queer little slip may be pointed out, though without any desire to find fault. It is stated that Robert Adam was elected a member of the "Society of Arts in St. Martin's Lane" in 1758. Now Robert Adam was elected a member of the Society of Arts in 1758. The Society at that time was only four years old: it will thus be seen that Robert was a very early member. In that year the Society occupied a house at the corner of Castle Court, opposite the New Exchange. It is by no means likely that he was ever a member of the well-known academy in St. Martin's Lane, and his name is not given in the only list of members of that academy which is known to the present writer—that by W. H. Pyne, the author who wrote under the name of Ephraim Hardcastle. Pyne's list was compiled from memory, and published years after the St. Martin's Lane academy had disappeared, and what was left of it merged into the Royal Academy, but it is fairly full, and probably the name of so well-known a man as Robert Adam would not have been overlooked.

To counterbalance this little bit of criticism, we may offer our thanks to Mr. Swarbrick for reproducing (opposite page 76) the knocker which still adorns the door of the Society, as well as an excellent photograph of its House.

* The whole work was finely reproduced by a French publisher in 1900 and following years.

GENERAL NOTE.

Educational Books for British Prisoners of War.—Arrangements have been made, with the approval of the Foreign Office, for extending to British prisoners of war interned abroad the benefits of the scheme, which has been in operation for the last year in connection with Ruhleben, for supplying selected books of an educational character to those of the interned who may be desirous of continuing their studies in any subject. An appeal is therefore now made for a plentiful supply of new or second-hand books of an educational character (light literature and fiction is available from other sources) to meet the needs of the many thousands of British prisoners interned in enemy or neutral countries. It is to be hoped that to this appeal there may be a liberal response. A circular explanatory of the educational book scheme can be obtained by sending a postcard addressed to the Board of Education, Whitehall, S.W., to Mr. A. T. Davies, who is in charge of the arrangements.

London: Printed by William Clowes & Sons, Ltd., Duke Street, Stamford Street, S.E., and published for the Royal Society of Arts by G. Bell & Sons, Ltd., York House, Portugal Street, W.C., in the Parish of St. Clement Danes, in the City of Westminster.—July 28, 1916.

FRIDAY, AUGUST 4, 1916.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICE.

INDIAN SECTION COMMITTEE.

The following is the list of the Indian Section Committee, as appointed by the Council :—

Dugald Clerk, D.Sc., F.R.S. (Chairman of the Council).
Sir William Duke, K.C.S.I., K.C.I.E. (Chairman of the Committee).
Lord Ampthill, G.C.S.I., G.C.I.E.
Sir Arundel T. Arundel, K.C.S.I.
Sir J. Athelstane Baines, C.S.I.
Sir Charles Stuart Bayley, G.C.I.E., K.C.S.I.
Sir Steuart Colvin Bayley, G.C.S.I., C.I.E.
Thomas Jewell Bennett, C.I.E.
Sir M. M. Bhownaggree, K.C.I.E.
Sir George Birdwood, K.C.I.E., C.S.I., M.D., LL.D.
Sir Valentine Chirol.
Sir William Henry Clark, K.C.S.I., C.M.G.
William Coldstream, B.A., I.C.S. (retd.).
Laurence Currie, M.A., J.P.
Right Hon. Earl Curzon of Kedleston, K.G., G.C.S.I., G.C.I.E., D.C.L.
Right Hon. Sir Henry Mortimer Durand, G.C.M.G., K.C.S.I., K.C.I.E.
Sir Steyning William Edgerley, K.C.S.I., K.C.V.O., C.I.E.
James Fairbairn Finlay, C.S.I., I.C.S. (retd.).
Sir Frederic W. R. Fryer, K.C.S.I.
Sir Krishna Govinda Gupta, K.C.S.I.
Colonel Sir Thomas Hungerford Holdich, R.E., K.C.M.G., K.C.I.E., C.B., D.Sc.
Sir Philip Perceval Hutchins, K.C.S.I.
Lord Inchcape, G.C.M.G., K.C.S.I., K.C.I.E.
Sir Henry Evan M. James, K.C.I.E., C.S.I.
Sir John Jardine, Bt., K.C.I.E., M.P.
Louis James Kershaw, C.I.E.
Sir Frederic S. P. Lely, K.C.I.E., C.S.I.
Charles Campbell McLeod.
Sir John Ontario Miller, K.C.S.I.
R. A. Leslie Moore, I.C.S. (retd.).
Right Hon. Sir Joseph West Ridgeway, G.C.B., G.C.M.G., K.C.S.I.
Sir Charles Montgomery Rivaz, K.C.S.I.
Sir Frederick Alexander Robertson, LL.D.
Colonel Sir Richard Carnac Temple, Bt., C.B., C.I.E.
Carmichael Thomas.
Sir James Thomson, K.C.S.I., M.A.
Sir James Wilson, K.C.S.I., M.A.
Colonel Charles Edward Yate, C.S.I., C.M.G., M.P.
S. Digby, C.I.E. (Secretary).

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

OPTICAL GLASS.

By Walter Rosenhain, D.Sc., F.R.S.,
Superintendent, Metallurgy Department, National Physical Laboratory.

Lecture I.—Delivered November 29th, 1915.

The national importance of the whole question of optical glass is so fully recognised at the present time that when I was invited by the Society of Arts to deliver a course of Cantor Lectures on this subject I felt unable to decline that invitation, although intense preoccupation with other matters—including the practical side of this very subject—made it a matter of extreme difficulty to devote the necessary time and energy to the preparation of lectures of any sort. It is by now a commonplace to say that optical glass is of first-rate importance in connection with war, both on sea and land; and it is also well known that the outbreak of the present war found us unable in this country to produce, without much delay and difficulty, a supply of glass adequate in quality and quantity to meet the demands of the army and navy. Since that time very great efforts have been made, and a very considerable measure of success has been attained so far as meeting the immediate requirements for war purposes is concerned. Still, even that measure of success is not yet entirely sufficient, and we have, besides, to look a good deal further in such a matter. We must not be content with tiding over the present difficulty by what may well be termed eleventh-hour heroic measures. Now that it has been brought home to us that the production of optical glass has become an industry of national importance, it behoves us to see that we shall never again drift into anything like dependence upon any foreign country for one of our vital requirements. We have to see to it that in regard to this industry we

shall achieve not only equality with the best that is done elsewhere, but that we shall put forth our best efforts to attain a leadership in this as in other technical matters. I am happy to say that this point of view has been most fully recognised by those in authority, and as at least one step in that direction, the Government have provided the National Physical Laboratory with reasonable funds for the purpose of initiating extensive research into the fundamental problems which beset this whole industry of optical glass manufacture. It is one of the objects of these lectures to set out the nature of some of these problems, by describing first the nature and properties of optical glass, and particularly those properties which distinguish it from ordinary glass; the present process of manufacture will then be described—and I am fortunate in having had over five years' actual experience of that process on the industrial scale. I shall then hope to analyse the present process in such a way as to make clear the causes of difficulty, and to show the limitations and possibilities so far as our present knowledge of glass allows us to formulate them. This general survey, brief as it must necessarily be, will perhaps serve to clear the ground and to enable those who, like myself, may be approaching this subject from the point of view of researches directed towards the improvements which are needed, to realise more fully than is possible from other existing literature what are the principal factors of the problem before us.

What, then, are the fundamental properties which distinguish "optical glass" from "ordinary glass"? We must guard ourselves at the outset from misconception by remembering that the term "optical glass" is used to cover a fairly wide range of material in regard to quality. Thus the cheap glass, which can be used for very small and low-power telescopes, is a very different material from the best kinds of optical glass used for the lenses and prisms of a range-finder or a large telescope. Thus ordinary plate glass of good quality is used in large quantities for the production of certain types of small and cheap lenses, while some of the cheap pressed lens-blanks which were produced in such very large quantities in France are really of no higher quality. In order, however, to narrow the range somewhat, it will be well, in what follows, to confine the term "optical glass" to the best kinds of glass, such as would be fit for use in the best optical instruments.

If we think of "optical glass" in that way, it is readily distinguished from even the best of ordinary glass by a whole series of important properties. These can, however, be summed up in two groups: (1) Properties relating to "general quality," in regard to which "optical glass" is simply a "better quality" than ordinary glass; and (2) Properties of a more specifically "optical" kind, relating to the refractive and dispersive powers of the glass. In regard to these, optical glass must meet certain definite and stringent requirements which are not at all applicable to glass used for other purposes. It will be convenient to discuss these two groups of properties separately and in the order named, since the first group is applicable to all kinds of optical glass, while the second group vary from one kind of glass to another.

Of the general properties of glass, that which is most important for optical glass is "transparency." If we use this word in its widest and strictest significance, it denotes the power of transmitting light without diminution as to quantity and without introducing any irregularities or disturbances into its path. We commonly think of an object as "transparent" when we can "see clearly through it," but the object is perfectly transparent only if we can "see through it" as perfectly as if it did not exist at all. The only really close approach to a perfectly transparent material—if we may call it that—is a perfect vacuum, *i.e.* the free ether. But even in inter-stellar space there appears to be some very slight power of absorbing or scattering light. In dealing with glass, therefore, too great a degree of perfection need not be expected; and it is surprising to find how very "transparent" good optical glass of the best kinds really is. It requires very refined measurement indeed to show that there is any absorption of light at all in such glass—at all events in the range of visible light. For the short waves of the ultra-violet region and for the long waves below the red end of the spectrum, however, glass—no matter how pure and clear—still shows very strong powers of absorption.

If now we consider how the best optical glass differs from ordinary glass in this matter of transparency, we shall immediately touch upon some of the most important properties of glass from our present point of view. First, as to *colour*. The quality of ordinary glass, such as tableware or window glass, is most usually judged by its colour; but this judgment is

apt to err, because the apparent colour of a given quality of glass depends so very much upon how it is examined. Looking through a sheet of window-glass in the ordinary way, we are scarcely conscious that it is at all coloured. If we take a piece of the glass and lay it down on a sheet of white paper, we notice a slight tinge of colour, because now the light, instead of merely traversing one thickness of the glass, has had to pass through it twice—once before it reaches the paper and a second time after being reflected back by the paper. The effect of contrast with that part of the white paper not covered by the glass is a further help. The colour of the glass, however, only becomes strikingly apparent when, instead of looking through the glass and allowing the light to traverse a thickness of only one or two tenths of an inch, we look lengthwise through a long strip in such a way that the light has to traverse a thickness of ten or twelve inches of glass. Examined in that way, ordinary window glass looks a deep sea-green; even the purest and best of optical glass shows a noticeable colour when light has to traverse it in great thicknesses. This phenomenon gives rise to a curious effect which is obtained when a large block of good glass is placed beside a heap of small pieces made of a precisely similar block of the same glass: while the single large block looks distinctly coloured, the heap of small pieces looks absolutely free from any trace of colour.

For good optical glass, the greatest possible freedom from colour is generally demanded, and since in the majority of glasses colour is the result of the presence of impurities in the glass, this demand can be met by adequate care in manufacture and in choice or preparation of raw materials. Various kinds of glass, however, differ widely in sensitiveness to colouring effect, and an amount of impurity which would produce a negligible effect in a hard crown glass, for instance, would bring about a distinctly green tinge in a dense barium glass. The popular classification of glass according to colour, however, has produced a deep-rooted prejudice against all visible colouration in lenses. This is really a prejudice, because in most optical instruments the thicknesses of glass used are only small, and colouring effects would not be serious. But the result has been rather a curious one. Glass-makers, in order to meet the demand for material free from the greenish tinge associated with the poorer kinds of glass, have resorted to the use of what are known as "decolourisers." These act by the introduction of a compensating or complementary colour into the glass—so that a substance is added which by itself would produce a slightly pink tinge. When this is superposed upon the slight greenish tint of the glass the result is a "neutral" tint in which no definite colour is discernible. For optical purposes, however, this remedy is undoubtedly much worse than the disease—as will appear at once if the manner in which this result is obtained is considered. The glass appears green in the first instance because it absorbs some of the red rays of the light which passes through; if now a pink tint is superadded, this results in the simultaneous absorption of some of the violet or blue rays, so that the absorptions at the two opposite ends of the spectrum are approximately balanced. The result is a neutral-tinted glass which actually transmits considerably *less* light than the slightly greenish glass which it is designed to replace. For most optical purposes, the glass having the greater total absorption is much the worse, so that the demand for "colourless" glass for optical purposes may at times defeat its own object. Ultimately we are, of course, led to the conclusion that the only satisfactory way of producing colourless optical glasses is to do so by the elimination of all colouring impurities, and by entirely avoiding the use of "decolourisers."

While in the majority of glasses the presence of visible colouration is due to the presence of impurities, there is another aspect of the matter which is worthy of brief mention. To pursue this particular matter very far we should have to enter into the details of the very ingenious electro-magnetic theory of refraction and dispersion which is associated with the name of Drude. It will be sufficient, however, to point out that the very transparency of glass is intimately bound up with its electrical properties. Glass is a very excellent electrical insulator for electric impulses which alternate at the enormous rate which obtains in the waves of visible light; if these electrical properties were identical throughout the entire range of electric waves, we should probably find little refraction and no dispersion in our glasses. The dispersion particularly is closely associated with the fact that for some wave-length or rate of alternation lying not very far outside the visible range at either end there is a band or region in which the glass behaves almost like a good conductor of electricity rather than as an insulator—with the result that those particular wave-lengths

are absorbed and the glass is practically opaque for waves of that particular length. In the vicinity of such absorption bands, the differences in the behaviour of light of different wave-lengths become very much accentuated, and consequently the optical properties of a given glass, so far as visible light is concerned, are found to depend upon the distance from either end of the visible spectrum at which these invisible absorption bands are situated. If near the blue end, then the blue end of the spectrum is greatly drawn out, and vice-versa if the absorption lies near the violet end. The interesting point in regard to the visible colour of a glass, however, arises here—for in those glasses in which there is very great dispersion, particularly near the violet end of the spectrum, we should be led to conclude that the active absorption band was situated not very far beyond the limit of the visible spectrum and in extreme cases near enough to that limit to affect the visible colour of the glass. It is interesting to find that the very dense flint glasses, in which dispersion reaches its extreme values, are distinctly yellow in colour. This yellow colour is not due to impurities but is inherent in the glass and closely associated with its most characteristic properties. Not only this—it is further known that the absorption bands of a glass move appreciably when the temperature is changed, and we might expect that in flint glasses not quite so dense as those just referred to, and therefore colourless when cold, the presence of the absorption band near the violet end of the spectrum might make itself felt when the glass was heated, and the band thereby displaced. This is a well-known phenomenon in all the denser flint glasses, which, although colourless when cold, become very decidedly yellow when heated. We cannot pursue this very interesting matter further in this place, but enough has perhaps been said to suggest that the colour and absorbing powers of glass are far more intimately connected with their most important optical properties than one would at first sight imagine.

The transparency of glass will obviously be diminished to a definite extent by the presence in its mass of any substance which is not glass. Such foreign bodies are unfortunately by no means of rare occurrence in glass, and their presence has to be carefully guarded against in optical glass. Bodies accidentally included can, as a rule, be cut out and avoided during the preliminary selection of the glass, and indeed their occurrence can be to a large extent avoided by adequate care during manufacture. There are, however, two types of "foreign body" which are produced within the glass itself, and these are not so easily dealt with. The first of these types are the bubbles or "seed" which are apt to occur in all glass. When glass is melted, the raw materials are introduced in the form of powder and much air is enclosed in this mass. A much larger quantity of gas—mostly carbon dioxide and oxides of nitrogen—is generated by the decomposition, during fusion, of the raw materials, since the glass-making oxides are generally employed in the form of carbonates or nitrates. If the glass-maker is free to adjust his mixture to suit his furnace and mode of working, he can generally arrive at a mixture which evolves this gas in the form of large bubbles which rise rapidly to the surface and carry all their smaller brethren with them —the glass is said to "come to a good boil" and is finally left entirely free from all bubbles. In making optical glass, however, the skill of the glass-maker in this direction is entirely hampered by the restriction that the mixture must produce a definite chemical composition if the desired optical properties of the glass are to be attained. Consequently many of the optical glasses "fine" with difficulty, the mixture generating extremely small bubbles which hardly rise to the surface at all. In some cases there even seems to be a continuous production of fresh bubbles—either by the gradual volatilization of one of the constituents of the glass or by some interaction between the glass and the pot in which it is contained or with the furnace gases diffusing through the somewhat porous walls of the melting pot. In these cases the glass cannot be entirely freed from all small bubbles, and this necessity has been accepted by opticians and by the public—who have both come to recognise that the presence of these small bubbles, which do not diminish the light transmitted by more than 0·02 per cent., is of no appreciable disadvantage to the finished lens.

More serious—where they occur—are the "foreign bodies" of the second type. To understand their nature we must recall the fact that glass is not really a "solid" in the strict sense of the term—it is really a liquid which has "congealed" by becoming gradually stiffer and stiffer, but without ever passing through the definite transformation from liquid to solid which we meet with in the majority of bodies. Most molten substances pass from the liquid to

the solid condition by a definite act or process of crystallization. In most cases, however, this act of crystallization can be prevented by cooling the substance very quickly—as, for instance, by quenching it in cold water. If this is done, the result is a vitreous body possessing some of the properties of glass. The conclusion is fairly well established that glass is really a congealed liquid which has been prevented from assuming the truly solid or crystalline condition by too rapid a rate of cooling. "Too rapid" is, of course, in this sense, a purely relative term, since a rate of cooling which will prevent the crystallization of one kind of substance will be far too slow to prevent another from becoming completely crystalline. If this view is correct, it ought to be possible to make glass assume the truly solid crystalline condition by cooling it very slowly so as to allow the crystals to grow in the thick sluggish liquid. This can be done, but the same result can also be achieved by merely heating the glass to a temperature a little below that at which it would crystallize or "freeze" if very slowly cooled. At this temperature—in most glasses a dull red heat—the glass soon becomes entirely crystalline. In this condition it loses its vitreous nature and becomes an opaque material of an entirely different character. Now in the case of most varieties of glass the rate of cooling must be very slow indeed, or the period of re-heating must be very prolonged, to bring about this crystallization—or "devitrification," as it is called. But when the composition of a glass is pushed to an extreme in order to obtain some desired optical property, it sometimes happens that a substance is produced in which crystallization sets in much more readily, and such a glass, if cooled at the ordinary rate, may be found to be studded with a large number of small specks, each a small mass of crystallized glass. In some cases the crystallization may even extend throughout the glass, reducing it to a porcelain-like opaque mass. In extreme cases this phenomenon makes it impossible to produce satisfactory glass of such a composition at all, while in other cases it is possible to overcome the difficulty by taking steps to cool the glass more rapidly through the dangerous zone of temperature.

We have next to deal with the most serious of all the obstacles to "transparency" which is met with in glass. These are the "striae" or veins which exist in all ordinary glass, and which must be removed before glass can be used for the higher purposes of optics. The nature of "striae" is most readily understood by glancing at any piece of ordinary glass which has been polished on two opposite faces—as, for instance, a piece of ordinary plate-glass which has been polished on its *edges*. Their nature and mode of formation, as well as the means for removing them, can be well studied by pouring a little glycerine into a glass or beaker, and then pouring some water on top of it. As soon as the two liquids begin to mix—which can be brought about by stirring them with a glass rod — strongly-marked "striae" make their appearance, and these can only be made to disappear by prolonged and vigorous stirring. What happens is that the two liquids do not dissolve in one another rapidly, and mixture takes place by the intermingling of layers and streams of the two liquids. As they possess different densities and different refractive indices, the rays of light traversing the liquid are refracted and even reflected and scattered at all the bounding surfaces between these layers and streams, and the liquid thus becomes turbid and distinctly non-transparent. Only as the stirring proceeds, and the two liquids gradually become entirely mingled and dissolved in one another, does the turbidity disappear, until at last the mixed liquids are perfectly limpid and clear again. The same series of phenomena—or at least the earlier stages of the series—occur in the melting of glass. Glass is a mixture of a number of chemical substances, which can be made to assume the state of complete mutual solution, much as glycerine and water can be made to do; but when the glass is simply melted, the various molten liquids which are present in it are not generated in the form of a homogeneous solution, but in streaks and streams and layers, much like those which are formed in the earlier stages of mixing of glycerine and water. So far as we have yet gone, however, we should expect that vigorous and prolonged stirring would effect satisfactory mixture, and would entirely eliminate striae. Unfortunately, however, there are other causes at work which militate against such a result. The most serious of these is the interaction which takes place between the crucible or pot in which the glass is melted and the glass itself. Glass in general, and particularly the more extreme kinds of optical glass, unfortunately possesses the power of attacking and dissolving the substance—fireclay—of which glass-melting pots have always been made, and the resulting solution, which contains a fairly large proportion of alumina derived from the pot, is a

particularly "thick" or viscous liquid which only mingles slowly and grudgingly with the rest of the glass. During the progress of any stirring operation, this interaction of glass and clay continues, and if care is not taken to keep the stirring implement away from the walls of the pot fresh striaĕ are constantly stirred into the glass. Stirring is thus an operation which has to be conducted on a principle of compromise between opposite difficulties, and it cannot therefore be carried out to completion. The result is that—at best—only a small proportion of the contents of a pot are obtained free from striae.

The absence of striae in finished lenses is of such vital importance that it becomes necessary to examine glass intended for important work very carefully before taking it into use. Gross striae can be easily seen with the unaided eye, provided that they are looked at from a suitable direction. Thus, in plate glass and in ordinary window (sheet) glass there are very plentiful striae, but they are not very evident when we look through the glass in the ordinary way,

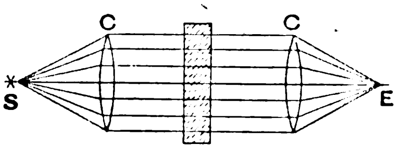

FIG. 1.

because we look through fairly uniform layers of them, each layer being parallel to the surface of the glass. If such glass is polished on its edges, however, and we look through it in a direction parallel to the original surface, we see the striae very clearly. In optical glass the striae are never so pronounced as in plate-glass, and at times they can only be detected by careful observation and with instrumental aid. The best method is to place the glass in a beam of parallel light, and to look at it through a lens or eye-piece which condenses the parallel beam so as to enter the eye. If the glass is free from striae, it appears, in these circumstances, uniformly bright. Striae at once make their presence apparent by disturbing the uniform illumination, producing either a brighter line or a dark shadow, according to the precise conditions. A sufficient approximation to parallel light can be obtained for this purpose by looking through the glass at a small source of light a few yards away, but a more convenient arrangement is that shown in the diagram (Fig. 1).

We have yet to deal with one further defect which frequently occurs in glass—this is internal strain, such as tension or compression, or a combination of both. In ordinary glass this condition frequently exists to a very considerable extent, but provided that the strain is not severe enough to bring about rupture, very little harm is done. In the case of optical glass, however, matters are very different, for the optical properties are materially altered by strain, and since in a finished lens the strains are rarely symmetrically distributed, a distortion of the image is produced. It is therefore of fundamental importance, for all the better kinds of optical work, to secure glass entirely free from internal strain. Fortunately, although this defect is not at all easy to eliminate entirely, it differs from such defects as colour or striae in that it can be removed from the finished glass without re-melting. What is needed is extremely careful annealing. This will be readily understood when the origin of the internal strains in glass is considered. They arise during the cooling of glass from the molten or soft condition. The outer layers of glass naturally cool and stiffen, while the interior of the mass remains hot; but the outer layers during cooling have been fairly free to contract. The inner layers, on the other hand—when in turn they cool down—are not free to contract, because they are held by the stiff solid outer layers. The tendency to contract as they cool is thus resisted so far as the inner layers are concerned, and these consequently remain under a very severe tension, while the outer layers, being obliged to resist this tension, are subjected to very severe compression. If the rate of cooling is rapid, these stresses may become so severe that fracture results. In other cases fracture may only occur after weeks or months. In the case even of badly-annealed optical glass the stresses do not approach this degree of severity, but they are severe enough to spoil the glass for optical uses. The remedy is, of course, obvious—the rate of cooling must be reduced to such an extent that the setting of the inner and outer layers is approximately simultaneous, so that all parts of the glass may be permitted to undergo their natural contraction during cooling. The actual rate required is extremely slow, and it must be perfectly steady, since a short but rapid variation of the temperature may spoil the whole process.

The presence of strain in glass is readily detected by the use of polarised light, since strained glass exhibits double refraction to an

extent which varies with the amount of strain which is present. Glass may be examined between crossed Nicol prisms, but since these, unless very small, are extremely expensive, it is best to use a dark reflecting surface, such as a sheet of black plate-glass, as the polariser, using a small Nicol prism as analyser, holding it in such a position that the light is reflected from the plate-glass at the polarising angle, as indicated in the diagram (Fig. 2). The glass should be placed on a stand (not held in the hand) in such a way that the light passing through it reaches the analyser. Examined in this way, a badly strained piece of glass exhibits brilliantly-coloured patterns resembling the crosses and brushes seen in crystals under polarised light. Slightly-strained glass merely shows a few dark and light patches, while thoroughly well-annealed glass shows only the slightest shading, and even this is absent in the best examples.

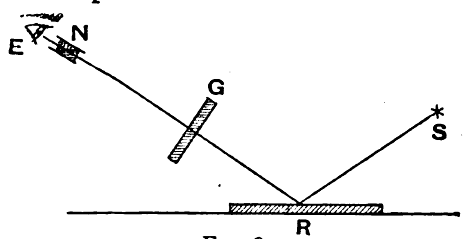

FIG. 2.

We have now considered most of those properties in which optical glass differs most strikingly from ordinary glass, but two others remain to be mentioned which, while undoubtedly of importance for all kinds of glass, become increasingly so for optical glass. The first of these is "hardness." Of this property no very accurate definition can be given, and its actual measurement is correspondingly troublesome. It may be measured by abrasion, by indentation, by resistance to scratching and other methods, but this very variety of method shows how indefinite is the idea conveyed by the term "hardness." In the case of glass for optical purposes, however, "hardness" is of importance only in two directions, viz., in regard to the resistance of the glass to the abrasive processes which are applied to it during the manufacture of lenses, and the resistance of the surface of the finished lens to accidental abrasion or scratching. Provided that the glass is not excessively hard or soft, however, these considerations are generally overshadowed by much more serious factors, so that "hardness" is rarely considered in relation to the optical uses of glass. It is worth taking into account, however, where other factors permit, and at least an effort should be made to use the hardest available glass for the externally-exposed members of a lens system.

Of far more vital importance for optical purposes is the question of the durability of different kinds of glass. It must be noted at once that in this respect glasses differ very widely from one another—in fact, in certain glasses, such as the borate flint and the phosphate crown series, glasses which would otherwise be of the greatest value for optical purposes have had to be abandoned because of their insufficient durability. Want of durability in a glass simply implies that it does not adequately resist the chemical action of the atmosphere, moisture, or the contact with those materials with which it is touched in use. The best glasses—such as certain of the "hard crown" and "boro-silicate crown" types—are remarkably indifferent to all chemical actions, and the moisture and carbon dioxide of the air, as well as the organic matter present in dust and liable to be left on glass surfaces when touched with the fingers, produce no appreciable effect upon them. Some glasses, on the other hand, while not readily attacked by moisture and carbon dioxide, are sensitive to contact with organic matter, and if dust is allowed to gather on such glasses they are liable to become spotted at points where particles of organic matter have rested upon them. These latter glasses are principally the very dense "flint" glasses containing much lead. If the composition of a glass can be chosen merely from the point of view of producing great resistance to chemical action, extremely satisfactory results can be obtained—as, for example, in the modern glass-ware for chemical purposes, which resists the prolonged action both of hot water and of alkalies and acids extremely well. But when chemical composition must be adjusted to obtain specific optical constants, difficulties are apt to arise in this connection. Particularly the presence of high proportions of alkalies, and of such substances as barium oxide and boric acid, tends to render a glass liable to chemical attack by the atmosphere. The worst offenders in this respect are glasses containing much alkali, or containing alkali in a form which leaves it exposed to external attack. So much is this the case that a "durability" test for glass has been evolved which depends entirely upon the amount of alkali which is liberated upon a fresh surface of the glass after a definite exposure to moist air, and by this test it is at present customary to

group optical glasses into definite classes. This test is subject to the very serious limitation that it can take account only of chemical action leading to the liberation of alkali, and consequently glasses which suffer decomposition owing to their excessive content of barium, boric acid, or other substances, are classed among the more durable kinds while in reality they lie nearer the opposite.

The test itself, which is now in regular use at the National Physical Laboratory, is an interesting one. Specimens of the glass to be tested are freshly fractured in such a way as to afford a fairly definite area of freshly-exposed glass. The specimens are then exposed in a closed vessel containing some water—so that the atmosphere is saturated with moisture—for a period of seven days at a temperature of 18° to 20° C. At the end of this time the glass is dipped into a reagent which consists of a water-ether solution of an aniline dye known as Iodesin or Erythrosin B. This dye has the property of combining with alkali, and as a result the artificially "weathered" surface of the glass becomes coated with an extremely thin film of sodium-iodesin. By washing the glass in dry ether, all traces of the uncombined or free iodesin are removed, but the sodium-iodesin remains undissolved. The sides of the pieces of glass are then carefully cleaned, great precautions being taken not to disturb the weathered fractured surface. Finally the sodium-iodesin is removed from the fractured surface by passing the latter through a very dilute solution of sodium carbonate in water. In this solution the pink sodium-iodesin at once dissolves, imparting a pink colour to the solution. The depth of the pink colour of this solution is now measured by careful comparison with a very dilute but accurately standardised solution containing known amounts of sodium-iodesin. The quantities of alkali involved in these manipulations and measurements are extremely minute, but very great accuracy is attainable. The results are expressed in terms of milligrammes of sodium-iodesin per square metre of glass surface—although the actual surfaces employed rarely exceed 5 square centimetres. The classification of glasses at present adopted is as follows:—

	Milligrammes per sq. metre.	
Glasses yielding	0 — 5	Class H_1
,, ,,	5 —10	,, H_2
,, ,,	10 —20	,, H_3
,, ,,	20 —40	,, H_4
,, ,,	above 40	,, H_5

It is now becoming customary to specify the "class" of optical glass in lists and catalogues, and the optician who uses any particular class knows in a general way what to expect of it in regard to permanence of surface. The requirements of many modern lens designs unfortunately cannot be met without the use of certain types of glass belonging to the lower of the five classes named above, but in such cases care is generally taken to protect their surfaces by using them in positions where they are cemented to other lenses.

The principal physical properties of glass, and the particular requirements relating to them when the glass is to be used for optical purposes, have now been briefly reviewed, and in order to complete our survey we must consider the more definitely "optical" properties of glass. These are the powers of refraction and dispersion which different kinds of glass possess in such varying degrees. In order to facilitate discussion of the optical properties of the various types of glass, it is desirable at the outset to state clearly the quantities or "constants" in terms of which the optical properties of glass are stated. The first and simplest of these is the "Refractive Index." This is almost universally stated as the refractive index measured for yellow or sodium light, as represented by the well-known D line of the spectrum. Usually, in optical literature, this quantity is denoted by the symbol μ_D, and it will be convenient to adopt that notation. The fact that the refractive index has thus to be defined in terms of light of one particular colour or wave-length at once indicates the further well-known fact that the refractive power of glass is different for light of different wave-length. This fact is at once evident when we look at a spectrum produced by allowing a beam of white light to pass through a glass prism. The white light is spread out into the coloured spectrum band, because the rays of each colour undergo refraction (*i.e.* change of direction) to a slightly different extent as they pass through the prism. We can express this by saying that the refractive index of the glass differs for light of different wave-length or colour; so that we have for a given glass not only a constant n_D representing the refractive index for light from the D line of the spectrum, but also a whole series of such constants for every other wave-length of the spectrum. Those which are most frequently used in optical work are n_A, n_C, n_F and $n_{G'}$, where A, C, F, and G′ are spectrum lines usually denoted by those letters. Most of

these (C, F, and G′) are found as bright lines in the spectrum of hydrogen, and it is the ease with which they can be produced which has led to their adoption, in spite of the fact that they are not as well distributed through the visible spectrum as could be wished. When all these refractive indices are known, the entire optical properties of a given glass are specified, and the optician has all the data he requires for his calculations. It is, however, convenient to group these various figures together in certain ways in order to obtain constants which express the optical character of the glass in a readier and more comprehensive manner. Thus, the power of glass to spread white light into a spectrum is termed its "Dispersive Power" or, more shortly, its "dispersion." We define the "mean dispersion" as the width of the spectrum between the lines C and F, and this quantity is measured by the difference between the refractive indices for C and F respectively, thus

$$\text{Mean Dispersion } \Delta = n_F - n_C.$$

We have also to deal with the various "partial dispersions"—which are the differences between the refractive indices for adjacent lines of our system, viz., $n_C - n_A$, $n_F - n_C$ and $n_{G'} - n_F$. And there is one further quantity which it is desirable to define, because it really expresses the properties of the glass in regard to dispersion most concisely—this is the quantity usually denoted by the Greek letter ν; it is obtained by dividing the refractive index, minus one, by the mean dispersion, thus

$$\nu = \frac{n_D - 1}{n_F - n_C}.$$

There is no generally accepted name for this quantity, and it is therefore almost universally spoken of as ν, and by that name it will be best to refer to it in what follows.

Now it is obviously not possible, within the present limits, to enter into the precise manner in which the optician, in designing and calculating his lenses, utilises these optical constants, but if we are to appreciate their meaning and importance from the point of view of technical optics and of the optical instruments upon which so much must depend at the present time, we must follow the matter a little further.

The images produced by the action of simple lenses, *i.e.* by lenses consisting of a single piece of glass ground and polished to simple spherical curves, suffer from a considerable number of defects. If we look at such an image as can be produced by means of an ordinary simple magnifying glass, these defects become very apparent. Most of them are due to what may be termed "geometrical" causes, and they can be corrected by suitable combinations of lenses, provided that glasses of suitable refractive index can be obtained. But there is one defect which is of a somewhat different nature; this is due to the fact that the glass not only refracts the rays of light but also disperses them. The image of a white object is not formed as a single white image, but as a series of partially overlapping images in all the colours of the spectrum. The image is thus slightly blurred and surrounded by a well-marked fringe of colour in the order of the spectrum. Even the lenses of our eyes are not free from this defect, and the coloured fringes can be seen if carefully looked for. This defect is known as "chromatic aberration," and is perhaps the worst of all optical defects. It can, however, be cured to a considerable extent by causing the various coloured images to recombine. If only one kind of glass were available, then the negative lens required to remove the colour fringes would entirely neutralise the original lens, and the combination would behave like a piece of plain parallel glass. But if a second glass is used in which the relation of dispersion to refraction is different from what it is in the first—if, in fact, the two glasses have different values for ν—then the second lens can be made to neutralise the dispersion produced by the first lens, but without entirely neutralising the lens-action of the first. Such a combination is an "achromatic" lens.

We need go no further here than to state the general conclusion that the defects of simple lenses can be to a very large extent corrected by the optician if he has suitable glasses at his disposal; and it is not difficult to realise that the larger the selection and range of the available glasses, the more perfectly is the optician likely to be able to effect his corrections. Now, until the pioneer work of Schott and Abbe at Jena opened the new era in regard to optical glass, the range of optical glasses available for the optician was extremely limited. The older types of glass, known as "crown" and "flint" respectively, afforded a wide range of refractive indices and of ν values, but this range was very much restricted in its usefulness by two circumstances. The first of these is that in these older glasses the values of n_D and ν were rigidly connected by a simple linear relation—in other words, every increase in n_D entailed a corresponding decrease in ν, so that a high refractive index was unavoidably linked with

a large amount of dispersion. One of the great advances effected by the "new" glasses was the provision of types in which high refractive index is combined with low or moderate dispersion (n_D and ν high at the same time). The second and more subtle circumstance was this, that the two types of glasses formerly known—viz., "crown" and "flint"—not only differed in regard to the values of the mean dispersion, but differed in another way when the partial dispersions came to be considered. If we compare the spectrum produced by a prism of hard crown glass with that produced by a dense flint prism, we find first—as the higher dispersion of the flint would lead us to expect—that the second spectrum is very much wider than the first. This difference, however, can be overcome by using a flint prism of different angle, and thus the two spectra can be made to assume identical total width. If now one of them could be reversed and then superposed upon the other, we should at first sight expect them to compensate one another completely and to produce a band of white light. But actually this would not be the case, because if we examine the two spectra more closely we find that the spectrum from the flint glass is considerably more drawn out in the region of the blue and violet, while in the crown-glass spectrum it is the red end which is most widely spread out. If two such spectra are superposed and carefully adjusted, accurate balance can at best be obtained for only two definite places in the spectrum; at all other points a residue of unbalanced colour will be left over—a sort of "residual spectrum." What we have here supposed to occur with two superposed spectra is what actually takes place where crown and flint glass lenses are used together to form an "achromatic" lens. Such a lens can be made truly "achromatic" only for two of the spectrum colours, and residual coloured images remain. If the two corrected colours are well chosen so as to lie in the region of greatest visible brightness, then the residual colours are relatively dark and faint and remain unnoticed in many cases. But where the powers of optical instruments are to be pushed to their utmost limits—as for instance in telescopes and microscopes—these residual colours become very noticeable and militate seriously against the perfect working of the instrument. Accordingly, it is another very important achievement that the newer types of optical glass evolved from the work of Schott and Abbe afford means of finding pairs of glasses in which this difference in the distribution of the dispersion is either entirely absent or very much reduced, as compared with ordinary crowns and flints. This last problem—of finding a pair of perfectly "apochromatic" glasses—as such pairs are called—having a reasonably large difference in their ν values, is not even yet entirely solved, particularly if regard is paid to the other important qualities of glass which have been dealt with in the earlier portions of this lecture.

Without going further into the interesting, but intricate and difficult, subject of lens design and correction, enough has perhaps been said to indicate the nature of the optician's requirements and the extent to which they have been met by modern development in glass production. It will be realised at once that opticians who had at their disposal new materials of such vital importance as the glasses evolved by Schott and Abbe had it in their power to make revolutionary strides in the design and construction of optical instruments. Of this opportunity the German opticians were not slow to avail themselves, and in this way they obtained an advantage which has yet to be fully regained. If we, in turn, can push forward the production of optical glass so as to gain an ascendancy, such a step will bring with it at all events the possibility of gaining a corresponding ascendancy in the production of optical instruments generally. Nor must it be supposed that the mere reproduction in this country of the principal types of "new" optical glass which have been produced and used on the commercial scale in Germany during the past fifteen or twenty years is enough to make up the lee-way. For the scientific knowledge, method, skill and enterprise which made the first advance possible, have not been lying idle meanwhile. Fresh advances have been continually made, and, although not so epoch-making as the first work of the Jena laboratories, they have proved sufficient to maintain the lead originally gained. If we wish to overtake our rivals in this matter, we must first endeavour to attain the real lead in the production of optical glass.

FLOUR-MILLING IN JAPAN.

Flour-milling by machinery in Japan dates back some twenty years—to the formation of the Japan Flour Mill Company—from which date a gradual development is to be noted, despite increasing imports of foreign flour. This development became much more rapid after the Russo-Japanese War, owing largely to the industrial mania which seized

Japan after the close of hostilities and to the raising of the import duty. In a report Consul-General George H. Scidmore, of Yokohama, alludes to this expansion, pointing out that during the *post bellum* period four flour-mills were established in the Kwanto district and three in the Kwansai area, whilst all the companies then established made extensions to their mills. As is so frequently the case, this period of active construction was followed by one of general depression. The new companies formed during 1907 and 1908 were forced to curtail their production almost from the start, because foreign flour was still largely imported on account of depreciation in price, and because of the general economic set-back which affected practically every industry in Japan. These conditions are, however, now rapidly passing away, and there is a good deal of evidence to hand that flour-milling in Japan will again develop, and develop on more conservative and assured lines. For some time past the price of flour has appreciated practically throughout the world, and whilst the supply of domestic flour is ample, perhaps, for her home demand, Japan is able steadily to build up her exports of this commodity. For many years Japan has exported flour to China and Chosen, and, granting all possible progress to the milling industry in China, China must for some years to come be an increasingly important purchaser of flour from abroad, and no country is better situated or more alive to her requirements than Japan.

INDIAN MINERAL INDUSTRIES.

Speaking at the annual meeting of the Mining and Geological Institute of India, Mr. H. H. Hayden, the president, discussed the steps being taken to enable India to profit by the new conditions established by the war in the mineral industries of the world. The wolfram output of Burma is being expanded, the tungsten industry has been taken out of German hands, and a new British industry has been established. Prices for wolfram ore of the average quality which Burma can produce now range from £180 to £190 per ton as against £100 before the war, and thus every inducement exists for larger production. The measures taken by Sir Harcourt Butler in Burma to expand the production of the mines in Tavoy, now one of the chief producing districts of the world, have not yet become fully operative, but it is believed that from four to five thousand tons of the ore will eventually be won annually. The point has to be considered whether this industry can be placed on such a permanent footing that it will not suffer when prices drop after the war, and the excessive demand for high-speed tools in connection with the manufacture of armaments ceases to exist. Mr. Hayden considers that if the industry is now placed on a sound foundation it will be able hereafter to survive the competition which will come from Portugal, the United States, and parts of South America. The present high price of the ore, he says, offers a favourable opportunity for development to be carried out in the most efficient manner, and those mines that now take advantage of this will be in the best position afterwards to keep their cost of production within a figure that will enable them to compete with producers in other parts of the world. The suggestion is made that it would pay to make ferro-tungsten on the spot if the electrical method can be economically introduced into Tavoy. If this is not possible, the wolfram ore might be carried to the neighbourhood of the Bengal coal-fields, there to be heated by the reverberatory furnace method with cheap fuel available in abundance. India must always be at a disadvantage as regards cost of carriage, and hence the proposal to export the finished or partially finished product instead of the raw material. The suggestion is one well worth considering, as every effort should be made to prevent a collapse when normal prices are re-established. In respect of manganese ore, Dr. Fermor has shown that the manufacture of ferro-manganese may be regarded as a sound commercial proposition. If then India can arrange for the partially finished product to be exported instead of the ores, the wolfram and manganese industries should be assured of that permanence which is so desirable. Mr. Hayden touched also upon the question of coal-tar dyes, the manufacture of which in India does not seem promising, and upon the glass industry, which he regards very hopefully, especially in the matter of the supply of glass bangles. The outturn of sulphate of ammonia could also be expanded for use in artificial manures, though a large trade in these is not in view. The production of aluminium on a big scale would only pay if an outlet outside India could be found.

INCREASE IN CHINA'S LEATHER IMPORTS.

The importation of leather and leather manufactures into China, according to the U.S. Vice-Consul of Shanghai, has steadily increased in recent years.

Among the reasons for this were the purchases of new equipment for China's army, including boots, shoes, belts, etc.; the establishment of cotton, silk, and flour mills, which has created a demand for belting; and the adoption of the Western style of dress by many of the Chinese, with incidental purchases of shoes, trunks, bags, and other articles. Although a few tanneries have been established in the coast and principal cities, and, to some extent, in the interior (one of some importance in Szechuan Province), they have not been, thus far, very successfully operated. Various causes are responsible for this condition, poor business management and a lack of proper technical knowledge of the trade being predominant. There are indications that China will continue to have a great part of its leather needs supplied from abroad for some time.

A large proportion of the leather imported into China is transhipped at Hong-Kong, and it is therefore impossible to ascertain its origin from the Chinese maritime customs statistics. Undoubtedly the greater part of it comes from Singapore, and the remainder from various European countries. Japan's share of the trade is also very large, particularly in leather manufactures. Its proximity to China, the low cost of production, and the opportunity for prompt deliveries, are largely responsible for this condition. The inferior quality of the Japanese product is advantageous, for the Chinese almost invariably consider price before quality. In fact, Japanese competition is not a factor in the higher grades.

There has been considerable trade in boots and shoes. China imported in 1914, 227,174 pairs, valued at $392,819. Of this amount 65·8 per cent. came from Russia, 11·21 per cent. from Japan, 7·55 per cent. from the United Kingdom, 7·46 per cent. from the United States, and 4·2 per cent. from Hong-Kong. The importations of boots and shoes into Shanghai during 1914 were 37,695 pairs, valued at $69,680.

BLIGHT-PROOF COFFEE FOR THE PHILIPPINES.

When, twenty-five years ago, the coffee blight, which was then sweeping over the entire East, visited the Philippines, it destroyed, so far as production for export was concerned, a formerly flourishing industry; and since that time the cultivation of coffee in the islands has been confined to one or two mountainous districts, where the altitude was sufficient to exclude the blight. In these localities almost every house has had its coffee patch, and on them, despite careless methods of cultivation, an excellent quality has been grown. The quantity of this product has been inconsiderable, however, from a commercial point of view, and coffee has never again taken a place of any importance in the list of Philippine exports. There has never seemed, however, any conclusive reason why a blight-proof stock should not be successfully introduced, as had been done in Java and Ceylon, with the result of rehabilitating the coffee industry of those countries to a great extent, though they had originally been almost as hard hit as the Philippines. According to the *Manila Daily Bulletin*, experiments with this end in view have been somewhat numerous, and not long ago it was announced that measures would be taken to import a supply of the *robusta* variety of coffee plants for distribution. For some time, however, it proved impossible to secure satisfactory stock in sufficient quantities; and it has only lately been announced that, as a result of negotiations with the Dutch Indian Government, a supply has at last been assured from Java. The chief of the plant-breeding station at Buitenzorg has undertaken to send 200 lb. of selected varieties, and it may be that this will mark a definite beginning of the work of putting on its feet again an industry which at one time made a good many fortunes in the Philippines.

DETERMINATION OF BARIUM COMPOUNDS IN RUBBER GOODS.

Specifications for purchasing rubber goods frequently permit the use of barytes (barium sulphate) as a mineral filler without having the sulphur which it contains count as part of the specified total sulphur. In such cases the barium sulphate must be determined in order properly to correct the total sulphur.

When barium sulphate only is used, the amount present is readily ascertained by determining the total amount of barium present. If barium carbonate is used, it is necessary to separate the two salts. By means of tests made on compounds of known composition prepared at the United States Bureau of Standards, a method has been devised which permits the quantitative determination of barium carbonate in the presence of either lead sulphate or barium sulphate, the two sulphates most commonly used in rubber goods. The accuracy of the determination is satisfactory for all practical purposes.

These tests are described in Technologic Paper No. 64, "The Determination of Barium Carbonate and Barium Sulphate in Vulcanised Rubber Goods," which may be obtained by interested persons from the Bureau of Standards, Washington, D.C.

FISH-CULTURE SERVICE IN THE UNITED STATES.

Preliminary data gathered by the United States Bureau of Fisheries establish the fact that a new record has been set in the output of the Federal fish hatcheries. This has exceeded 4,300,000,000, or about 250,000,000 more than in 1914. The Bureau calls this a normal healthy growth, representing increased activity and efficiency in the various fields. "This very satisfactory result," it says, "has been accomplished without material increase in appropriation, and has depended largely on the faithful execution of carefully-laid plans by the hatchery officials and their assistants."

During the year the production of the commercial food fishes of the interior and coastal waters, and of the basses and trouts which, while classed as game fish, nevertheless enter largely into the food supply, has been augmented.

THE DEVELOPMENT OF THE TEXTILE INDUSTRIES.

Manufacturers and Scientific Teaching.—Appreciable headway begins to be made in the promotion of scientific research into the problems of the textile industry. In the West Riding funds have begun to flow for a scheme which includes the endowment of research and the foundation of numerous scholarships, and involves incidentally a new alignment of the textile schools in the county. The initiative comes from the University of Leeds, the county

and borough education authorities co-operating, and the most influential manufacturers throughout the area have been already won over. The heads of some of the greatest industrial organisations in the world attended the recent meeting at Wakefield, cheerfully giving up time that is supremely valuable at present and exhibiting every symptom of enthusiasm and unanimity in the liberal ideas propounded by the speakers. In terms of money the object is to raise £5,000 a year for five years by the contribution of some hundreds of subscribers whose subscriptions are to form a new bond of interest between them and the schools. The object will not be fully achieved unless large numbers of manufacturers become contributors of advice and suggestion, and in an entirely new degree make the schools their own. There are at any rate good prospects of a closer partnership and the efforts made can be no other than beneficial.

A Standard Technical Course.—A re-organisation of local textile schools in an area where they are somewhat numerous is necessary for economy and efficiency, and it is clearly advisable that the schools which cannot advantageously give a five years' course should cease to attempt to do so and confine themselves to a two-years' course. Two years' technical training combined with the study of modern languages is a curriculum recommended for commercial travellers. Two years with art training is advocated for designers, and the same two years with other special training for other specialists. The Yorkshire scheme has many features to recommend it in the eyes of manufacturers who are accustomed to standardisation and to the bulking of all requirements. The plan being good it remains only to be seen that the preliminary two years' course is the right one, given by teachers of the requisite gifts and attainments, and in time the standard of teaching can probably be more easily raised under the scheme than under the somewhat chaotic conditions which have hitherto prevailed.

Current Textile Research.—The co-ordination of schooling involves the transference of the most promising students to central institutions and thereby leads to the prosecution of research in premises suitably staffed and equipped. In the West Riding, at Leeds, Huddersfield and Bradford, certain researches in colour chemistry are well under way and others are in project. At Leeds, with the co-operation of physicists, research directed towards the electrification of fibres is proceeding, and there is room to relieve spinners of a considerable burden by the application of new knowledge to an old and obscure problem. At Leeds also, research is being pushed into the colloidal nature of the wool fibre, and explanations of familiar phenomena may be expected from it—if no more. For the rest, those who are wishful to undertake specific researches are waiting to hear what it is that the manufacturer most wants to know. It has been suggested that useful research might be conducted upon certain conditions in the works of manufacturers who find themselves confronted with a technical difficulty. A final decision has not been reached, but the committee acting in the West Riding contemplates an arrangement which would leave new discoveries private to individual manufacturers for a time.

Research upon Silk.—Meantime, the Silk Association of Great Britain and Ireland has tabled an articulate scheme of research for which funds are being sought from all parties concerned with British silk. The object is of interest to all sections alike, and may most shortly be described as a research into the causes of defective brightness of finished result. Raw silk is composed both of soluble and insoluble constituents, and the investigation proposed deals with the chemical composition of those constituents which are suspected of creating difficulties in "de-gumming," dyeing and finishing and of setting up detrimental subsequent changes in silk manufactured goods. It is proposed to carry on the laboratory work at the Imperial College of Science and Technology and simultaneously to obtain practical confirmation of the results by observations made within industrial premises. It is proposed that the findings shall be reserved to members and contributors for a length of time to be determined by the Advisory Council for Scientific and Industrial Research. Of the £1,000 to be expended in the next two years members of the silk trade are invited to contribute £400, the balance coming from the Government grant. There is no industrial user of silk to whom these experiments are not important, and the conditions afford a complete guarantee of the best employment of the money. This modern effort for the advantage of the silk industry recalls certain earlier ones made by the Society. An attempt to establish the culture of silkworms in this country had to be abandoned by the Society in favour of a not very productive encouragement of sericulture in Carolina and Mauritius. The name of the Society is linked with certain improvements in the Jacquard loom which, one hundred years ago, was more exclusively a silk loom than it now is.

The Matter of Holidays.—Official representations have not been quite successful in inducing textile workers and employers to forego or rearrange the usual summer holidays. The holiday week which is looked to, and saved against, for the whole of the rest of the year

represents a great deal to the textile operative. Particularly in Lancashire the week forms a very large slice of the amenities of life. To employers the week in which the mill is stopped gives a necessary opportunity of effecting repairs which cannot be made with the engines running. The batch system of holiday by relays is not seriously practicable in the spinning industry, although some weaving manufacturers are practising it this year. The annual holidays fixed in the summer are made to correspond generally with the slack season in trade, and thus the normal timing is doubly advantageous. Any other period for holiday taking would be less convenient for all parties, and although it is possible that a better occasion will present itself to the tired munition workers, it is not certain that the pressure upon some classes of textile operatives will relax. The more the circumstances are understood the more it appears that manufacturers have generally been doing the best that they can even where official advice seems to have been discounted.

The German Industry.—The United States Consul at Breslau, in an address delivered in Philadelphia, affirms that since March 1915 German imports of American raw cotton have practically ceased, and that every available pound has been consumed. Mr. Seltzer adds that the rags of cotton piece goods are being torn up to be respun and rewoven into materials for military purposes. The statement that German mills are able to run something less than half-time points to the receipt of raw cotton, probably from Turkey. The speaker exerted himself to deny the possibility of an influx of cheap German manufactured cottons in the period immediately following the war, and upon this point the position in respect of raw material is not the only one to be considered. Mr. Seltzer declares that labour is dear and scarce at present, and holds that the days of German cheap labour are gone. The opinion is interesting, if more speculative than the assurance that after the war the foremost need of the German textile industries will be more capital and large supplies of raw material. American hosiery manufacturers were adjured to "put in more boilers, more steam, more enthusiasm and more salesmen." While the German textile industries will, as a whole, need more capital, it has to be recalled that good profits are being made by the concerns doing Government work. It is conceivable that the days of cheap labour have gone as conclusively from some other manufacturing countries as from Germany. Certainly in this country employers do not see how the prevailing high wages can be readily reduced, and are more actively concerned to see that the rates are earned than that they are pulled down.

GENERAL NOTES.

The Future of German Railways.—The Germans are laying countless plans and forming countless projects for the period "after the war." They are even discussing utilising the special war rolling-stock, of which they and the Austrian railways now possess so much, for commercial purposes after the war. For example, the ambulance trains, infection trains, hospital trains, kitchen trains, provision trains, carriages for consumptives, ammunition waggons, etc., are all to be put to some use or other. The bath and disinfection trains, it is suggested, by means of which 2,400 soldiers can have a bath and have their clothes disinfected and cleansed in a single day, might be very suitable, with perhaps but little modification, for long distance *trains de luxe*—at any rate the bath compartments might. It is pointed out that passengers able to travel by these trains would willingly pay extra for bath tickets, the expense of the bath compartments being thus easily recouped.—*The Engineer.*

Electric Power Production at Chicago.—In an article recently published in the *Electrical World*, Mr. L. A. Ferguson describes the development of power-station practice at Chicago. In the early days there were more than twenty-five separate generating stations, the fuel consumption per kilowatt here being 10 to 15 lb. of coal in the smaller and perhaps 6 lb. in the larger and better-equipped stations. The Fisk station was opened in 1903 with three 5,000-kw. units, the coal consumption of which was 115 per cent. more than that of the modern units recently installed. The cost per unit was also greater by the same amount, whilst the cost of attendance was 170 per cent. more. Moreover, in the thirteen years which have elapsed since the station was opened the cubic capacity occupied per rated kilowatt has diminished from 146·5 cubic ft. per kilowatt to 31·3 cubic ft.

Standard Tables for Petroleum Oils.—Samples of petroleum oils have been collected from different parts of the country by the United States Bureau of Standards, and the specific gravity determined over a wide range of temperature. From the data obtained tables have been prepared for determining the true specific gravity and volume of oil at the standard temperature, when these quantities are measured at other temperatures. Tables have also been prepared for showing the relation between specific gravity, Baumé degrees, and pounds per gallon. The new tables will be especially useful in determining the quantity of oil in large shipments. These will very largely supersede the privately issued oil tables heretofore used. Circular No. 57 of the Bureau of Standards presents the results of these experiments, and copies may be obtained by interested persons from that Bureau at Washington.

NOTICES.

COLONIAL SECTION COMMITTEE.

The following is the list of the Colonial Section Committee, as appointed by the Council:—

Dugald Clerk, D.Sc., F.R.S. (Chairman of the Council).
Lord Blyth (Chairman of the Committee).
Marquess of Aberdeen and Temair, P.C., K.T., G.C.M.G., G.C.V.O.
Earl Brassey, G.C.B.
Byron Brenan, C.M.G.
Richard Ernest Brounger.
Hon. Sir John A. Cockburn, K.C.M.G.
Captain R. Muirhead Collins, R.N., C.M.G., Official Secretary to the Australian Government in Great Britain.
Edward R. Davson.
Edward Dent, M.A.
W. L. Griffith.
Lord Inchcape, G.C.M.G., K.C.S.I., K.C.I.E.
Hon. J. G. Jenkins.
Major Edward Humphrey Manisty Leggett, R.E., D.S.O.
Sir Charles Prestwood Lucas, K.C.B., K.C.M.G.
Hon. Sir Peter McBride, Agent-General for Victoria.
Major the Hon. Sir John McCall, M.D., LL.D., Agent-General for Tasmania.
Hon. Sir Thomas Mackenzie, High Commissioner for the Dominion of New Zealand.
Brigadier-General the Hon. Sir Newton James Moore, K.C.M.G., Agent-General for Western Australia.
Sir Montagu F. Ommanney, G.C.M.G., K.C.B., I.S.O.
George Robert Parkin, C.M.G., M.A., D.C.L., LL.D.
Sir Westby B. Perceval, K.C.M.G.
Sir Robert W. Perks, Bt.
Hon. Sir George Halsey Perley, K.C.M.G.
Right Hon. Sir George Houston Reid, G.C.B., G.C.M.G., M.P.
Right Hon. Sir Joseph West Ridgeway, G.C.B., G.C.M.G., K.C.S.I.
Major Sir Thomas Bilbe Robinson, K.C.M.G., Agent-General for Queensland.
Lord Sanderson, G.C.B., K.C.M.G.
Hon. William Philip Schreiner, K.C., C.M.G., High Commissioner for the Union of South Africa.
Sir Thomas Sutherland, G.C.M.G., LL.D.
Carmichael Thomas.
Sir William Hood Treacher, K.C.M.G.
George Wilson, C.B.
Hon. Bernhard Ringrose Wise, K.C., Agent-General for New South Wales.
Sir John Wolfe-Barry, K.C.B., LL.D., F.R.S.
Hon. Frederick W. Young, LL.B., Agent-General for South Australia.
S. Digby, C.I.E. (Secretary).

EXAMINATIONS.

The results of the Advanced (Stage III.) Examinations, held from May 29th to June 7th last, were posted to the centres concerned on the 2nd inst.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

OPTICAL GLASS.

By Walter Rosenhain, D.Sc., F.R.S.,
Superintendent, Metallurgy Department, National Physical Laboratory.

Lecture II.—Delivered December 6th, 1915.

In the present lecture I propose to describe the process of manufacture by which the optical glass obtainable at the present time is produced. Before doing this, it would be interesting and instructive to follow up the entire history of this particular process and to consider the various steps in the achievements of optical glass makers. This would be the more interesting because this very business of producing satisfactory optical glass—particularly in large blocks or discs—has attracted the attention of many of the greatest men of science, including such names as Fraunhofer, Faraday, Arago, Dumas, Harcourt, and Stokes. But we are primarily concerned with the present-day process and its problems, and the hopes for future improvement, so that we cannot dwell on the historical aspect. It must therefore be sufficient to say that the fundamental discovery in regard to the production of optical glass was made, not by a practised glass-maker, but by a Swiss watchmaker, named Pierre-Louis Guinand, who about 1790 found that by continued stirring of the molten glass it was possible to remove the veins and striae which render ordinary glass useless for optical purposes. Guinand's process was taken up, through the influence of a statesman named Ützschneider, in Bavaria, and Fraunhofer

became associated with it. It is interesting to note that Fraunhofer's discovery of the dark lines in the solar spectrum was rendered possible by the fact that he possessed prisms and lenses made of optical glass which had not up to that time been available to other workers. We have in this a striking example of the way in which progress in optical glass at once opens the way for unexpected progress in other directions.

The process introduced into Bavaria by P.-L. Guinand was further developed in Bavaria by his eldest son, while the second son, Henri, took the secret to Paris and endeavoured to establish the industry there in conjunction with Bontemps, who was then director of the glass-works of Choisy-le-Roi. Their joint work did not prosper and the partnership was soon given up, but Bontemps carried the work to success. In 1848 political troubles caused Bontemps to leave Choisy-le-Roi and to join the glass-works of Messrs. Chance Bros. at Birmingham, where a very successful optical glass industry was at that time established. Meanwhile Henri Guinand developed the industry in Paris, at first in a very small way; these works, however, developed and became famous for their products under Feil, the grandson of H. Guinand. Feil has in turn been succeeded by Mantois and later by Parra-Mantois. Meanwhile, however, other efforts had been made, in England and elsewhere. Here we may mention first the prizes for optical glass offered by this Society of Arts as early as 1768 and awarded in 1770 and 1771, and then the work of Faraday, under the auspices of a Committee of the Royal Astronomical Society. Faraday came to the conclusion that the problem of producing optical glass of good quality was a mechanical and not a chemical one, and he succeeded, by exceptional skill, in making satisfactory blocks of a very dense lead-borate glass—known as the "heavy glass" of Faraday. This glass, however, suffered from great lack of durability, and there-ore had to be abandoned for practical purposes. Subsequently Harcourt made numerous experiments in glass-melting, and Stokes and John Hopkinson also interested themselves in the subject.

No very considerable advance was, however, made until Schott and Abbe undertook their great pioneering work at Jena. Up to that time, the materials used in glass-making were very few in number, including only silica, lime, soda, potash, and lead. It is the great merit of Abbe to have realised that these limitations of material must be left behind, and to have suggested a systematic study of the elements with a view to ascertaining which of them could enter into glass and what would be the effect of each.

Aided by liberal grants from the Government, Schott and Abbe were not only able to carry out their investigations, but to translate their results into industrial practice. Far-reaching as the results of their work have been, however, it must be noted that they worked primarily on the materials of the glass itself, and not on the means of producing optical glass. Certain modifications and improvements they undoubtedly introduced—particularly in regard to annealing—but the general method of making optical glass at the present time, whether at Jena or elsewhere, still remains essentially the method of Guinand.

Our survey of this aspect of our subject will be rendered easier if it is stated at once that the "method of Guinand" consists first in the systematic stirring of the molten glass in order to remove the striae, and next in allowing the glass, after completed stirring, to remain at rest in the melting-pot so as to solidify without any disturbances which might again introduce striae. Each melting of glass thus involves the sacrifice of a melting-pot, and occupies a very considerable time.

We will begin the detailed account of the present-day method of optical glass-making by a consideration of the raw materials which are employed. The key-note to this aspect of the matter is contained in the one word "purity." There is probably no other branch of industry in which slight traces of impurity are liable to produce such serious ill effects. Chemical analysis of the finished glass can scarcely serve as a guide to the limiting amounts of various impurities which can be permitted in optical glass: the reason is that there is probably no chemical test for detecting the presence of impurities like iron or sulphur which is so sensitive as the "colour test" in glass itself. As we have seen in the previous lecture, a very faint tinge of colour, which is quite invisible in small pieces of glass, becomes very obvious when large thicknesses are examined—and this method of examination undoubtedly allows of the detection of quantities of colouring impurity which pass utterly undetected by other chemical means, with perhaps the exception of the spectroscope. Even in a fairly deeply-coloured glass of the dense barium type, the analytical determination of the iron or sulphur present is extremely difficult. Since, in the case of iron,

at all events, "what goes into the pot comes out again," it follows that extreme care is required to avoid the entry of iron into the mixture. Further, since the pot or crucible in which the glass is melted is partially dissolved, the iron-contents of the fireclay of which the pot is made are also of importance. So extreme is the need for specially pure materials that for certain kinds of optical glass the glass-makers themselves are obliged to undertake the further purification of chemicals which are purchased as "pure."

The most important of all the raw materials is undoubtedly sand, which serves as the source of the silica present in the glass. As many glasses contain well over 70 per cent. of silica (SiO_2) the importance of this material is obvious. In this respect glass-makers in England are unfavourably situated, since there are at present no very suitable sands available in this country. Whether exhaustive search might lead to the discovery of a suitable deposit is doubtful, because a large number of firms have already sought for good glass-making sands, and find it difficult to supply even the requirements for ordinary window (sheet) glass. The sand employed for optical glass has therefore to be imported into England; at present it is obtained from Fontainebleau, near Paris, where an extremely pure sand is obtainable. Germany is fortunate in possessing several good sources of pure sand, one of them being probably the purest yet found—it shows a silica-content of 99·98 per cent. This necessity of importing at considerable expense that material which constitutes the greatest proportion of optical glass involves a commercial disadvantage to British industry in this direction, and still leaves us dependent, in a vital matter, on a source outside the King's dominions. A systematic search in various parts of the British Empire would, however, be certain to reveal a source of really pure sand suitable for this purpose, and if the cost and difficulty of transport were not unduly great, this might solve the problem.

While chemical purity is the most vital necessity in regard to sand as a raw material for optical glass, it is not the only point to be considered. The character of the grain is also of importance. In this respect, uniformity of grain is the chief essential, since it allows a uniform rate of melting throughout the charge. If there are a few large grains among a mass of finer ones, these large particles are apt to remain undissolved when the rest have melted—and this leads to serious defects in the glass.

Passing on to other materials, we find that the various glass-forming substances are introduced into the mixture, or "batch," in various forms, but principally in the form of carbonates. Thus lime, magnesia, soda, potash and barium are generally employed in the form of carbonates. Sometimes hydrates are used, such as boric acid, alumina, and sometimes lime (in the form of slaked lime). In some cases it is possible to use the oxide—as in the cases of lead and zinc. Finally, for the purpose of introducing strong oxidising agents into the mixture, some substances are employed in the form of nitrates—principally saltpetre (potassium nitrate) and nitre (sodium nitrate), and, in some cases, barium nitrate. Glass-makers attach a good deal of importance to the proper "balance" of these various substances, and there is some little justification for their views, since the volume of gases which are evolved during melting, and the precise period when they are given off, must depend upon the form in which the ingredients of the mixture are introduced. Another circumstance which is affected by this selection is the extent to which the mixture will froth during the early stages of melting; since this factor governs the rate at which the pot can be filled, it is of considerable practical importance.

In all these materials, extreme purity and a state of uniformly fine division are the essential features. In the manufacture of ordinary glass, particularly in tank furnaces and in open pots, it is usually found undesirable to use materials in a very fine state of division—principally on the ground that the very fine particles are apt to be blown away by the draught of the furnace. In optical work, however, this consideration does not arise, because covered pots are used, and the materials are not exposed to draught. From the point of view of rapidity and ease of melting, there can be no doubt that extremely fine division of the materials, coupled with very intimate mixing, is a considerable advantage.

As an illustration of the kind of meticulous care which is required in the production of optical glass, another point may be mentioned. Some materials—notably potassium carbonate and sand—are apt to absorb a certain amount of moisture, and their moisture-content tends to vary appreciably with atmospheric conditions. Consequently, the amount of actual silica (SiO_2) which is introduced into the mixture by weighing out 100 lbs. of sand will depend upon the exact state of moisture of the sand at the

moment of weighing out. If accurate results are aimed at, a determination of the moisture must be made each time and a correction applied to the weight used.

Since optical glass mixtures are generally required in relatively small quantities, they are weighed out and mixed by hand. The latter process is a very unpleasant one, in consequence of the irritating dust which arises. Very intimate mixing is desirable, and it therefore seems probable that mechanical mixing would afford considerable advantages, provided that it could be done without risk of introducing iron into the mixture.

Whenever possible, the mixture of raw materials receives an addition of "cullet"—*i.e.* of broken pieces of the same kind of glass as that which it is desired to produce. The presence of this "cullet" is useful, not only as utilising what would otherwise be waste glass from previous meltings, but also in facilitating the fusion of the new batch. The action is due to the fact that the finished glass is more fusible than its ingredients, and that when these pieces of glass melt they dissolve up the adjacent materials and assist them to come together. It is, however, perfectly possible to make satisfactory glass without the use of "cullet," and indeed this has frequently to be done in practice.

We have now to consider the process of converting the "batch" or mixture of raw materials into glass by melting it in a suitable furnace. The type of furnace used for the production of optical glass differs in certain essential features from those used for producing other kinds of glass. In order to understand the causes of this difference we may recall that in ordinary glass-furnaces of the "pot" type, a number of pots or crucibles containing either identical glass or at least glasses of closely similar type are heated together. As the contents of all the pots behave in a closely similar manner, it is possible to work with a considerable number, ranging from four to as many as twenty-four, without any great difficulty. In the case of optical glass, such an arrangement is impossible, for several reasons—each pot of glass requires its own special treatment in regard to time and temperature of heating, etc.—so that it becomes essential to have only one or at most two pots in the furnace at one time. Not only this, but the amount of skilled attention which each pot requires is so great that one "furnace crew" could hardly deal with more than two pots. Further, in ordinary glass-making it is the aim of the glass-maker to adopt a mixture which will melt and "fine" well, so as not to put any excessive strain on the furnace, either as regards temperature or duration of heating; in fact, the glass is adjusted so as to work nicely in the furnace. In the case of optical glass, on the contrary, no such adjustment is possible; the composition of the glass is fixed by the requirements of the optical properties, and the furnace must be worked and regulated so as to suit the glass. Finally, in ordinary glass-making the pots and furnace are worked in so-called "journeys" (from the French "journée")—the pots are filled with raw material, the glass is melted and fined and then it is taken out of the pots while still liquid, either by being gathered on the pipes of the glass-blowers or by being taken out in ladles. This whole cycle of operations may occupy a period of from 20 to 30 hours, and is then repeated; it is only for a few hours during the "fining" process that the furnace attains its maximum temperature. The pot itself remains in the furnace for a whole series of such operations—sometimes for as long as 10 or even 20 weeks. In the case of optical glass, on the other hand, a new pot is required for each melting, while the melting itself occupies from three to four days, during which the furnace may be exposed to its maximum temperature for 18 or even 24 hours on end. It will be seen at once that the furnace requirements are widely different from those for ordinary glass-making. Facility for inserting and removing the pots is one important requirement, and facility of regulation, together with the power of maintaining very high temperatures for prolonged periods, is also essential.

The actual furnaces used for this work are, however, of a surprisingly simple character. The older type, which remained in use in this country until a few years ago, was heated by a direct coal fire, maintained on a very large deep grate and under strong draught. A section of one of these furnaces, showing the pot and the stirring apparatus in position, is given in Fig. 3. It will be seen that the pot stands in the centre of a fire-brick chamber, with the two large deep grates on either side of it; the products of combustion leave this furnace chamber through a number of small openings by which they escape into an outer conical space which acts as chimney. This simple—almost primitive—type of furnace has, of course, many obvious disadvantages: it is uneconomical of fuel and requires specially expensive fuel (large picked coal); it is laborious to work, since the

coal must be shovelled on by hand and the grate must be freed from clinker—also by hand—at intervals, while during these intervals the temperature of the furnace is liable to drop dangerously. Modern practice has therefore replaced these coal-fired furnaces by those of

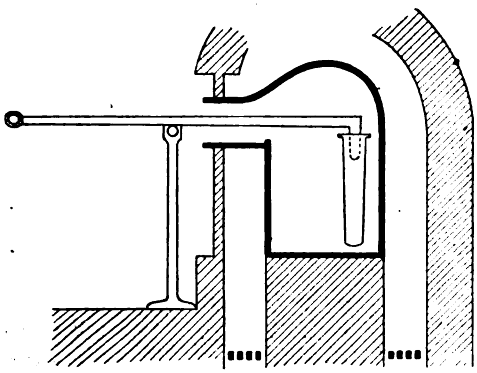

Fig. 3.

Sectional Diagram of Optical Glass Furnace (Old Coal-fired Type), showing the covered pot and stirring apparatus in position.

the regenerative gas-fired type. These are exactly similar to other gas-fired furnaces except that they are small and are built to work with either one or two pots, and of such a shape that the pots can be readily inserted and removed through a wall of false-work at the back of the furnace. Glass-makers always prefer to have what they term a "bottom-heat" in their furnaces, and these are accordingly arranged so that the flame plays principally about the lower portions of the pots. This secures that melting shall begin, as far as possible, from the bottom of the mixture; in the contrary case, if the surface layers melted first, the molten surface layer would cover over the unmelted lower portions and very much retard their fusion and hinder the escape of the gases evolved during fusion.

In addition to the melting furnace itself, a number of subsidiary furnaces are required for optical glass production, but it will be convenient to refer to these in connection with the various operations. We have, however, to consider a very important factor in the whole process—viz., the pot or crucible in which the glass is melted.

The pots employed for optical glass production are somewhat similar to those used in flint-glass manufacture, but usually somewhat smaller. They are known as "covered" pots, because the crucible or pot proper is covered over by a dome-shaped upper portion which is formed at one side into a neck; this neck is so placed as to project through an opening in the wall of the furnace, and through this neck the raw materials are introduced and all manipulations are carried out. The shape is illustrated by a vertical section taken through the neck, which is seen in Fig. 3, and by a perspective sketch in Fig. 4. The size employed is the largest which can be conveniently handled in a given works, since it is advantageous in every way to use a large pot; the limitation arises, however, from the great weight of the pot when full of glass, for—as we shall see presently—the full pot has to be taken out of the furnace while hot. In practice, pots measuring from 24 ins. to 40 ins. in diameter are employed.

The production of these large domed vessels is a matter which requires considerable skill and care. The first point is the choice and preparation of the fireclay out of which the pot is to be made. This point will be more fully dealt with in the third lecture, and here we need only dwell on the care required throughout the whole process. The clay itself must be properly "matured" by prolonged keeping in the damp and the dark. This maturing of clay is a well-established phenomenon which was known to the ancient Chinese potters, who handed down their wet clay "bodies" from father to son as a most precious possession, only using them after long years—or even centuries—of storage. Modern investigation has indicated that the action is largely bacterial—in fact, attempts have been made to grow cultures of special

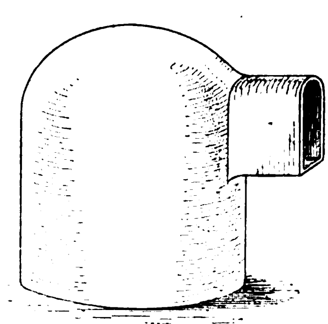

Fig. 4.

Covered Pot used for Melting Optical Glass.

clay-maturing bacteria. That an evil ammoniacal smell is produced is quite certain. It has also been found that an addition of certain colloidal substances, such as gallic or tannic acid, produces similar improved properties. We need not, however, pursue this subject—

enough has been said to indicate that there is a good deal more in this matter of "pot clay" than appears on the surface.

The actual making of the pot is necessarily a somewhat gradual process. The thick lower portions are sometimes formed in a wooden mould, but this part of the pot must be allowed to dry sufficiently to become fairly hard before the upper portion is added—otherwise the weight of the upper portion would push the lower part out of shape. On the other hand, if the lower portion is allowed to get too dry, the upper portion will not adhere properly, or there may be too great a difference of shrinkage and one part may crack. Finally, when the pot is completed—after a process extending over something like four months—it must be very slowly and steadily dried by prolonged storage in rooms whose temperature and moisture must be carefully regulated. This drying process generally occupies a further period of four months, although glass-makers usually feel safer in using pots which have "matured" for at least six months.

When the finished pot—now "air dry"—is to be used, it is taken with very great care, since it is very weak and fragile, from the drying-room to the furnace-room. But the "green" pot in this condition cannot be placed directly in the hot melting furnace. If this were to be attempted, the pot would fly to pieces immediately. This is due to the fact that the dry clay still contains water in a state of loose chemical combination known as "hydration," *i.e.* the silicate of alumina of which the clay consists is still chemically combined with a considerable amount of water. The pot must, therefore, be heated very slowly and gently until this water of hydration is driven off. At that stage, however, the clay is extremely friable, since the water acts to a large extent as the binding medium in the "green" clay. When the clay has been strongly burnt, on the other hand, it is held together by a cementing medium which arises from the very first beginnings of fusion or melting in the clay itself. In the intermediate stage, when the water has been driven off but this incipient melting has not yet been reached, the clay is left very weak and friable. As a result of these properties of clay, the heating-up or burning of a large thick vessel like the optical glass pot is a matter requiring great care in regulating the temperature of the kiln or furnace in which the operation is conducted. The operation consists in raising the temperature of the chamber in which the green pots are placed slowly and steadily up to about 900° C. (a bright red heat), but this must be done without allowing a single tongue of flame to lick the pot before it has attained a dull red heat. If such an accident occurs—or if the kiln is heated too quickly, or if a cold draught is allowed to play upon the pot—then a crack is certain to result. Such a crack is not always at once apparent, but it becomes only too obvious when the pot is placed in the melting furnace. Even a slight crack is a fatal defect, as it is almost certain to open out during the fierce heating at the later stages of the process. Consequently, if a crack is seen, the pot is usually rejected as useless.

When the pot in its kiln or "pot arch" has attained a bright red heat, it is ready to be transferred to the furnace proper. The furnace is opened and allowed to cool until its temperature is nearly the same as that of the pot arch; then the doors of the latter are thrown open and the pot is taken out. The heavy red-hot pot is handled for this purpose by being picked up on a great fork with a long heavy iron handle; this fork rests on an axle which is carried by two small stout wheels. The prongs or "tynes" of the fork are placed under the pot and the handle is depressed until the pot is lifted up on the fork. Then the whole is wheeled up to the furnace and the pot is deposited in the furnace in its proper position. The "false wall" of the furnace is rapidly built up by workmen protected from the heat by thick felt or asbestos "armour," and then the temperature of the furnace is gradually raised. It is at this stage, when the outside of the empty pot is necessarily hotter than the inside, that cracks generally open out and become readily visible. If such a calamity is avoided, however, the furnace and pot in a few hours attain the temperature required for commencing the melting process.

The first step is that of "glazing" the inside surface of the pot. For this purpose a small quantity of cullet, of the same kind of glass as that which is to be produced, is thrown into the pot and allowed to melt. Then, with a suitably-shaped iron rod, this small quantity of molten glass is smeared all over the walls of the pot in order to coat it with a thin layer of glass. The object of this glazing operation is to protect the walls of the pot from the chemical action of the raw materials which are next introduced into it. Since the glass contains the various ingredients in a more or less "balanced" form it is usually less violently

active in a chemical sense than some of the raw materials. To this extent the "glazing" serves to protect the pot.

The next stage is that of introducing into the pot the raw materials or "batch," whose nature and preparation we have already considered. The pot can only be filled by stages, since the raw mixture not only occupies much more space than the molten glass, but also the very heavy evolution of gases from the melting material causes it to "froth" very strongly. The quantity of mixture introduced at one time is, in fact, governed by the consideration that it shall not "boil over" to any serious extent. Thus the filling of the pot can only be accomplished in many stages—from six to eight or ten. When the whole of the "batch" has been filled into the pot, the glass should just slightly overflow the lip of the pot, in order to allow the slightly impure surface layer to be easily removed or "skimmed" off.

Then the "fining" process begins. At this point the glass, although completely melted, is still full of bubbles of gas. These arise partly from air which has been enclosed in the melting glass, but to a much greater extent they are derived from gases evolved during the chemical reactions which accompany the fusion of the glass. Carbonates, nitrates, hydrates are all decomposed, and give off their carbonic acid and water and nitric oxides as heated gases. To remove these bubbles the glass is heated until it becomes thoroughly fluid or "thin," so as to allow the bubbles to rise to the surface. When the bubbles are large this occurs very readily and the glass is said to "fine" easily. In fact what the glass-maker most desires is to see the glass "boil" well. If on the other hand the bubbles are very fine and numerous, it becomes extremely difficult and in some cases impossible to remove them. Here again optical glass presents a problem of much greater difficulty than that met with in ordinary glass making, for while in the latter the exact composition can be varied in order to produce a mixture which evolves large bubbles or "boils" well, such an adjustment is not possible in the case of optical glass, for the reason that the chemical composition of the glass itself is definitely fixed by the optical requirements, so that no very considerable variations in the mixture are possible. Such variations are, in fact, confined to changes in the exact form in which the various elements are introduced—whether as hydrates, carbonates, nitrates, etc.—and this variation alone is not always adequate to make the glass behave in a satisfactory manner during "fining." There are other difficulties also to be faced; with most commercial varieties of glass the fining can be accelerated by pushing the furnace to its extreme limit of temperature, the glass becoming increasingly fluid as it gets hotter. This, of course, also applies to optical glass, but there are two serious limitations. Very high temperatures tend to change the chemical composition of glass, owing to an appreciable loss of certain constituents by volatilization. Where the chemical composition is so important from the point of view of attaining exactly the desired optical constants, these changes are liable to be of serious importance. In some kinds of glass, moreover, the temperature must not be raised beyond a very definite limit, as higher temperatures result in spoiling the colour of the glass—perhaps by increased action on the pot or by chemical reaction with the furnace gases diffusing through the walls of the pot. These special difficulties in connection with the "fining" of certain kinds of optical glass are now so well recognised that whole series of optical glasses are habitually accepted and employed while contaminated with a very obvious sprinkling of very fine gas-bubbles. These are, fortunately, quite harmless from the optical point of view, merely scattering a very minute proportion of the light, but without interfering with the definition of the images.

The completion of the "fining" process is determined by means of samples or "proofs" taken from the surface of the molten glass. In some works these are merely the sheaths of glass which solidify on a flat iron rod which is passed into the glass, but in other works a little of the glass is gathered on a small glass-blower's pipe and blown into the form of a flask, in which the presence of small bubbles is very readily detected.

When a satisfactory "proof" has been obtained, the furnace is allowed to cool down somewhat in readiness for the next operation, that of stirring. We have already noted that it is this operation and its consequences which are the distinctive features of optical glass manufacture as at present practised—more or less in pursuance of the original invention of P.-L. Guinand. The stirring implement employed is a simple cylinder of fireclay, which for a pot of ordinary size would be some four to six inches in diameter and long enough to reach from the surface of the glass down to within about six inches of the bottom of the pot. The upper end of the cylinder is provided with a rim or

lip, while a square hole is formed in the centre, reaching some four or five inches from the top along the axis of the cylinder. This simple form of stirrer is made of the same fireclay as the pot, and is separately preheated or burnt. When the glass has cooled down to the proper temperature for stirring to commence, the fireclay cylinder is taken red hot from the kiln and is held in the pot over the glass for a short time in order to acquire the temperature of the glass. It is then carefully lowered down to the surface of the glass and slowly rolled over so as to become coated with glass, the inclusion of air-bells being avoided as far as possible. When it has thus been introduced into the glass, the stirrer is laid in such a position that it rests with its lip upon the edge of the neck-opening of the pot, the rest of the weight of the cylinder being easily borne by flotation in the glass. It then becomes necessary to close up the pot and

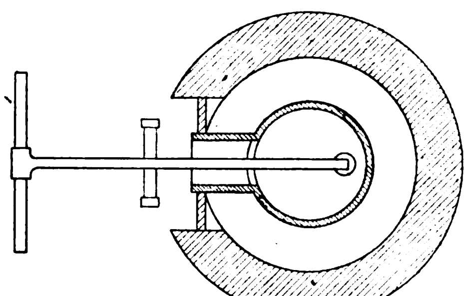

FIG. 5.
SKETCH PLAN OF STIRRING ARRANGEMENTS.

to raise the temperature in order to expel any air bubbles which, however carefully the operation may have been carried out, will yet have been caught between the glass and the clay cylinder. When time has been allowed for these to rise to the surface, the stirring operation itself may begin. For this purpose a long iron bar is used, one end of which is turned down into a short right-angled hook. The down-bent portion of this hook is pushed into the hole in the stirring cylinder, and consequently when the bar is held horizontally the cylinder is held in a vertical position in the glass, with its upper edge or lip an inch or so above the level of the surface. The relative position of stirrer, hooked bar, pot, and furnace at this stage has already been shown diagrammatically in Fig. 3. A plan view of the arrangement is shown in Fig. 5.

The stirring process consists in moving the fireclay cylinder round through the glass with a steady circular sweep, care being taken to keep the stirrer well away from the walls of the pot and also not to move it so rapidly as to throw up waves or splashes. Originally, this operation was entirely done by hand, and it was extremely laborious and trying on account of the heat and glare from the glass. Recently, however, it has been found possible to move the stirrer by mechanical means, and although it is said that the result is not as good as could be obtained by the best and most careful hand stirring, yet the mechanical method has the very great advantage of constancy and regularity and relative independence of individual skill.

The length of time during which stirring can be carried out continuously is limited by the fact that the glass cools down by loss of heat through the open mouth of the pot, and after several hours becomes too cold and stiff to be readily stirred. At that stage the stirring operation is suspended, the pot closed up and the glass reheated; then the stirring operation may be resumed. The total time of stirring required depends upon the nature of the glass: the denser flint glasses are known to need much more prolonged stirring than the lighter crown glasses, but this is a matter which can only be decided for each kind of glass by actual experience—and even then there is always a risk that in any given melting the stirring may have failed to produce the desired result, viz., the removal of striae. If the stirrer is allowed to come too near the wall of the pot and then drags with it some of the viscous glass rich in alumina which accumulates there, the further stirring operation may only serve to disseminate this viscous glass through the entire mass in the form of fine threads, which do not mix with the rest of the glass and leave it at the end full of striae and useless for optical purposes.

When the stirring has been carried on as long as is, in the judgment of the operator, necessary, the temperature is allowed to fall, and the stirring continued as the glass grows increasingly stiff, until finally the stirrer can only just be moved. At this stage the stirrer is brought round to the front and either left in the glass, with its lip resting on the edge of the pot, or it is sometimes slowly withdrawn, bringing a considerable quantity of glass with it. In either case, the individual stirring cylinder can never be used again.

The accelerated cooling which has been employed during the last stages of stirring is now permitted to continue a little longer, or—in the case of the modern gas-furnace—it is still

further accelerated by removing the pot entirely from the furnace. This operation is almost the exact reverse of that described in connection with the placing of the pot in the furnace at the beginning of the found, but with this difference that the pot is now full of glass and is consequently very heavy. Usually it is sufficient to place the pot on a fire-brick pedestal and to allow it to cool down naturally in the air until the surface of the glass is hard enough to ring when struck with an iron rod. In some glasses, however, there is a very strong tendency to crystallization, and this must be counteracted by more rapid cooling. In these cases a stream of water is sometimes directed upon the cooling pot. Even without this drastic measure, however, the cooling is generally so fast that the thick fireclay pot cracks in many places. Fortunately at this stage the glass is sufficiently thick or viscous not to escape through moderate cracks, and in order to prevent the formation of wider gaps the pot is wound with strong iron chains which hold it together in spite of cracking.

If the cooling of the glass were permitted to continue at the rapid rate just described, the contents of the pot would break into small splinters and become useless. As soon, therefore, as all chance of movement or crystallization in the glass has passed, the pot is placed in a kiln which has previously been heated to a dull red, and in this it is sealed up and allowed to cool slowly—the ordinary temperature being reached in three or four days. The kiln is then opened and the cracked pot with its contents withdrawn for examination. Sometimes the contents of the pot are found in the shape of one single block or lump of glass, but more frequently they consist of a considerable number of fragments of various sizes. These are freed from the pot, which is broken into fragments, and the glass is taken away for examining and sorting.

The first examination, which is made on the lumps as they come out of the pot, is necessarily somewhat rough, since the fractured surfaces of the glass do not allow of careful examination, and still less of testing by any of the means described in the first lecture. Coarse striae and defects such as bubbles, solid particles, etc., can be detected, and the piece of glass in which they occur is either rejected entirely or the defective parts are chipped off by the aid of a hammer. The selected blocks are then ready for the next operation, which consists in moulding the glass into some regular shape such as a block or plate.

The moulding process is a very simple one. The blocks of glass are slowly heated until they are soft enough to be plastic, and then by suitable means, such as moulds and presses, they are given the desired shape. Some skill is required in judging the necessary degree of softness for each kind of glass, and also in manipulating the glass with hand-tools before putting it into the press. This latter manipulation is necessary because the glass must not be allowed to fold or double over—no satisfactory joining-up would take place where two surfaces came together, and the "lap" would remain as a serious defect in the moulded block.

Moulding must necessarily be followed by "annealing," which in the case of glass consists simply and entirely of very slow cooling. If the glass is merely being moulded up into blocks for purposes of examination, and will have to be moulded into its final shape at a later stage, then ordinary slow cooling such as is obtained by sealing the glass up in a hot kiln and allowing it to cool down naturally, is quite sufficient. But if the glass has been moulded into its final shape, then very perfect annealing is essential. This is one of the most delicate and difficult of all the operations which optical glass must pass through.

It has already been indicated that extremely slow cooling is necessary for the "fine annealing" of optical glass. Fortunately, this slow cooling need not commence at any very high temperature; this depends, of course, upon the character of the glass, since the harder glasses will be stiff enough to set up strains at temperatures several hundred degrees higher than that at which the softer glasses will still be perfectly plastic. The actual range for "fine annealing" for the majority of glasses lies within the limits of 600° C. to 200° C., but even so, a cooling period of several hundred hours may be required, and very special appliances are needed in order to maintain such a slow rate in a perfectly steady manner.

For its final examination before sending it out for use, the moulded glass—now in the form of plates, prisms, blocks, discs, or even approximately moulded lenses — is roughly polished so as to make it possible to examine it carefully for striae, contamination, strain, etc. As the preliminary examination has necessarily been rough, a very considerable proportion of the glass is rejected at this stage, thus adding to the labour which has been lost in its preparation.

When the whole circumstances of the process

which has here been described in outline are considered, it will not be surprising to find that at the end, the yield of optical glass fit for use for the best purposes which can be sent out in the form of moulded plates or discs rarely exceeds 25 per cent. of the weight of the entire contents of the pot, while cases occur only too frequently where an entire melting is either lost during the found—as, for instance, by the cracking or perforation of a pot—or where it has to be entirely rejected owing to defects, such as striae or colour. Again, in other cases, the optical constants do not turn out exactly as desired, and the glass, which has been made to meet certain definite requirements, cannot be used for that purpose, and has to be put aside until an opportunity for disposing of it may arise. But there is probably no need to emphasise the difficulties of the process any further; it is not surprising to find that it is not regarded as a process of manufacture offering any great attraction from the commercial point of view—there is indeed room for surprise that such a process has been found capable of commercial application at all.

INDUSTRIES OF SPITZBERGEN, FRANZ JOSEF LAND, AND NOVA ZEMBLA.

SPITZBERGEN.

According to a report by the United States Commercial Attaché at Petrograd, plans have been under consideration for some months in that city for consolidating into one company under Russian organisation all the coal-mining claims and properties (including an important American property) in Spitzbergen, about 500 miles due north of Norway and nearly 80° north latitude. On this territory in the Arctic Ocean, which is about the last outpost toward the almost unknown region surrounding the North Pole, the coal-mining already carried on, chiefly by American capital, easily holds the "farthest north" record of organised industry, just as the penguin-oil industry of Macquarie Island in the Antarctic Ocean, belonging to Tasmania, has held the "farthest south" record.

Spitzbergen has a population of about 400 persons, mostly Norwegians, but including several Americans. Practically all the population is engaged in coal-mining, the most important operations being conducted at Advent Bay by an American company, which has been working its claims for ten years, and now takes out about 50,000 tons of coal per annum. All this coal, which is said to be of exceptionally high grade (soft coal, 15 per cent. superior to Newcastle coal), is shipped to Tromso in Northern Norway, and sold to the Norwegian Government for use on the State railways. There are also three Norwegian companies working claims in Spitzbergen, one at Advent Bay and two at Green Harbour.

To carry out the project of combining all the coal properties in operation at Spitzbergen under one company, there has been preliminary organisation of a syndicate of Russian capitalists in Petrograd, which, at a cost of over £4,000, bought options for the right to purchase before the beginning of the present year all the properties and claims in Spitzbergen, including those of the American company. A well-known mining expert was engaged by this syndicate to investigate the claims and properties in question, the intention being, in the event of the report proving favourable, to organise in Petrograd a company capitalised at over £800,000 to purchase and develop the mines and claims.

The conditions at Spitzbergen are unique, in that this is probably the only inhabited and promising part of the world that is under the sovereignty of no country, has no government of any kind, and no police force, courts, laws, or regulations. No person or company can expect to hold or own any property or claim in Spitzbergen unless it is actually worked or occupied. In case of any claim or property being usurped by newcomers, there could apparently be no redress or damages except by the use of force, or through negotiations between the Governments of which the two claimants might be subjects.

In June 1914, Norway, Sweden, Denmark, Russia, Netherlands, Germany, France, Great Britain, and the United States sent representatives to Christiania to organise some form of administration for the island, but adjourned on July 30th without completing their labours. The proposed resumption of their work in February 1915 was prevented by the war.

Communication with Spitzbergen is effected chiefly by means of a steamer belonging to an American coal company, which makes the distance of 400 miles between Tromso, Norway, and Advent Bay, Spitzbergen (one-third of the distance between Tromso and the North Pole), in about forty-eight hours. The passage between Spitzbergen and Norway is made only during June, July, August, and September, the ice around the island rendering it inaccessible during the rest of the year. The steamer mentioned can carry a load of 3,400 tons weight, and makes enough passages during the four months to take away from Spitzbergen the entire annual output of coal from the American mines, as well as to bring to Spitzbergen needed supplies and equipment.

While Spitzbergen is not mountainous, the surface is broken up by hills 400 ft. to 700 ft. high. All the coal is found above sea-level, mostly in two layers under the surface. It is mined with

comparative ease, conveniently near the coast-line, by driving lateral shafts through the hills. The ground is honeycombed with these shafts, until the surface above is supported only by a few columns. These are then taken away and the surface falls in, the mining then being easy, open work. As the coal is thus mined above sea-level and near the beach, its conveyance to the ship is simply arranged by letting it drop down through chutes.

As there is no timber in Spitzbergen, all that is used for dwellings or for mining purposes has to be brought from Norway. Most of the food also is imported, but there is a fairly plentiful supply of fish, seal, reindeer, and white bear. The climate of Spitzbergen, notwithstanding its extreme cold, is said to be remarkably healthful, and there is little or no sickness there. Moreover, the conditions of mining are exceptionally safe, owing to the fact that explosions of gas can never occur; the mines are free from water or dampness, and the formation of dangerous gases is impossible. The frozen condition of the ground and the location of the mines above sea-level account for the absence of moisture. Although Spitzbergen has never been carefully explored nor carefully studied except near the coast, surface indications point to the presence of many hundred million tons of coal in this remote northern part of the world.

Franz Josef Land.

About 200 miles east of Spitzbergen, and lying just above the eightieth degree of north latitude, is Franz Josef Land, which was discovered accidentally in 1873 by an Austro-Hungarian subject, and has been considered as belonging to Austria-Hungary. In August 1914, shortly after the European War broke out, an expedition from Russia, which had gone to Franz Josef Land primarily to rescue certain persons stranded there, planted the Russian flag and made formal claim to the land for the Russian Empire. There is a certain amount of sealing and fishing around the southern shores of Franz Josef Land, but it is not yet known whether this region, like Spitzbergen, contains resources of great economic value. The period during which ice conditions permit of visits to Franz Josef Land is much more limited than in the case of Spitzbergen.

Nova Zembla.

Nova Zembla, belonging to Russia, lying about 300 miles south of Franz Josef Land and separated by a narrow strait and by the Kara Sea from Western Siberia, is said to have resources in lead and copper, but the existence of such metals in paying quantities has never been carefully investigated. A small group of persons live at the southern end of Nova Zembla, chiefly those in charge of a wireless station for the Russian Government. The principal duty of the wireless station is to report ice conditions in the Kara Sea, so that navigators may be apprised concerning the feasibility of entering the waters north of Siberia, and also to report the presence of any persons shipwrecked, stranded, or caught in the ice. There is a fair amount of sealing and fishing around Nova Zembla, but no other industry at present.

OSAGE ORANGE EXTRACT FOR DYEING.

From a report recently published by the United States Department of Commerce, it appears that the production of osage orange extract on a commercial scale has been established in the United States, and this material is now available for the tanning, textile, paper, and other industries wherever a natural dye can be used. It is hoped that this will serve, not only to relieve the situation caused by a shortage of aniline colours in certain shades, but also in normal times to replace the use of foreign fustic by a wood indigenous to the country.

The study of osage orange as a dyewood was begun by the United States Forest Service about three and a half years ago, and was the result of an investigation of the utilisation of osage orange mill waste. As about 4,000 tons of fustic were imported annually for dyes, a series of competitive dyeing tests was made between the extract obtained from osage orange and that from fustic. This work was then extended by the co-operation of a number of textile schools. Later, the material was tried as a leather dye by Dr. L. E. Levi, of Milwaukee, and the entire subject was brought before the American Leather Chemists' Association last year at the Atlantic City meeting. A prominent firm became interested in the subject at this time, and is now producing the extract on a commercial scale.

The dye is the same as that present in fustic, but it is a pure compound, free from the varying admixture of a reddish colouring matter, which renders the use of tropical fustic somewhat uncertain. The orange-yellows, old gold, deep tan, olive, and chocolate shades obtained with chromium and iron mordants are equal to, if not better than, those obtained with the use of fustic.

The mill waste alone from the present manufacture of osage orange amounts to more than 25,000 tons annually, and if this waste could be set down at the mill for $10 to $12 (41*s.* to 50*s.*) per ton, it is believed that it could compete successfully with fustic in both cost of production and quantity of colour produced. The osage orange is found in large quantities in the Mississippi Valley, and is especially abundant in Oklahoma and Texas.

A NEW PHILIPPINE OIL NUT.

It appears, from an extract from the local press quoted by the United States "Commerce Reports," that a new oil nut has recently been discovered by accident in the Philippines. Some months ago, twenty-five bags of an oil-bearing nut were sent to Manila from Catanduanes as lumbang nuts. The recipient saw at a glance that they were not lumbang nuts, but did not know what nuts they actually were. He got in touch with the Bureau of Science, which was unable to identify the plant by the nut alone, but offered to extract the oil and investigate. This Bureau found that the nut produced 45 per cent. of a dark fatty, non-drying oil that made very good soap. Some time later leaves and wood were secured, and a botanist was able definitely to classify it as *Chisochiton cumingianus* (Harms) of the natural family Meliaceæ, the order to which santol belongs. He also stated that the field labels indicate it as "abundant," and that no information as to the presence of oil in the seed was on hand.

The recorded native names are: In Catanduanes and Camarines, balucanag; in Benguet and Union, batuakan; in Laguna, balucanag, kalimotain, salaguin; in Cagayan, marambolo, akalsa, macalsa; in Bataan, cato; in Albay, dudoa; in Bukidnon, valita; and in Negros, malacalad. The fruit grows to the size of a double fist in very large numbers on very large forest trees, each of the fruits having four seeds or "nuts" in them. A company in Manila has had two shipments of the nuts, one being of 288 piculs (39,600 lbs.). The oil is used for soap, and the company pronounces it satisfactory.

ARTS AND CRAFTS.

War Memorials at Conduit Street.—It is not unnatural that the question of war memorials and their design should be very much in the air just now. The times, the casualty lists, and our feelings all combine to bring the subject continually to our notice. It has been ventilated in the public press, lectures have been given upon it, and books brought out, and, what is perhaps still more important and significant, it is being very freely discussed by all sorts and conditions of people. Everyone seems determined that the memorials erected during and after this war shall be better than those from which we suffered after the campaign in South Africa. On the other hand, there seem to be very divergent views as to how a better state of affairs can be brought about. There are people who go so far as to say that memorials should always take the form of useful public works, and, short of this attitude, there are many who hold that memorial tablets and the like should be simple and comparatively inexpensive. There is, again, a growing desire that the most modest and private memorials should have some artistic value. All this is, undoubtedly, very much to the good, but the fact remains that the public as a whole is lamentably ignorant of how to set about finding more satisfactory memorials. It is difficult for them to know to whom to go for such work. The calling in of an artist is to many people rather a formidable undertaking, which is likely to involve them in expenditure on a scale beyond their means. Further, they do not know to whom they ought to apply. They are probably familiar with the names of a few painters, but of sculptors, carvers, stained-glass workers and other craftsmen they are quite ignorant, and, *faute de mieux*, they go to some shop or firm and take more or less reluctantly what is offered them. That may have satisfactory results (some firms take a pride in producing really good and artistic work), but very often it has not. The remedying of this state of affairs is one of the main objects of the Civic Arts Association, which held an exhibition of designs and models sent up in competition for prizes which they had offered, at the galleries of the Royal Institute of British Architects, last month. In assessing the success of such an undertaking at the present time we have to bear in mind the existing conditions. While it is true that many artists are badly in need of work, there is the other side of the picture. All the younger men who are physically fit are at the front or in training, and therefore this is not a time at which we are likely to discover a great amount of new talent. Competitors must be drawn from the men over military age, delicate men, and the women who are not engaged in war work. Some of the largest normal sources of supply are for the moment dried up. It would not be fair, therefore, to judge the recent exhibition by quite the ordinary standards. All things considered, it was in many respects a good deal better than could have been expected. The prize-winning designs in Class I.—the first by A. Richards and Henry Poole, the second by Eric Gill and Charles Holden—were both, in their very different ways, full of interest and of life, and there was other good work. The level in some of the classes, however, really hardly seemed above that of the student work sent up in the old local examinations of the Board of Education. There was one other rather serious defect in the working of the competitions. In some of the classes the work was estimated to be carried out for a specified sum, but it was not always apparent that either the competitors or the judges had paid much heed to the fact. As the association is prepared to put people who want memorials in touch with artists who will carry them out, this is rather a serious failure. Public confidence would have been more easily won had the fulfilment of the conditions laid down been insisted upon more rigidly. Again, the very charming design which took the prize in Class VII. was eminently unfit for a fountain on an open

site in a country town or village. It called aloud for a formal garden and a hedge planted at least fifty years ago—in short, for conditions sometimes to be found in private grounds, but difficult to contemplate in a normal town or village. Some of the simple memorials for the home were both suggestive and practical. Miss Ivan Kingsford's beautifully written and slightly illuminated little memorial parchment was altogether admirable, and would be fit for any surroundings, rich or poor. Mr. Arthur Stratton's rather classic medal stands, on which the decorations of the fallen could be hung, showed a happy inspiration satisfactorily carried out; and Mr. Rowley's box for mementoes was a good idea. If people can only be made to see that such simple objects are in many cases the most intimate and appropriate memorial, a great step in the right direction will have been taken.

The Decorative Art Group.—From the rather staid exhibition of the Civic Arts Association to the little show held at the Modern Gallery by the Decorative Art Group is a far cry. Despite the name of the exhibition, the works were mainly pictures with a certain decorative tendency. Mr. Carlo Norway's little "glinter glass" pots, the exhibits nearest to applied art, were neither very remarkable nor very beautiful, but some of his panels in which he has used all sorts of contrivances, such as combining different colours with, not stencilling, but a stencil plate, show the true decorator's joy in making the most of his material. Miss Nancy Smith's work too, especially the Robinson Crusoe panel with its beautifully curly waves, and the japanesque parrot, is executed with decorative intent and suggests great possibilities in the way of really artistic poster work. The exhibition was in some ways extravagant, but there was a note of sincerity about it, and some of the members of the group showed an unusual amount of feeling for and appreciation of decorative ideals and necessities.

NOTES ON BOOKS.

GIULIA HOFFMANN TEDESCO MICHELE TEDESCO L'OPERA. Prefazione di S. Di Giacomo. Milano: Alfieri & Lacroix.

The works of the two Italian artists Michele Tedesco and his wife are perhaps not very well known in this country, though two of Michele Tedesco's pictures are in public galleries in London; one at the Guildhall, "Sibariti," representing the invasion of a garden of the Pythagoreans by a party of Sybarites; and one in the Victoria and Albert Museum entitled "Gli Amici di Dante." It is, however, to be hoped that the publication of this work, consisting as it does of a large number of reproductions, both in monochrome and in colour, of the works of the two artists, may draw attention to their pictures.

Perhaps even in their own country their work, though well known, is less appreciated than it deserves to be; because it belongs to the older school of artists known as the Macchiaioli, such as Nino Costa and others, with whom the more modern schools have not much in common. Besides this, it has always been characteristic of the work of husband and wife that they were never much preoccupied by considerations as to the taste of their day, the criticism to which they were subjected, or the probability of selling their pictures. They have always conscientiously worked to give expression to their own ideals in their own way, and, as their admirers believe, were inspired by a culture and a sense of natural and spiritual beauty not common in much of modern production. Such independence of thought as their work exhibits naturally does not lead to great popularity, but its delicate beauty is admitted even by those who have little sympathy with its chief characteristics.

The book itself consists entirely of the pictures, which are left to speak for themselves, with the aid only of a very brief preface or introduction, which gives the very shortest account of the two artists, now both well advanced in years—for Michele Tedesco was born in 1834, and they have been married over forty years.

THE PRINCIPLES AND PRACTICE OF COMMERCE. By James Stephenson, M.A., M.Com., B.Sc. London: Sir Isaac Pitman & Sons, Ltd. 5s. net.

As a nation of shopkeepers, this country has perhaps been somewhat slow in turning its attention to the scientific study of commerce. Of late years, it is true, a good deal has been done to recognise the importance of the higher branches of the subject: many of our universities now give degrees in economics or commerce and in the London School of Economics we have a whole institution of university rank, admirably equipped and staffed and numerously attended, which devotes itself entirely to the more advanced aspects of the question. For students of this rank there is comparatively little difficulty in finding text-books and treatises dealing with the various branches of their curricula; but there is a much vaster army of less advanced pupils who have hitherto had difficulty in finding in one compendious volume a solid and reliable account of the elements of commerce.

Mr. Stephenson, the author of the book under review, has had experience which renders him singularly well fitted to write such a work as was required. As the head of the Higher Commercial Department of the Polytechnic, Regent Street, he knows precisely what is wanted by young students of commerce. The book, he says, has been specially written with

the object of meeting the needs of those preparing for the different stages of the examinations of the Royal Society of Arts and the Lancashire and Cheshire Union of Institutes. It is divided into nine sections: General Principles; Industry; Commerce; Trade; Exchange, Banking and Finance; Transport and Insurance; Warehousing; Monopoly; and the State in relation to Commerce. The author is a man of some academic distinction, and he treats his subject with a sound scientific thoroughness that ought to make it interesting and easily intelligible to his readers. A series of test papers enables the student to examine himself on the subject-matter of each chapter.

The great portion of the book strikes us as admirably clear and practical. We are not quite so certain of the value of one or two of the diagrams, notably those illustrating "Commerce in its relation to the Economic System," "Methods of eliminating Middlemen," and "Elimination in the Export Trade," for they seem to us only a complicated and laboured way of explaining the obvious. It is possible however, that for certain types of mind a diagrammatic representation is as comforting as the blessed word Mesopotamia is for others.

A TEXT-BOOK OF PAPER-MAKING. By C. F. Cross and E. J. Bevan. Fourth Edition. London: E. & F. N. Spon, Ltd. 15*s*. net.

The first edition of this well-known text-book appeared in 1888. Since then much care has been devoted to the scientific study of paper-making materials, and in preparing the fourth edition of their work the authors have taken pains to embody the results of their working experience of paper-making problems. Naturally also great advances have been made in connection with paper-mill machinery. This side of the work has been specially dealt with by Mr. J. F. Briggs, who writes with a very wide practical experience of the subject.

A valuable feature of the book is its sixteen plates and ninety-nine illustrations, particularly the admirable photo-micrographs prepared by Mr. John Christie, who also supplies some of the matter in the very interesting chapter on statistics of the paper trade.

The volume forms a thoroughly practical and up-to-date text-book for all interested in the manufacture of paper, while those who wish to study any branches of the subject in greater detail will find a useful guide in the bibliography.

GENERAL NOTES.

POTASH IN LAKE MUDS IN UTAH.—Potash in large proportions is present in the brines and muds of the Salduro Marsh, a sink in the Salt Lake Desert, about 60 miles west of the south-west edge of Great Salt Lake. From the clays underlying the salt body which covers the marsh, the United States Geological Survey collected samples at depths of 8 to 12 ft., in which the dissolved salts were found to contain from 2 to about 3¼ per cent. of potash, and 2½ per cent. was found in the soluble salts at a depth of about 4 ft. According to analyses made by the Survey, the brines and muds from the Salduro Marsh contain considerable magnesium chloride as well as chlorides of potassium and sodium, and so are somewhat similar in composition to the deposits from which potash is manufactured in Germany.

RATTAN-FURNITURE INDUSTRY AT HONG-KONG.—The raw material for the Hong-Kong furniture industry comes from a variety of sources. The best price, according to a United States Consular report, is paid for that from Sarawak and British North Borneo, but supplies from the Dutch East Indies, French Indo-China, and the eastern and northern parts of the Malay Peninsula are also handled. Practically all of it comes to Hong-Kong direct from Singapore, being shipped to the agents of dealers of the latter place. When shipments arrive at Hong-Kong the agents distribute samples to the trade, and the supply is auctioned off. Several species of rattan grow in Southern China, but not in sufficient abundance to be exploited commercially. Very little of the Philippine product reaches the Hong-Kong market. Since the outbreak of the war the prices of both raw and prepared rattan in Hong-Kong have increased 50 to 75 per cent., mainly as the result of inadequate shipping facilities. The best grade of cane is now claimed to bring as high as $400 per long ton.

ADHESION TESTS FOR FABRICS IN RUBBER INDUSTRY.—The United States Bureau of Standards has installed in its rubber-testing laboratory a newly-designed autographic machine for testing the "friction" or adhesion between the different plies of canvas used in rubber hose, rubber belting, automobile tyres, etc. This machine, by means of a diagram that is made automatically during the test, shows the exact value of the adhesion between adjacent layers of fabric at all points. The machine was designed and built at the Bureau of Standards. The bureau is experimenting with several rubber compounds that have been made into eyeshades for use in connection with the range-finders on battleships. Some of these shades have been moulded in the bureau's experimental laboratory, and will be tested in service to ascertain the compound best suited for such use. An important recent test was in connection with fire hose purchased for use in the district of Columbia. Samples representing 28,000 ft. of fire hose were tested both physically and chemically to determine if the specifications had been complied with.

London: Printed by WILLIAM CLOWES & SONS, LTD., Duke Street, Stamford Street, S.E., and published for the Royal Society of Arts by G. BELL & SONS, LTD., York House, Portugal Street, W.C., in the Parish of St. Clement Danes, in the City of Westminster.—August 11, 1916.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

OPTICAL GLASS.

By Walter Rosenhain, D.Sc., F.R.S.,
Superintendent, Metallurgy Department,
National Physical Laboratory.

Lecture III.—Delivered December 13th, 1915.

In the previous lecture I have discussed in some detail the present process of optical glass manufacture and have dwelt upon some of its difficulties. Some of these are more or less peculiar to English circumstances, but the majority of them are inherent in the process as it is at present practised. It is only fair to point out that these difficulties are largely responsible for the fact that a vigorous and prosperous optical glass industry was not developed in this country in the first decade of this century. It is, perhaps, not too much to say that the manufacture of optical glass is even at the present moment not really a commercial process, and it is doubtful if it has been carried on in recent years as an independent profitable industry. In Jena there is little doubt that financial success has been achieved by the close inter-relationship of the firm of Schott with the immensely successful enterprise of Zeiss. In addition to this profitable co-operation between the glass-maker and the optical instrument maker, the Jena firm has undertaken glass manufacture on other lines besides those of optical glass—such as chemical laboratory ware, and more especially lamp-chimneys for gas-burners. These activities, taken up by a firm originally intended to deal only with the production of optical glass, serve as a good indication of the business aspect of the manufactures in question. We may, then, well inquire as to the future prospects of optical glass manufacture in this country, and I think there are only three courses open to us. The first is that of *laissez-faire*, as a result of which optical glass production would be left more or less in the old groove or to the efforts of those who regard the matter from the purely business point of view. The probable results of that course may be gauged from what was achieved between the years 1905 and 1914 by effort on the same basis. The second possibility is to aid the industry by some form of subvention or fiscal protection. Such protection may, perhaps, be justly claimed by firms or individuals who have put money and energy into an effort to meet the emergency demands for optical glass at the present time of crisis. But there are obvious disadvantages in such a course—leading to questions which I cannot discuss here. This much, however, is obvious: that if our industry needs State aid or protection we have yet fallen short of what should be our real object—viz., that of being able to meet the competition of Germany on an equal footing in the open markets of the world. The third course is by far the most difficult, but it is the only one which can lead to real success in this as in any other branch of technical industry; this course is the vigorous pursuit of a policy of progress—of setting about discovering the best way to deal with this problem of producing optical glass—by means of laboratory researches and works experiments—by scientific activity and industrial enterprise to put this industry on a better and more rational foundation, so that we may learn how to make better optical glass and to make it more cheaply than has yet been done elsewhere. If we do this we shall gain a real leadership, and with it the proper fruits of such a victory. But such victory requires to be organised, even as military victory does, and it cannot be gained if we are afraid to incur the requisite expense. Happily there is evidence that this strong course is to be pursued, and, in fact, vigorous research work is already well in progress.

While the results of any campaign cannot be predicted, it is of considerable interest even at this stage to survey the ground to be covered, and to consider the lines upon which the problem

must be attacked. It is the survey from this point of view which I propose to undertake in the present lecture.

If we consider the present process of optical glass manufacture carefully, we see at once that its disabilities as a commercial process arise from the fact that it is long and laborious and only produces a relatively low yield of saleable product. For the production of something between 250 and 350 lb. of good optical glass we have a series of operations occupying at least a week—not counting the time of producing the pot—and involving much manual labour and skilled supervision and a large quantity of relatively costly raw materials. Even then, there are risks of total loss to be reckoned with each time. It therefore becomes interesting to inquire why the process is so lengthy and laborious.

The long duration of a "melting" arises principally from two factors. In the first place the temperature employed must be carefully regulated, and cannot be indefinitely increased in order to secure really rapid and efficient melting. There are two special reasons for controlling temperature in this way. In the first place, the chemical action of the molten glass upon the wall of the pot exposed to contact with it increases rapidly with rising temperature. With the more active kinds of glass, unduly high temperature at once results in the destruction of the pot by "drilling"—the glass simply eats its way through the pot in a few isolated spots. But even apart from this, the pot itself cannot stand an excessively high temperature—the fireclay of which pots are usually made becomes soft at a bright white heat, and the weight of the molten glass would bulge the pot and lead to its destruction if temperatures like 1800° C. were used. On the other hand, the use of very high temperatures is essential if the rate of melting is to be materially accelerated. Here, of course, the heat-resisting power of the furnace itself would also be involved, but this is essentially the same problem as that of the pot—since both furnace and pot are usually made of the same type of refractory material.

But even without employing furnace-temperatures higher than those at present in use, it would be possible to accelerate the melting of the glass very much if it were possible to use a simple open pot or crucible instead of the domed covered pot—somewhat like a flat-bottomed retort—which is at present employed. With the open pot, the heat of the furnace has direct access to the glass or the glass-making materials, but in the covered pot the heat has to pass through the walls of the pot and of the dome—with the result that the rate of melting is materially diminished for a given type of glass and a given furnace temperature. We therefore inquire what are the reasons for using the covered pot in the melting of optical glass?

The answer is that the use of the covered pot is simply the result of adopting the ordinary process of flint-glass making. Flint glass, which is, of course, lead glass, is always made, in this country at all events, in covered pots very similar in shape to those used for optical purposes. Now, in the early days of optical glass manufacture, the real problem was to produce optical *flint* glasses, and the obvious step was to adopt the process of the habitual maker of flint glass. This adaptation was perfectly rational, because in the making of lead glass it is necessary to protect the molten "metal" from contact with reducing gases such as those which exist in the furnace—and more particularly in the old coal-fired furnaces. Protection is also needed from contamination by flying ashes and dust, and even by "droppers" from the crown of the furnace, and this necessity applies with equal force to the production of optical flint glasses, so long as the same type of furnace is used. Recently, by the rational use of the regenerative gas-furnace, some French works have succeeded in producing excellent flint (lead) glass in simple open pots, and for optical purposes some types of "crown" glass have also been made in open pots. It must be admitted, however, that for a large number of optical glasses such a proceeding is out of the question; in fact, the degree of protection from furnace gases which is secured by the use even of the covered pot is not really adequate—the hot fireclay is sufficiently porous to admit of a certain amount of diffusion of the furnace-gases into the interior of the pot. The rational solution of such a difficulty would therefore seem to be—if we cannot exclude them satisfactorily and have to use an inefficient and clumsy covered pot on their account—to eliminate the ordinary furnace gases entirely. The means for doing this would appear to lie at hand in the modern development of the electric furnace, and it seems at all events possible that in this direction may lie one of the lines of future progress in the production of optical glass.

With this possibility in view it may be worth while to glance very briefly at the various existing types of electric furnace and to consider their possibilities from the present point of view.

Essentially there are only three types of electric furnace in existence, together with types which are combinations of two of the fundamental forms. These three types are the "resistance," the "arc," and the "induction."

The "resistance" type of furnace is by far the simplest in every way. In its most elementary form it consists of an electric conductor, which is heated by the passage of a suitably large electric current. Usually this conductor is so arranged as to surround—more or less completely—the furnace-space proper where the objects to be heated are placed. The ordinary electric tube furnace, in which a metallic wire or tape serves as resistance, is limited in regard to temperature by the properties of the metal employed. Even platinum, which is prohibitively expensive for any but laboratory purposes, cannot resist a temperature exceeding 1400° C. for more than a very short time; the recently-introduced refractory alloys containing large proportions of nickel and chromium (known as "nichrome") cannot be continuously used for temperatures exceeding 1200° C. For glass-melting purposes, where any but the most fusible glasses are concerned, these temperatures are insufficient. But the resistance type of electric furnaces is not confined to those using metallic resistances. Carbon resistance furnaces have been made and worked on the large scale, both in the form of tubes or rods of carbon serving as heaters and also by the employment of resistances formed of granulated carbon contained between walls of suitable refractory material. But in these types there is much room for development, since none of the existing forms are readily applicable to glass-melting. In these, as also in the "arc" and the "arc resistance" type, if the carbon is not to be rapidly consumed, a strongly reducing atmosphere must be maintained, at all events in the spaces immediately surrounding the carbon. In the glass-melting chamber of a furnace, however, if open pots are to be used, an oxidising atmosphere is essential, and thus one of the special problems to be faced in applying electric furnaces working with carbon to glass-melting purposes consists in finding satisfactory means whereby the reducing atmosphere surrounding the carbon can be effectively separated from the oxidising atmosphere required in contact with the glass.

The induction furnace, the best-known types of which are those of Kjellin and of Roechling-Rodenhauser, depends upon the generation of extremely powerful alternating electric currents in the material to be heated, by the process of induction. For this purpose the electric power is applied as an alternating current passing through a set of windings placed on a large magnetic "core." This "core" passes through the centre of the furnace, the crucible or melting-chamber being arranged as a ring or annulus around this core in such a way that the contents of the crucible form a "winding" of one single turn about the core. The whole arrangement acts as a transformer, and when an alternating current is passed into the external coil currents of lower voltage but correspondingly higher current density are generated in the contents of the crucible. The working of this type of furnace, however, requires in the first place that when the electric current is first turned on, the contents of the annular crucible shall constitute a good conductor of electricity. Now glass only becomes a conductor at a fairly high temperature, so that a furnace of this type could not be started from the cold state. Even if this difficulty could be overcome by means of auxiliary heating appliances or by other means, the difficulty still remains that the crucible must be of the ring form. This form would be so disadvantageous from the point of view of the area of glass in contact with the refractory containing vessel as to put this type of furnace, in my opinion, entirely out of court for the present purpose.

Of an entirely different type and offering totally different conditions are the "arc" furnaces. In these, the heat is generated by one or more electric arcs, playing between carbon electrodes in the upper part of the furnace chamber, leaving the heat to be conveyed downwards to the contents of the furnace by radiation and conduction. Where extremely high temperatures are to be employed and only small quantities of material are to be treated, the arc can be used to play directly upon the object to be heated. In the furnaces of the "Stassano" type, on the other hand, the intense local heating effect of the arc is not desired, and here a number of arcs play in the upper part of a furnace chamber, the heat being moderated and equalised by keeping the arcs at a little height above the contents of the hearth or "crucible." At first sight it would seem that this mode of electric heating was directly applicable to glass-melting, but two serious difficulties arise. The first of these is again the question of the reducing atmosphere generated by and to some extent necessary to the arcs themselves, while the second arises from the fact that the carbons used for carrying the arcs are gradually consumed and that the ash which is left by their

combustion, as well as fragments of the carbons themselves, would fall down into the glass below. If an intervening dome or roof must be employed, then the disadvantages of the ordinary gas-fired furnace are again admitted. The use of the arc-furnace pure and simple would thus seem to be somewhat difficult, but it is quite possible that a modification of this type of furnace could be devised which would render it directly applicable.

The "arc-resistance" type of electric furnace, however, which is so largely used in steel metallurgy at the present time, would appear to offer rather more interest from the glass-melting point of view. As an example of this type of furnace, we may take that variety in which two carbon electrodes are used, hanging down from above with their lower ends close to the surface of the molten material in the hearth of the furnace. Between each of the carbons and the molten material an arc is formed, the current passing from one arc to the other through the molten layer. In steel metallurgy, of course, this layer is the slag with which the surface of the steel is covered. Theoretically, the molten glass itself, or even the raw materials in incipient fusion, might serve to carry the current, but if this were done the difficulties just described in regard to the simple arc furnace would still apply. But in order to suggest the directions which adaptation to the needs of glass-making might take, it may be mentioned that most of these difficulties would be avoided if the molten or melting glass could be covered with a layer of molten material of a different kind, much as the steel is covered by the slag. For instance, fused sulphate of soda floats upon the surface of molten glass without mixing with it to any considerable extent, and no doubt other fused salts or mixtures of salts could be found to answer such a purpose.

Another possibility consists in using such an arc-resistance furnace, or any other type of electric furnace, to heat a bath of neutral slag, or even of metal, and to immerse the crucible in which glass is to be melted in this bath. This arrangement, again, would overcome most of the difficulties of the arc furnace, but other difficulties would arise, such as that of keeping the current-density on the two sides of the crucible equal so as to avoid local over-heating. The necessity of avoiding the "pinch" effect, which tends to constrict and finally to disrupt a liquid conductor when too great a current-density is applied to it, would also have to be borne in mind. I do not suppose, therefore, that either of the proposals here indicated is likely to offer the final solution of this problem; they serve, however, to suggest that adaptation and modification are both necessary and possible if the problem before us—of adapting the electric furnace on the large scale to the production of optical glass—is to be solved. We have here one of the problems upon which research in this subject should be directed.

Apart from all questions connected with the furnace, the main difficulties which we have discussed in our brief account of the process of optical glass manufacture have been related to the crucible or pot in which the glass is contained during the whole operation. The mere production of the pot and the process of getting it ready for the melting operation is very long and laborious and full of risks of failure and loss. The operation of building the pot up out of the previously prepared fireclay is a matter occupying a period extending over four months, and at least four further months are needed before the pot is sufficiently dry. Most glass-makers prefer to dry their pots for at least six months before taking them into use. And during the entire period, careful supervision is needed, since any considerable oscillation of temperature in the pot-rooms is apt to cause cracks.

When the pot is safely "air dry" it has to be taken out of the drying-rooms and transferred to the pot-arch, where it is to undergo its preliminary burning. If it escapes injury during transit, it may yet be ruined—as we have seen in the previous lecture—by a single "flash" of premature flame licking over it. Thus the pot, when "set" in the furnace, safe and sound, and ready for filling, represents a decidedly costly product. The circumstance that for each melting one such pot must be sacrificed therefore represents one of the most serious drawbacks to the whole process from the commercial point of view. For the sake of economy in production, therefore, it becomes a matter of first-rate importance to devise means whereby the same pot might be used for a whole series of successive meltings. If this could be done, it would easily counterbalance any increased cost of the pot itself, such as might arise from the use of raw materials for pot-making rather more costly than the present fire-clays.

The troubles for which the pot is responsible do not end, however, with the destruction of the pot itself at the close of a successful melting. Actually, the low yield of useable glass (20 to 30 per cent. of the total glass melted) and the occasional failure of entire meltings, are largely traceable to the nature and properties of the pot. Fire-clay is an impure silicate of alumina,

generally containing more or less free silica mixed with it, and also contaminated with iron in various forms of combination. Now all these materials can be, and are, used as actual constituents of various kinds of glass, and all of them are to a greater or less extent soluble in glass—much as sugar is soluble in water. When, therefore, glass is heated for a long period in contact with a vessel made of these materials, a certain amount of attack occurs and the glass gradually dissolves the constituents of the clay. This process only occurs slowly and to a small extent with most ordinary varieties of glass, such as ordinary sheet or flint glass, so that the pots withstand many meltings of these types of glass before they are so far dissolved away as to fail. But in the case of certain kinds of optical glass the rate of solution is very rapid. The rate of attack attained by a dense barium glass, when the temperature is kept fairly high, is indicated in Fig. 6, which is a photograph slightly magnified (10 diameters) of a cross-section of the wall of a pot which has been exposed to the attack of such glass for three hours. The original thickness of the wall is indicated by the dotted line. Here the attack has been fairly uniform over the entire surface of contact of glass and pot; in other cases, such as that illustrated by the section photographed in Fig. 7, the glass appears to find a few weak spots in the clay and the pot is then "drilled" with astonishing rapidity. A pot 3 in. thick

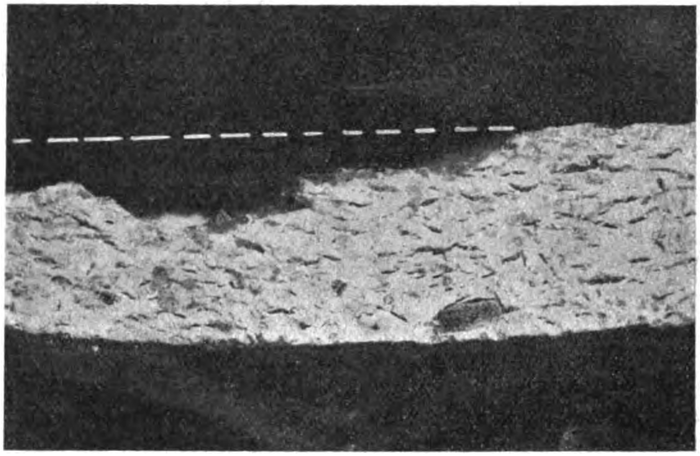

Fig. 6.

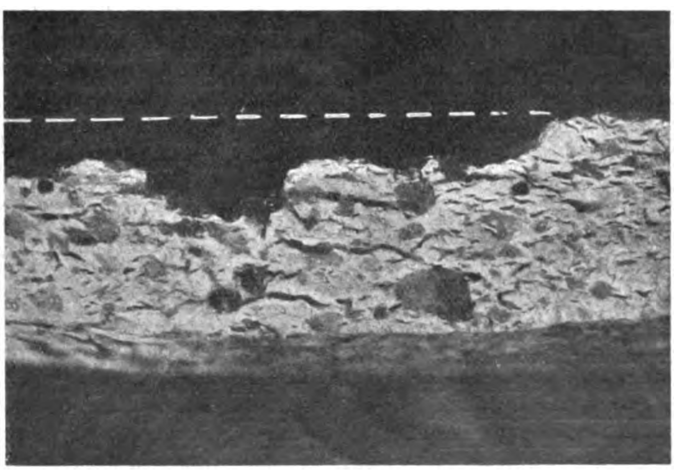

Fig. 7.

may be pierced in this way in two or three hours.

The worst evil which arises from this action of the glass upon fireclay, is not the mere mechanical destruction of the pot itself, but the resulting contamination of the glass. Where the fireclay contains a notable amount of iron, this is rapidly "washed" out by the glass, which—if it is sensitive to colouring oxides—rapidly assumes a greenish tint. The presence of notable proportions of iron can be largely avoided by the choice of particularly pure clays, but the glass also dissolves silica and alumina, and these are essential constituents of the clay. It is true that silica and alumina do not produce colouration of the glass, but they contaminate it none the less by producing close to the walls of the pot a layer of glass rich in alumina. This glass is extremely viscous and will not readily mix with the rest of the contents of the pot, while it is also distinguished by a markedly different index of refraction. During the stirring process, care must be taken to avoid dragging this thick viscous glass away from the sides of the pot, and the stirring cylinder is therefore made to give the walls of the pot a wide berth. This, however, results in two difficulties. In the first place, it limits the vigour of the stirring operation, and the risk is run of not stirring the glass enough to render the body of it homogeneous, for fear of spoiling the whole by dragging cords or veins of the aluminiferous glass from the pot-walls into the body of the glass. Further, even if the stirring operation is successfully concluded and the glass in the centre of the pot is free from striae, the glass must be allowed to "set" as rapidly and with as little disturbance as possible lest the stringy glass around the sides should be permitted to mix with the good glass in the centre. This is why it is essential to allow the glass to cool in the pot in which it was melted —thus necessitating the destruction of the pot at the end of the melting, instead of removing it by ladling, pouring or gathering and thus leaving the pot available for further use.

It would thus appear that the solubility of the material of the pot in molten glass is one of the worst features of the present process of optical glass making, since it gives rise to all the most seriously disadvantageous features of the whole process.

The first aim of research intended to bring about the improvement of optical glass making must therefore be the improvement of the pot with a view to rendering it, if possible, completely inert and insoluble in the molten glass to which it is to be exposed. If the solubility of the material of the pot in the molten glass were eliminated, most of the difficulties of optical glass making would vanish. The removal of striae could be completely effected by vigorous mechanical stirring which need take no heed of leaving the outer layers of glass undisturbed, while the glass, when finally stirred to complete homogeneity, could be rapidly removed from the pot, and the pot could be used again and again. Even if this complete solution of the problem is not attained, any notable progress in that direction would be of considerable value, as it would tend towards a greater yield from each individual melting and to the reduction of the number of entirely useless meltings.

The material of which glass-melting pots are universally made is the substance known as "fireclay." The constitution and properties of fireclays have of late years formed the subject of much detailed study and investigation, principally in Germany and America. Chemical purity, combined with certain well-defined physical properties, has been recognised as the primary necessity for good fireclay. As in the case of sands, so also in regard to fireclays Germany is fortunate in possessing specially good natural resources, and these have been thoroughly studied and exploited on a sound scientific basis. As a contrast to this we may take the attitude of certain British clay-workers: one of the firms concerned, in answer to a request that they should supply a sample of their best pot-clay for purposes of experiments intended to improve pots for optical glass making, wrote to the effect that their pot-clay was already so good that they did not see that any experiments could possibly improve it. Fortunately, this is an illustration of an extreme attitude not adopted by many of those concerned, but the fact remains that such fireclay resources as we possess in this country are not as fully studied and utilised as they should be. Quite recently great progress has been made in regard to certain types of refractory goods, such as gas retorts, but in regard to glass pots the best available British material is still far below the standard attained in Germany. A first step towards the elimination of what we may term "pot troubles" in regard to optical glass is, therefore, the systematic study of fireclays and the production of better clay pots. And our survey for this purpose should extend throughout the Empire, in order to supplement the resources of this country with those of the wider lands beyond the seas.

While thus strongly urging the necessity for improvement in regard to our fireclay pots, I think that it would be too much to expect that any fireclay would suffice to solve the problem with which we are here faced—viz., that of providing an entirely inert melting vessel for optical glass. In order to effect further improvement we must either abandon clay entirely and turn to totally different refractory materials, or we must in some manner protect the clay from direct contact with the molten glass. One of the most obvious ways of doing this would seem to be by coating the fireclay with a refractory and inert glaze such as the glaze that is used on porcelain or earthenware intended for containing acids, etc. The problem, however, is much more difficult, because while the ordinary porcelain glaze has only to resist the acid at temperatures far below a red heat, the glaze on a glass-melting pot would require to resist the action of molten glass at a very high temperature—a red or even a white heat. It would thus seem necessary to employ a glaze whose melting-point is much higher than that of the glass to be melted in the pot. Such "glazes" could, no doubt, be prepared, but the difficulty of applying them would be extreme, as a moment's consideration of the case will show. A "glaze" can only be applied to the surface of a pot by melting it on. In ordinary pottery the material of the glaze is applied to the surface of the "biscuit" pottery in the form of finely-divided powder; the whole is then heated until the materials of the glaze melt and form a continuous coating over the surface. An essential condition for this operation is that the material of the pot should be much less fusible than that of the glaze, since otherwise the pot itself would soften and melt while the glaze was being melted on. In the case of the glass-melting pot, however, it would be difficult, if not impossible, to fulfil this condition, since the temperature required to melt the glass itself is generally quite as much as the pot can stand; "melting on" a still more refractory glaze would therefore be impossible —unless, indeed, one had at one's disposal a "fireclay" whose softening temperature lay many hundreds of degrees above the temperature required for "fining" the glass. Even the best of known fireclays do not approach this degree of refractoriness. In practice, up to the present time, the application of "glazes" is confined to two operations. The first of these has already been described; it consists in "glazing" the inside of the pot with molten glass of the same kind as that which is to be melted in the pot; this procedure, however, merely serves to protect the pot from the violent action of the raw materials, and in no sense can it protect the pot from the action of the glass itself. The second operation consists in glazing the outside of the covered pots with some refractory glaze, applied in strictly limited quantities, for the purpose of closing the pores of the pot and preventing or retarding the entry of furnace gases into the pot. Since the pot is very porous and tends rapidly to absorb any liquid spread over its surface, this process is of doubtful value; either the glaze is absorbed by the pot without filling its pores or, if enough is used to stop the pores effectively, it acts as a flux and brings about the fusion and destruction of the whole pot.

It would thus appear that if fireclay pots are to be protected from the attack of molten glass this will have to be done by means of a refractory lining—*i.e.*, of a lining which is not melted during any of the operations. Such linings are well known in metallurgy, and it does not seem unlikely that they can be employed for the present purpose. There are, however, serious difficulties to be overcome. The first and most fundamental of these is that of finding a lining material which is really indifferent or inert to the action of molten glass. Fortunately, there is some hope that such materials may be found. Beyond this, comes the difficulty of forming such materials, which will probably not possess the remarkable plastic properties of clay, into linings and of making these linings adhere to the fireclay walls of the pot. Finally, the shrinkage of the clay during burning, and the difference in shrinkage and in thermal expansion and contraction between the walls of the pot and the lining, all tend to disintegrate the latter. The difficulties of this type, however, have been successfully overcome in the case of ordinary pottery work. If an unsuitable glaze is applied to a given piece of ware, on cooling after firing the glaze is found to be cracked—or "crazed" —in all directions; in extreme cases the glaze may even chip off entirely. When this occurs it is due to a difference in the contraction of the body and the glaze, and it can be corrected, in most cases, by varying the chemical composition of the glaze in such a way as to adapt its physical constants to those of the body. If this is not entirely possible, a "modus vivendi" may sometimes be found by interposing an accommodating layer having intermediate properties, so as to soften the contrast between the two materials. It seems probable that similar

devices could be employed in the case of refractory linings in fireclay pots. A further difficulty arises from the very refractory nature of the lining material. The latter, in order to be converted into a reasonably coherent mass, must be raised to a temperature where its most fusible portions are approaching fusion; when thus heated, the material becomes "fritted" and attains the requisite degree of strength. But in the case of certain extremely refractory materials, the temperature required for this purpose is so high that the fireclay itself could not resist it. Here again it will be necessary to adopt devices which will surmount this difficulty; but the use of the most refractory fireclay will in itself serve to diminish it.

Finally, if the difficulties just indicated cannot be overcome by any reasonable method, it may become necessary to depart from fireclay entirely, and to adopt some different refractory material for our pots. The very great possibilities which exist in the way of "new" refractory materials are indicated by a number of new products which have been developed in America, where this branch of the subject has received very great attention. There the view has rightly been taken that the advance of metallurgy and of furnace practice generally is dependent upon better refractories, and as a result we have such valuable materials as alundum, carborundum, siloxycon, etc., and the possibilities are doubtless still far from being exhausted. Here again the electric furnace offers the means for exploring new fields, since the properties of many substances are materially altered by preliminary heating or even melting in the electric furnace at extremely high temperatures. The electric furnace may thus become of primary importance to optical glass manufacture as a means of preparing the necessary refractories.

The whole question in regard to the problem of the melting pot for optical glass thus becomes one of finding the suitable material and means for utilising it on the large scale. Just as the work of Schott and Abbe was epoch-making, because they introduced new materials into optical glass itself, so the next great forward step in this industry will be made by the introduction of a new material for the pot in which the glass is to be melted.

The difficulties which beset the production of optical glass, in so far as we have yet considered them, arise to a considerable extent in the production of all types of optical glass. There are, however, other troubles which are peculiar to certain types of glass. Thus, in the case of flint glasses, which contain large proportions of lead oxide, there is the well-known effect of reducing gases, which blacken the glass by the reduction of metallic lead. For this reason the use of the covered pot is regarded as essential by all makers of flint-glass in England. In certain works in France it has been found possible to make flint glass in open pots by the use of a special type of gas-furnace in which the flame itself is kept away from the pots and an oxidising atmosphere is maintained around the pots.

These flint glasses also exhibit an exceptionally great tendency to develop striae, and to exhibit small but noticeable variations of their optical constants in different levels of the pot. This arises from the difficulty of stirring these glasses as vigorously and thoroughly as would otherwise be desirable, although slight losses by volatilization from the surface of the glass may also play a part in the matter.

Still more serious difficulties of a special nature arise in the case of the very dense glasses of the "Barium Crown" type, which are of such great importance for optical uses. These glasses combine a relatively high refractive index (ranging up to and above 1·61) with a low dispersion (ν values up to 60). In order to attain these optical constants, such glasses are made with a barium-content of from 40 to 50 per cent., combined with 10 to 15 per cent. of boric acid and very little silica. These glasses, therefore, constitute extremely basic fluxes. This can be best realised by expressing their composition in terms of chemical symbols, so as to obtain an idea of the relative proportions of basic and acid molecules as compared with the same ratio in the case of a standard glass of the "hard crown" type. The two formulae read—

Very dense Barium Crown $Na_2O, 4BaO, 2B_2O_3, 2SiO_2, Al_2O_3$.

Typical Hard Crown . . . $Na_2O, CaO, 6SiO_2$.

The consequence of this extremely basic composition is, in the first place, very violent action upon fireclay; one of these glasses if strongly heated will drill holes through a thick fireclay pot in a few hours. A further difficulty with these glasses is their extreme sensitiveness to colouring materials. Melted without very special precautions, they assume a deep green tint. To some extent this colour arises from minute impurities in the raw materials, but beyond this there is some definite colouring action which occurs in the furnace; the iron contained in the material of the pot itself plays a part in

this action, but so do the furnace gases, since the same mixture and pot, employed in an electric furnace free from all carbon and sulphur gases, yield a colourless glass, while a deep green colour is produced in the ordinary gas furnace. It appears probable that the presence of sulphur and the resulting formation of a barium-aluminium-sulphur compound, somewhat of the type of "ultramarine," may come into play.

The extreme glasses of this type are subject to a further series of difficulties. One is that of freeing them entirely from small gas-bubbles. Interaction between glass and pot, and possibly between glass and furnace gases, appears to generate fresh bubbles as the melting proceeds, with the result that the glass is never entirely free from them. Their relatively harmless nature has already been discussed. More serious is what we may term the chemical instability of these glasses. This manifests itself in the finished glasses by liability to tarnishing and dimming of the surface owing to the action of the moisture and carbonic acid of the atmosphere. Sensitiveness in this respect is due to the fact that the barium silicates and borates present in the glass—which are themselves fairly stable bodies—are heavily laden with excess of free or very loosely combined barium oxide, which is left free to react with moisture and carbon dioxide.

During the cooling of these glasses from fusion, the fact that we are dealing with heavily-laden solutions makes itself evident in a strong tendency for the cooling solution to deposit its heavy burden in the shape of crystals which are formed during cooling. This tendency to crystallize during cooling may be counteracted to a certain extent by accelerating the cooling of the molten glass; the pot may be drawn out of the furnace and cooled in the air, and it may even be cooled still more vigorously by the aid of a jet of cold water. But even the most drastic methods cannot accelerate the cooling of a large mass of glass beyond a certain point. That this is so can be clearly seen if a large mass of molten glass is poured into water; the interior of such a mass remains visibly red hot for a long time in spite of the rapid cooling of the outer layers. It follows that in the case of a pot of glass intended for optical purposes a limiting composition will be reached when the glass still undergoes crystallization in spite of the most rapid cooling which can be applied to it. This circumstance supplies one very definite limit to the range of optical glasses which are attainable, in one direction at all events.

An interesting side-issue arises in regard to the determination of the temperature from which chilling must begin in the case of glasses which undergo "devitrification" or crystallization during normal cooling. It is obviously important to know the exact range of temperature through which rapid cooling is essential, in order to avoid on the one hand unnecessary risk involved from chilling the glass at an unduly high temperature, and on the other the risk of allowing the mass of glass to break up into useless fragments by carrying the chilling process down to too low a temperature. The necessary knowledge can be obtained by the application of a method with which metallurgists are familiar—viz., the taking of a "heating curve." For this purpose a small piece of the glass in question, which has been allowed to devitrify or crystallize as completely as possible, is slowly heated up in a suitable furnace and its temperature is observed, by means of a thermo-couple, at regular short intervals. When the temperature is reached at which the crystals present in the devitrified mass begin to melt, a retardation in the rise of temperature of the glass will make itself felt, and this will continue throughout the range of temperature during which crystals are melting. When all the crystals are melted, the rate of rise of temperature will again be accelerated. Now it is an assumption well justified by known facts that the temperatures at which these crystals melt are not widely different from those at which they crystallize from their vitreous solution—*i.e.* from the cooling glass. The range of retardation found during heating may therefore be regarded as defining the "danger zone" during which risk of crystallization exists, and may thus serve to indicate the range of temperature through which the glass must be cooled as rapidly as possible by some form of "chilling."

While the achievements of the Continental makers of optical glass make it clear that in regard to many valuable glasses which more or less closely approach these extreme types the numerous and serious special difficulties have been overcome, yet the fact remains clearly evident that there does exist a very well-defined limit to the possible range of glasses. A glance through the most extensive lists of optical glasses yet produced at once brings out the fact that the available values of the optical constants all lie between relatively narrow limits. Thus the refractive index (n_D) lies between 1·46 and 1·90, and the value of the constant ν ranges from 67 to 29. The question naturally

presents itself whether these limits are fixed and inevitable, or whether there is any prospect of exceeding them to a marked extent. From the point of view of optics, it is obvious that a much wider range in both constants would be of immense value, opening up possibilities in optical design not at present contemplated as even remotely practicable.

To some extent the facts just discussed in regard to the special difficulties which arise with those glasses which may be regarded as "extreme" in type serve as evidence for the view that the limits of optical properties for glass, as found in modern trade lists, cannot be greatly exceeded—for reasons of a chemical and physical character intimately bound up with the very nature of the vitreous condition. The conclusion is at all events probable that extreme optical properties are correlated with physical and chemical characteristics which tend so strongly to promote crystallization that the retention of the material in the vitreous condition becomes impracticable. If this is the case we must look for optical media whose properties transcend those of glass among crystalline substances. The practice of optics has actually taken this step in at least one very important case. I refer to the use of the mineral fluorite in the best microscope objectives. This mineral has a refractive index of 1·4338 and a ν value of 95·4, thus lying, in both respects, well outside the limits attainable in the case of glass. In this striking instance we have a verification of the view that such extreme optical constants are only attained by crystalline material, and an examination of the optical constants of many other minerals at once confirms this view. Thus the garnets possess refractive indices ranging up to 1·81, while in some of the spinels this constant attains the very high value of 2·096. Determinations of the ν values of these minerals are not available, but no doubt a correspondingly wide range would be found.

The general conclusion would thus seem to be justified that for an extension of the range of available optical constants we must look to crystalline transparent minerals. Unfortunately, there are very few minerals which can be satisfactorily employed for optical purposes. The great majority of these substances, as found in Nature, are more or less deeply coloured, and, moreover, their occurrence in large homogeneous and transparent pieces is rare; consequently their use for any but the smallest lenses is prohibitive on account of the cost. A further and fundamental limitation arises from the fact that the great majority of minerals are doubly refracting to a more or less marked degree, and this property renders their use in general impracticable. Thus at the present time fluorite and rock crystal (quartz) are probably the only minerals employed in the shape of lenses, although calcite is used for Nicol prisms and rock salt has been employed for special purposes.

The state of affairs just indicated, however, should not, in my opinion, deter us from the project of extending the range of our optical media by the utilization of crystalline materials. A considerable number of minerals are known which are free from double refraction—*i.e.* those crystallizing in the regular system, and the whole question resolves itself into the problem of obtaining crystals of these substances in sufficiently large sizes and of sufficient clearness and purity to be useful for optical purposes. As I pointed out in a paper on "Possible Directions of Progress in Optical Glass," presented to the Optical Convention of 1905, the problem of the artificial production of crystals of the size and quality required, although offering many difficulties, would not appear to lie beyond the range of possible practical solution. I still strongly hold the view that with adequate resources used in the light of modern knowledge of the process of crystallization, research on the question of the synthetic production of such crystalline material offers considerable promise of success. In a small way, and without any considerable expenditure of time or resources, I have made some experiments in the production of mineral crystals by means of diffusion processes, and these have yielded quite promising results. For an investigator approaching this subject with adequate resources, a very wide and promising field lies open.

Leaving these fascinating speculations on possible future developments, we may rapidly summarise the whole position in regard to the manufacture of optical glass.

The account of the process which has been given in these lectures, although far from complete, has perhaps been sufficient to convince the reader that optical glass manufacture is at once one of the most interesting and one of the most difficult of manufacturing operations. Indeed, were it not that optical glass is made and used in very large quantities, one would be inclined to take too serious a view of the numerous difficulties and obstacles and to imagine that the entire process was impracticable

as a commercial undertaking. To some extent this is probably a correct conclusion, as there is some reason to doubt whether optical glass manufacture by itself has ever been conducted as a profitable industry. Since, however, bitter experience has made it clear that this branch of glass manufacture is one of the most important "key" industries, it becomes clear that in one way or another the industry must be stimulated and maintained in this country. The possibility of accomplishing this end by what might be termed "political" means, such as the granting of subsidies or the erection of tariff walls, has already been suggested. On the other hand such devices can at best be regarded only as necessary evils—there is no real inherent reason why optical glass should not be made as well and as economically here as in Germany. The actual causes which have led up to the position as it existed before the war are fairly well known; it is one of those cases where a lead on both the scientific-technical and the business side was once gained and has subsequently been steadily maintained. The point of view which I would wish to urge is that the prospect of making good this lee-way by simply following upon the lines which they have struck out is not very bright. What is, in my opinion, required, is that we should strike out for ourselves in order to place the whole industry on a more rational and scientific basis. The existing process is in so many ways unsatisfactory and uneconomical that possibilities of radical improvement must exist in many directions; some of these I have tried to indicate in these lectures. If by a combination of extensive research conducted under the best conditions and with the aid of ample funds, with subsequent business enterprise and manufacturing skill, such a forward step can be achieved, then the leadership in this branch of industry may be restored to us, and we shall not need subsidies or tariffs to enable us to face the competition of those who are now our enemies—and that, surely, is the real goal to be aimed at. Fortunately the Government has already shown its appreciation of the necessity for research in this subject by making substantial grants for the purpose both to the National Physical Laboratory and to the Glass Committee of the Institute of Chemistry. Researches at these places are well in hand and are already yielding promising results—although the final goal is yet far ahead. The effort, however, is being made, and we have every reason to look forward with hope to the ultimate result.

ENGINEERING NOTES.

The Longest Tunnel in North America.—This, says the *Engineer*, is on the line of the Canadian Pacific Railway Company, and is being driven through the Selkirk Mountains in British Columbia, passing under Mount Macdonald. When finished the tunnel will be exactly 26,400 ft. or five miles long, and it will be longer than any tunnel in North America by three-quarters of a mile. It is on a new line constructed between Beavermouth and Cambie, and between the eightieth and ninetieth mile-posts west of Field. The old line which is being supplanted has some extremely heavy gradients; indeed, there are no less than 22·15 miles of 1 in 45 gradient in a total length of less than 30 miles. Moreover, the maximum elevation reached is as much as 4,330 ft., and the route traversed by the line is such that in the region of the summit there are no less than four miles of snow sheds. The new line will reduce the length between the two places mentioned by about 4½ miles; there will only be 6·61 miles of maximum gradient of 1 in 45; the greatest elevation reached will be only 3,791 ft.; the use of snow sheds will no longer be necessary; the total curvature will be much reduced, several loops being altogether done away with. These very important improvements are not, of course, being effected without considerable expense; it is said, in fact, that some £2,400,000 are being laid out on them; but the saving in running costs which will be realised will be very great, for not only will less locomotive power be required to carry on the same traffic, but there will not be the same trouble in keeping the line free from snow during the winter. The tunnel is to be 24 ft. high and 29 ft. in greatest width. Save for something under 400 yards at each end, where the material traversed consists of clay and boulders, the boring is through mica schist and quartzite rock. In the latter portion there is to be no lining, but for the softer materials a concrete lining is being used. The greatest depth of rock above the tunnel is very nearly 5,700 ft. A feature in the boring of the tunnel is the employment of what is termed a "pioneer bore," which is a subsidiary heading driven parallel to the centre line of the main tunnel at a distance, for the major portion of its length, of some 45 ft. from that centre line. This subsidiary tunnel measures 7 ft. by 8 ft. in cross-section, and from it, at intervals of something over a quarter of a mile, cross galleries are driven in the direction of the axis of the main tunnel, and when this axis is reached the main borings are begun in both directions. The tunnel, therefore, is being bored from a number of faces at the same time, boring also proceeding from the two portals simultaneously. The method of boring employed is first of all to run a heading 8 ft. by 11 ft. on the centre line

of the tunnel, and to excavate out to full section from that heading. Generally speaking, the grade of the "pioneer bore" is 10 ft. above the sub-grade of the main tunnel, but the eastern portal is 53 ft. above grade and the western portal 135 ft. above. The cost of driving this "pioneer" bore was naturally heavy, but as the railway company is paying a premium on every day saved on the contract time, and as the subsidiary tunnel has very materially hastened and cheapened the construction of the main tunnel, the contractor fully anticipates that the result will be that the money laid out will be more than counterbalanced by the savings effected and the bonus earned. Work on the undertaking was only begun in June, 1914, but it is anticipated that it will be completed in September of this year.

Port of London Improvements.—The Port of London is now and has been for some time past free from congestion. To-day all is working smoothly, and ships arriving in the port discharge and load without delay. One of the improvements is the widening and deepening of the entrance to the East India Import Dock. The entrance, which was built to meet the requirements of the old East Indiaman, was so narrow and of such a shape that the dock was inaccessible to anything larger than a 500- or 600-ton steamer; now it can be used by steamers of 8,000 tons. Other improvements include the construction of new two-story sheds at the London (Western) Dock, the enlargement of the sheds at the West India Dock, and the provision of new sheds at the South-West India Dock. The greatest of the improvements in the programme, the new Albert Dock extension, which is to cost £2,000,000, has not yet been finished owing to difficulty in obtaining machinery for the dock gates. Including this and the works completed or still in hand, the total outlay on improving the dock and dredging the river is estimated at £6,000,000. It is noteworthy that, in spite of the cost of these improvements, the Port Authority have not raised their charges beyond the 15 per cent. required to cover the two war bonuses they have had to pay. The Port Authority are now employing from 7,500 to 8,000 men daily, against a normal number of from 4,500 to 5,000, and the number of men employed by the shipowners and other interests in the port has probably increased in the same proportion.

Portland Cement: Attributes of its Constituents.—The major constituents of Portland cement are tricalcic silicate, dicalcic silicate, and tricalcic aluminate. Of these constituents, according to a statement made by George A. Rankin in a paper on Portland cement in the *Journal of the Franklin Institute*, the compound tricalcic silicate is the one which hardens and develops the greatest strength within a reasonable time. This most important constituent, which is the one formed with the greatest difficulty, makes up only about 30 to 35 per cent. of an average normal Portland cement. It may be said, therefore, that the essential process for the manufacture of Portland cement is the formation of this compound, and that any improvement in this process yielding an increased percentage of tricalcic silicate will increase the cementing value of Portland cement. In order to determine the most economical process for producing tricalcic silicate in the highest percentages, it will be necessary to study the rate of formation of this compound in a series of mixtures of various substances; this, in turn, necessitates the determination of the equilibrium relations of tricalcic silicate at high temperatures in such mixtures. Such a procedure will lead sooner to the discovery of the optimum composition in various cases and for various purposes than the empirical trial-and-error methods that have hitherto prevailed.

The London Postal Tube Railway.—Information just conveyed to Parliament by Mr. Asquith in a written answer that the tunnel was nearly completed, is to the effect that the purpose of the railway is to accelerate the transmission of mails and parcels and reduce the expenditure on road vans, incidentally relieving congestion in the streets. Starting at Paddington, it runs almost due east past the Western District Post Office to the Western Central District Office, where it turns in a north-easterly direction to Mount Pleasant. Then it takes a south-easterly direction as far as the General Post Office in Newgate Street, continuing thence almost due east past Broad Street and Liverpool Street stations to the Eastern District Post Office in Whitechapel. Its total length is about 6½ miles, and its depth below the surface varies from 28 ft. to 37 ft. Between stations there is a single tunnel, 9 ft. in diameter, containing two tracks of 2-ft. gauge, but at stations separate tunnels of larger diameter are arranged for the up and down lines, with space between them to give accommodation for lifts, shoots, and control cabins. No drivers will be carried on the trains, which will be driven electrically and worked on a distant-control system. The steel trucks carrying the parcels and mails can attain a speed of 35 miles per hour, but 25 will probably be nearer the average. At busy times of the day it will be possible to run trains at one-minute intervals. The whole system works automatically on the lines perfected by the British and Colonial Pneumatic Tube and Transport Company, as far as the electrical undertaking is concerned. The present line will ultimately connect all the main post offices in London, and also provide postal tube communication with the railway termini.

Locomotives for New South Wales.—The Assistant Minister for Railways, Mr. Hoyle, states that the Government has, through the Railway Commissioners, signed a contract with the Clyde Engineering Co., Auburn, near Sydney, for the construction of 300 locomotives, covering a period of five years, beginning April, 1917. He said recently that "The Clyde Engineering Company, being the lowest tenderers, have not only a very large order, but they have agreed to extend their plant, which will enable them to get out sixty engines per year—more than one per week. They will begin by increasing their output, and long before the expiration of the term of five years they will be turning out the sixty engines per year. At present the company's output is about one per fortnight. We consider this to be an excellent arrangement, and one of the first substantial efforts to make the Empire self-contained. We are launching a locomotive building industry here which will be the start of one of the largest of its kind in Australia. I have always had a strong desire to build up our industrial greatness, and this is the first result of efforts in that direction."

NOTES ON BOOKS.

Electrical Apparatus-making for Beginners. By Albert V. Ballhatchet. London: Percival Marshall & Co. 2*s*. net.

This little book has been designed as a guide to the beginner in making electrical apparatus, and to help him to proceed in a definite path, and with more method than is usually to be found in the very young student. After a preliminary chapter on the choice of tools and materials—and it is remarkable with what simple appliances a clever lad can produce workmanlike results—the author describes a variety of apparatus, ranging from the simplest cells to such complicated mechanisms as telephones and voltmeters. The instructions given are clear, and should be easily followed by any intelligent boy, while the plans should be of very material assistance when he comes to the actual making of the instruments.

Town-planning in Ancient Dekkan. By C. P. Venkatarama Ayyar, M.A., L.T. Madras: Law Printing House.

The squalor and ugliness of many of our cities have led, during recent years, to a crusade of town-planning in this country, while the scheme to create a new capital in Delhi has given rise to a similar development in India, whither, by the way, a considerable number of our enthusiasts have betaken themselves in order to assist in the movement. Town-planning, then, may be said to be very much in the air at present, and any good literature on the subject may be sure of finding a public. Mr. Venkatarama Ayyar has in this little volume devoted his attention to a particularly interesting branch of the question. India—and Southern India in particular—was, at no very distant date, one of the greatest city-making regions of the world, and the author has carefully studied the town-planning lore of the Tamil Shastras—a task for which, as Reader in Dravidian Philology in the University of Madras, he is singularly well equipped. From these sources he now presents us with full and excellent accounts of Madura, Vanji, Conjeeveram, and Kāvērippumpattinam, and these descriptions are followed by chapters on striking features of Indian town-planning, such as typical houses, the manram, or the open space in villages and towns, and the garden village.

It seems clear that ancient Indian cities were carefully planned, and were laid out with a view to securing the best possible sanitary conditions and the general convenience of the inhabitants; and the author concludes that a critical study of the older Tamil literature, which is a faithful record of the history and civilisation of the ancient Dekkan, would prove of great benefit to the future town-planner.

Trade as a Science. By Ernest J. P. Benn. London: Jarrold & Sons. 2*s*. 6*d*. net.

It is not perhaps the worst feature of this little book that it is provocative. Most readers will agree with a great deal of it; they will almost certainly disagree with a good deal more; and that will give them to think, which is no bad result for any book to boast.

The work falls into three sections: in the first the present position is sketched; the second puts forth a tentative scheme for the organisation of a Ministry of Commerce, and a system of official trade associations; while the third describes the more important branches of work awaiting the attention of the trades of the nation.

Mr. Benn has a good many faults to find with the British tradesman (which term he uses to cover "manufacturers, merchants, bankers, and all directly associated with trade"). He is unprogressive, narrow-minded, jealous of his trade secrets; "he is not even concerned with the welfare of his own trade as a whole, but confines his entire attention to the immediate problems of his particular establishment." If these charges are true, the author should hardly be surprised or indignant at the attitude which he alleges the public adopt towards business. As a matter of fact, we think he is quite out of date in both his criticisms: nowadays there are plenty of broad-minded and thoroughly progressive men of business, and there must certainly be very few fools left who would allege that brewing is about the only trade a gentleman can enter.

On the other hand, there is no doubt still room for a great deal of improvement in the British business world, and it is true, as Mr. Benn says, that "the discipline of war has prepared the way

for the organisation of trade, and there is now every hope that a far better state of things from this point of view will exist in the future." Whether all the good anticipated by him will result from the establishment of his Ministry of Commerce may perhaps be doubted; but the present state of things verges on the grotesque. Mr. Benn certainly scores a point when he relates how a deputation recently "waited upon the Prime Minister to present to him certain resolutions passed at a meeting of the Guildhall, London, to consider trade after the war. The deputation consisted of two Lord Mayors, two Sheriffs, three members of the House of Lords, one accountant, and Sir George Alexander."

On another point, it seems to us, Mr. Benn's zeal is greater than his discretion. He resents the attitude of our higher educational authorities towards business and commerce, and in particular he criticises the University of Cambridge (presumably he means the Cambridge University Press) for publishing in an industrial and commercial series of books for boys a general preface in which occur the words, "Industrial and commercial prosperity does not, in itself, constitute greatness, but it is a condition without which national greatness is impossible." One would have thought the worst that could have been said about this sentence was that it was a trifle trite and obvious, but to Mr. Benn "it discloses the hopeless and regrettable attitude of those who are shaping our most precious raw material." Possibly, if he had made further inquiries, he would have been surprised to find how much work the University of Cambridge has been doing for a good many years past to secure the proper co-ordination of science and industry, and to provide first-class men to fill important positions in the business world.

Although we have picked out one or two points for criticism, we readily admit that the book is none the worse for being provocative. It contains a great deal that is useful and stimulating, and it is to be hoped that it will be widely read by those who are interested in the future of British trade.

GENERAL NOTES.

PRODUCTION OF CYDER IN FRANCE.—The production of cyder in France last year, according to the latest published official returns, amounted to 22,942,000 hectolitres (304,724,044 gallons), or nearly 3,000,000 hectolitres (66,000,000 gallons) less than in 1913. Last year the quantity of apples and pears used for the making of cyder and perry, as well as for distilling purposes, was 44,824,000 quintals (4,411,811 English tons), as compared with 46,614,000 quintals (4,587,992 tons) in 1913, of which 2,094,000 quintals (206,102 tons) were exported, chiefly to Germany or Switzerland. Last year the export of apples for cyder-making was nil.

BRITISH FINANCE.—Speaking in the House of Commons on the 10th inst., Mr. McKenna gave some striking figures relating to our financial position. On the assumption that the war would continue until March 31st next, he estimated as follows:—

Total indebtedness	£3,440,000,000
Advances to Allies and Dominions	800,000,000
Net indebtedness	2,640,000,000
National Income, about . . .	2,500,000,000
Or, perhaps	2,600,000,000
Capital wealth	15,000,000,000

Mr. McKenna gave a batch of other figures to show how the war had been financed during the first four months of the financial year. They may be summarised as follows:—

Treasury Bills, increased by .	£275,000,000
Exchequer Bonds	154,000,000
War Expenditure Certificates . .	16,000,000
War Savings Certificates . . .	13,750,000
Paid off . . . . of 3 months securities.	46,000,000
Received in actual revenue . . .	100,000,000

A NEW FIBRE PLANT.—Attention is drawn by the *Textile Mercury* to the "malva blanca," a plant grown in Cuba, as a very promising source of fibre. The producers claim that they can grow and ship it profitably for less than 1½*d*. per lb. with their present crude methods, and that with proper machinery and equipment this figure could be materially reduced. The persons engaged in the industry apparently hope to supply the 20 million sugar sacks required annually in Cuba, and they are credited with the statement that 2½-lb. bags of malva fibre can be placed in the market at from 3½*d*. to 5*d*. each. It is said that malva fibre has about the same textile strength as Dacca jute, and that its fineness is between that of jute and flax.

ZOOLOGICAL SURVEY OF INDIA.—The details are now published of the Government of India scheme for the constitution of a Zoological Survey of India. The project has been approved by the Secretary of State, and the additional cost involved by it will, it is intimated, amount to about Rs. 3,300 a year. In recommending the creation of the Zoological Survey to the Secretary of State the Government pointed out that "since medicine, more especially tropical medicine, is intimately connected with certain branches of zoology, it is obvious that anything that furthers the interests of zoological research in this country will indirectly benefit medicine and sanitation materially." Attention was also directed to the fact that interest in Indian zoology has largely increased in recent years. The scheme as finally sanctioned provides that the headquarters of the Survey shall be the Indian Museum. The first Director will be Dr. Annandale, the present Superintendent of the Zoological and Anthropological Section, and the staff and establishment of the Section will be taken over by the Survey.

Journal of the Royal Society of Arts.

No. 3,327. VOL. LXIV.

FRIDAY, AUGUST 25, 1916.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICE.

EXAMINATIONS.

The results of the Intermediate (Stage II.) Examinations, held from May 29th to June 7th last, were posted to the centres concerned on the 18th inst., and those in the Elementary Stage were issued on the 24th inst. A printed list of results of the combined examinations is in course of preparation and will be published next month.

PROCEEDINGS OF THE SOCIETY.

FOTHERGILL LECTURES.

HISTORIC BUILDINGS IN THE WESTERN WAR ZONE: THEIR BEAUTY AND THEIR RUIN.

By the Rev. G. Herbert West, D.D., A.R.I.B.A.,

Author of "Gothic Architecture in England and France."

Lecture I.—Delivered February 7th, 1916.

BELGIUM.

Wordsworth forgot the Netherlands when he wrote—

Two voices are there, one is of the sea,
One of the mountains, each a mighty voice.
In both from age to age thou didst rejoice,
They were thy chosen music—Liberty.

There is a third voice; for as these low-lying plains, outcast of earth and ocean, are the result of stubborn conflict with the angry sea, so the genius of liberty has always inspired their inhabitants with as noble a spirit of resistance to oppression as ever it did the English or the Swiss. The words inscribed on the group of the Nervii at Antwerp in memory of their resistance to Cæsar, "Courage and Patriotism," have been the motto by birthright of the Flemish race all through their chequered history.

But the whole tribe of the Nervii was destroyed by Cæsar, and the modern Belgians are a mixed race, chiefly of two stocks—Teutonic Flemings in the north, Celto-Latin Walloons round Liége and in the Valley of the Meuse. Three famous figures in the first Crusade, which was largely a Belgian enterprise, may represent for us the three chief qualities of a rather complex national character—intense religious devotion, courageous noble-hearted chivalry, too great a love for the material delights of life.

We see the first in a Walloon monk, Peter the Hermit, who for two years wandered over Europe mounted on a mule, carrying a crucifix and preaching the First Crusade; the second in Godfrey de Bouillon, so called from his brave defence of his mother's castle of Bouillon when he was only seventeen, one of the most courageous, noble, and devout men that ever lived. Robert II., Count of Flanders, represents the third type. He would have been made King of Jerusalem before Godfrey, but refused to stand, saying, "I promised the Countess my wife to return to her on fulfilling my vow. It is a very long time since I had either a hot or a cold bath, or slept between white sheets, and it is well known how accustomed the Flemings are to good living, comfortable beds and warm houses."

But why in this flat, featureless land did cities arise, and where shall we look for them? In Roman times Flanders was a forest-clad, almost unknown corner of the world; but with Charles the Great it became the great trade-centre of his empire, and towns sprang up at the head of gulfs, like Bruges; on an estuary, like Antwerp; where a great road crosses a river, Maestricht, Valenciennes; where two rivers meet, Liége, Malines, Ghent; where a river ceases to be navigable and boats must therefore be unloaded, Ypres, Brussels, Louvain, Douai; and these will all be trading cities whose members will form guilds or trades unions for the protection of their own special industry.

Now what may we expect to be the chief buildings of a city? The account in the Book of Genesis of the building of the first city will tell us. The builders of Babel said: "Go to, let us build us a city and a tower." There you have the history of the beginning of all municipal art with a tower as the first building in a city. It is the first mark of the independence of a community, whether on the banks of the Euphrates, the Po, or the Scheldt. A watch tower, a place of refuge, whence the people might be called together to defend themselves, was the most valued possession granted in early charters to a city. Whether in Italy or Flanders, the belfry tower was the sign of the freedom and power of the community, and its height was in proportion to their greatness. Then came the church, and lastly the town hall, the meeting-place of the town council. But in Flanders, where the cities began as associations of traders, the market house, or meeting-place of the merchant guilds, or of the chief of them, that of the cloth weavers, comes earlier, and is more important than the town hall, attaches itself to the belfry, and even puts itself in front of and hides the church as it did at Ypres, which both in its buildings and its history was the earliest and remained the most typical of Flemish towns.

Note the position of the three buildings at Ypres. The centre of the Cloth Hall is the ancient belfry tower, which dated from 1201 and replaced a much older wooden one. The wings, east and west, forming a front 437 ft. long, were built on at different times as trade increased. The whole was completed by 1304, but always on the original design. The Town Hall, or Nieu Werke, was not built till 1620, but the old plans made in 1575 were those followed. This adhering to the original design, century after century, is one great characteristic of Belgian art. Consequently the latest buildings often appear to be far older than they really are.

The River Yperlee ran at first uncovered in front of the Cloth Hall and boats could unload directly into the open colonnade, the closing of the arches of which destroyed much of its original character. The original entrance was at the east end. Not until the merchant guilds had lost their power, and the town had become an ordinary municipality, was the Town Hall built in front of it.

Till 1383 Ypres was the chief seat of the cloth industry, but in that year there were rival Popes. Ypres supported the one at Avignon in France, the men of Ghent the one at Rome and they besieged Ypres, with English help under the leadership of the Bishop of Norwich. The inhabitants had anticipated modern warfare and barbed-wire entanglements by surrounding their city with an impenetrable barrier of thorn bushes. In memory of this successful device they put a statue in the Cathedral to Our Lady of the Thornbushes, or of the enclosures, and the first Sunday in August was Thorn Day. Alas! it is never likely to be kept again, for it was the very day of the declaration of war. The suburbs where the workmen dwelt were destroyed in the siege of Ypres and never restored, and as the city was besieged five times afterwards, one can only wonder that so much was left for the Huns to destroy.

The Cathedral, hidden behind the Cloth Hall, was a beautiful church, but with nothing very remarkable about it outside or in except the tower which was very fine. The exterior, as is frequently the case in Belgium, was unfinished; the interior had the usual simple cylindrical columns, characteristic of most Flemish churches, which show that they never seized the great principle of Gothic architecture—vertical continuity. The towns became wealthy too late for them to work out a style of their own, as the French and the English did; so they generally took the style of their churches ready-made from France, and they are usually internally of a somewhat uninteresting uniform type, with high narrow lancet windows. But during the fourteenth and fifteenth centuries rich benefactors delighted to make the furniture of the churches and the accessories of worship as splendid as possible. Nowhere was this better seen than in St. Martin of Ypres, where the chimes, the glass, the stalls, the confessionals, the font, the pulpit, were of the most splendid description. The only thing lacking there was a fine rood screen, such as we shall see in other churches, as at Lierre, where the screen, still, we hope, existing, is almost precisely like that of Dixmude, now destroyed. The stalls in particular were of the greatest beauty. Belgium has always been famous for its woodcarvers, and one of the very best of them was Urbain Taillebert, who carved these stalls and the still more famous choir screen at Dixmude. The pulpit, the work of two monks, and called the "Pulpit of Truth," was more astonishing than beautiful; but the copper screen, with alabaster statuettes, which enclosed one of the chapels was a delicate and exquisite work of seventeenth century art.

It is a pathetic ending to our account of

Ypres to quote the guide-book description of it before the war: "The strong seventeenth century fortifications were destroyed in 1852, and nowadays everything is very quiet and unwarlike. The bastions and lunettes, casemates and moats which spread in every direction round the town have disappeared, and those parts of the fortifications which remain have been turned into ornamental walks; a sleepy country town with clean well-kept streets, dull and uninteresting save for the Cloth Hall, which stands a silent memorial to the past." Now it is the home of desolation; the only living things left there are the rats that scamper over the heaps of stones which form the tomb of the glory that was Ypres.

The thirteenth and fourteenth centuries were a constant struggle by the free cities, especially Bruges, against the efforts of the kings of France to annex their country. In 1302 Philippe le Bel entered the city at the invitation of the Lilymen, or French party, who put into prison the two leaders of the Lion's Clawmen or Clauverts, De Coninck and Breidel. But they escaped, entered the city from opposite sides by night on May 31st, and in the morning slew all the French garrison, testing them, like Jepthah, by the shibboleth of "Schilt ende Vriendt"—shield and friend. This was the "Matins of Bruges." Next year a great French army came up against a small force of Flemish peasants outside Courtrai. As at Bannockburn twelve years later, the peasants dug pits covered with brushwood in front of their lines, and in the early morning a priest passed down the ranks blessing them, and each man raised a sod of earth to his lips and swore to die for his Fatherland—a lesson which they have never forgotten since. Archers formed the front line of the French army, and were winning the day till the French knights, shouting that they would not have common men win the battle for them, charged right over their own troops till they were brought up against a thin red line of men of Ypres, dressed in their own scarlet cloth and armed with thick sticks with an iron head, which were ever after called "Goeden Daegs"—Good Mornings—from the welcome which they gave to each knight as they cracked his skull. It was the first modern battle in which, as a little later at Crécy, a poorly equipped voluntary army, fighting for freedom, proved itself more than a match for the "mailed fist" and "shining armour" of the professional soldier. May the omen once again prove true! Such was the slaughter that it was called the Battle of the Spurs, from the hundreds hung up in the Cathedral. The French in their flight sacked and burned the town, as the Germans did Senlis the other day, and the town hall had to be rebuilt. There are, therefore, no very old buildings in the place. The great fifteenth century chimney-piece in the council chamber is the most interesting thing.

Though at this time Ghent stood aloof from the other two *bonnes villes*, Ypres and Bruges, it was on the whole the most patriotic of the three, and shortly after this, under the leadership of a remarkable man, Jacques van Artevelde, made an alliance with our Edward III. On the demand of his suzerain Philippe le Bel, who was fighting the English in Aquitaine, the Count of Flanders, Louis de Nevers, had had all the English in Flanders interned—the first instance, I believe, of that proceeding. So Edward stopped the export of English wool to Flanders. But that ruined the English sheep farmers as well as the Flemish weavers, numbers of whom came over to Norfolk and founded our English clothing trade. It was to put an end to this ruin of the two countries that Edward came over to help Van Artevelde against the King of France. But Philippe was undoubtedly the suzerain of the Flemings, who could not therefore legally fight against him. Edward, therefore, put forward his absurd claim to the French crown, so that the Flemings might be able to say that they were fighting for their true overlord the King of England, who claimed to be the rightful King of France, against a false claimant, the king actually in possession of the French throne.

With Ghent, therefore, are connected the beginning of our long Hundred Years' War with France, the origin of our woollen manufactures, and what matters most of all to us now, our first great naval victory. For though Edward's army did nothing in Flanders, owing to the murder of Van Artevelde, which put an end to the alliance and made him transfer operations to France—where six years later he won the battle of Crécy in 1346—yet his fleet of 300 ships and 4,000 men completely destroyed the French fleet of 800 ships and 35,000 men at Sluys near Zeebrugge in June 1340. The French, who were all crowded together, were suddenly attacked in the harbour by the English, who sailed in on the flow of the tide. The English archers poured in showers of arrows and then boarded, as at Trafalgar. The English lost only two ships, and 30,000 Frenchmen were drowned. No one dared to tell the French king of the disaster till

his jester said: "Oh, the English are cowards, they really are. Why, they didn't even dare to jump into the sea to save themselves as our brave Frenchmen did."

But it was not the military weakness of the people that made the record of the struggle with France one of almost unbroken defeat, but the trade rivalry of Ghent and Bruges. It was the opposition of the boatmen of Ghent to the people of Bruges making a canal to the sea, when their port of Damme was beginning to silt up, that made the latter bring Ghent to the verge of starvation by stopping all food supplies, till Philip van Artevelde, the son of the murdered Jacques, having watched all night on the top of the church tower, came down and roused them to action, saying—

Death opens every door
And sits in every chamber by himself.
If what might feed a sparrow should suffice
For soldiers' meals, ye have not wherewithal
To linger out three days. For corn, there's none,
A mouse imprisoned in your granaries
Were starved to death.*

So they set the great bell Roland ringing in the belfry, and, by a sudden assault against the gate of Bruges, took the city and destroyed the walls. That was in January 1382. But in November the French came, and Van Artevelde was defeated and slain at Roosebek, near Roulers, just where we have been fighting. Yet this disastrous battle, which laid Flanders at the mercy of France, had one good result—the common misery put an end to the enmity between Bruges and Ghent.

Two years later, by the marriage of the heiress of the Count, Louis de Maele, Flanders passed into the hands of the Duke of Burgundy, Philippe le Hardi, and so became absolutely dependent on France. Philippe had been taken prisoner at Poitiers, together with John, King of France, by Edward III., who gave him his name of le Hardi, or the Cheeky, because at a banquet in London he protested against Edward, the vassal, being served before John, his suzerain.

Philippe le Hardi and his two successors, who were harsh and cruel but wise rulers, crushed Flanders into one. The third Duke, Philippe, miscalled Le Bon, England's ally against France till 1435, starved out Bruges till 24,000 had died of hunger and defeated the men of Ghent under the walls of Audenarde, killing 20,000 of them.

But until then Bruges had been at the summit of her prosperity, and indeed she soon recovered, and in spite of all these troubles flourished exceedingly and was the centre of the commerce of the world. There were more than fifty great guilds, and the merchants of seventeen kingdoms had their palaces within her walls. Sadly few of them have survived, but for 600 years the famous belfry has watched over the rise, the glory and the fall of the city.

In 1280 a fire destroyed the old wooden belfry of the ninth century, and the two lower stories are very like Ypres. Too like—Bruges must have a higher tower than Ypres, to match with her greater glory. So stage by stage was added, till, beautiful as it is, it is out of all proportion to the Cloth Hall, which it crowns. As a whole, the building is far inferior to Ypres, though the interior courtyard is very picturesque. The Town Hall (begun 1376) is quite a small building by the side of it; its statues were gilded by H. Hubert van Eyck. All the streets are full of the relics of ancient splendour, but sadly shorn of their pristine beauty. One of the prettiest things is the late Gothic porch of the Church of Notre Dame, beside which is seen what is left of the house of Louis of Grunthuise, one of the most splendid of the merchants of Bruges. He was a self-made man who rose to be Knight and Treasurer of the Order of the Golden Fleece, and intimate friend of Edward IV., who took refuge with him when driven from England, and created him Earl of Winchester. He was the patron of William Caxton, who was himself Governor of the English "nation" in the city.

If the fourth Duke of Burgundy, Charles the Bold—or as he is better called, the Rash—had not deserved his name by his mad folly, he might have formed a strong united nation able to withstand the attacks of France. As it was, he undid all that had been done, and played the Kaiser to his father's Bismarck. Much of his most ruinous work was done in Hainault, to the cities on the Meuse, Huy, Dinant and Liége. These had never been industrial towns, and the Guild of the Copperworkers of Dinant was the only powerful one. On the whole, they had lived quietly under the somewhat patriarchal government of their Prince Bishop. But the people of Dinant and Liége, whose industries were becoming important, were beginning to be restless and turbulent.

By the machinations of Louis XI. Liége and Dinant were incited to revolt against their Bishop, Louis of Bourbon, nephew of Philippe le Bon. The people of Dinant hated the people of Bouvignes on the other side of the Meuse, and hanged an envoy whom they sent across, and

* Sir H. Taylor, "Philip Van Artevelde."

put up a dummy of Charles with a placard, "Tell your old mummy of a Duke to go home again. Louis of France is coming to help us." Then Bouvignes fired a dummy of Louis XI. across to Dinant from a catapult. The Dinantais refused to apologise, but instead had a parody of the "Joyeuse Entrée" of Charles. So Charles, with an immense artillery of very heavy guns, besieged and took the city almost at once. It was a surprise to the world very like that of the fall of Liége and Namur in 1914. The Liégeois were sending help, but it came too late, as some other help did in 1915. Dinant was sacked and utterly destroyed; 800 citizens were tied back to back and thrown into the river, others were thrown from the cliffs. But no outrages on women were allowed, and all offenders were hung in sight of the army. Charles has been beaten in barbarity by the Kaiser (August 28th–30th, 1466). Next year Charles entered Liége through the wall which was thrown down for him, and fined the city 115,000,000 florins and tortured nine chief citizens to death. Shortly after, acting on a false report that the Liégeois had killed their Bishop, he came again, bringing with him Louis XI., whose promise of help was the cause of all the trouble. He took the city in a week, and asked Louis what he should do. Louis replied: "My father was troubled with rooks. He destroyed the nests three times, but they built again, so he had the tree cut down." Charles then systematically burned the town and killed all the inhabitants. The few who escaped were being still hunted down in the woods three months after. His general, Antoine de Loisey, writing from Liége, says: "We don't trouble about justice. We just hang or burn anyone we come across. The city has been so utterly wrecked that there is not a scrap of paper left to write on. I had to tear this from an old book." There was therefore nothing old left in Dinant when the Huns destroyed it last year; but in Liége the Bishop rebuilt his palace in 1508. That and the Church of St. Jacques were the only important old buildings in the huge manufacturing city which Liége was before the war.

In 1477 Charles was defeated and killed at Nancy by what he called "the contemptible little army" of Swiss tailors and cobblers, and his body was found two days afterwards, half eaten by wolves, in a frozen ditch.

Louis XI. at once treacherously laid siege to Arras, and, in spite of the piteous appeals of his goddaughter—Mary of Burgundy, Charles's heiress—took it and completely sacked it. Consequently, as might be expected, very few houses older than the fifteenth century were left.

Mary of Burgundy died just after she had married Maximilian, King of the Romans, afterwards Emperor. Maximilian soon got into money troubles with the people of Ghent and Bruges. The latter, discovering that he had sent for an army from Germany, kept him prisoner in 1487 for eleven weeks in the Craenenberg, the windows of which they fitted with bars, for which the bills still exist. All his German followers were executed one by one, except one who escaped, disguised as a peasant woman carrying a basket of onions. They might have spared all the others, if only they had hanged that one, for he was the Count of Zollern, ancestor of the Kaiser.

In 1497 Maximilian's son Philip was married to Joan, the heiress of Spain, at Lierre, in front of its beautiful choir screen. In 1506 Philip died and poor Joan went mad with grief. Margaret of Austria, her husband's sister, became Regent till the infant Charles V. was of age. He was the most powerful monarch of his time, and no king has ever held so many titles, but failing health made him long for release from the burden of empire. There never probably was any scene more striking in the world's history than that which took place on October 25th, 1555, in the Hall of the Golden Fleece in Brussels. Crippled with gout, leaning on the shoulder of William of Orange (the Silent), he told the story of his reign, confessed his faults, and begged forgiveness of any he had wronged, and then placing his hands on his son's head, gave him his blessing and sank back sobbing in his chair, while all the audience were moved to tears. He went to live in a small house in Brussels for a year, and then retired to the Monastery of St. Juste in Spain, where he filled his rooms with clocks and watches which he tried in vain to make keep time, and when he failed he said: "All my life I have been trying to make men work together and I can't even make clocks do it." He indulged in one even more impressive ceremony, his own funeral Mass, which he had carried out as if he had been inside the coffin which stood in front of him.

Time would fail if we tried to give any account of the horrible persecution of the Protestants carried out by his mean and cold-blooded son Philip. It is fully told in the fascinating pages of Motley's histories.

The chief adviser of the Regent, who was Philip's half-sister, Margaret of Parma, was Cardinal Granvelle, Archbishop of Malines,

whose tyranny roused the three chief nobles who had so far been on Philip's side, to send a letter protesting against it. They were Count Egmont, who had greatly distinguished himself in the battles of Gravelines, and of St. Quentin on St. Laurence's Day, 1557, when by his strategy the French army was practically annihilated, and Philip, in his joy, had ordered the building of the Escurial. The other two signatories were Count Horn and William the Silent, Prince of Orange, the greatest man of the three. Philip, on receipt of the letter, sent the Duke of Alva to be Governor of the Netherlands with orders to arrest and execute Egmont, Horn and William within twenty-four hours of his arrival. William at once took refuge in Holland, and Egmont said to him, "Farewell, landless Prince," to which William replied, "Farewell, headless Count!" Counts Egmont and Horn were executed in front of the guild house of the Cross-bowmen (Maison du Roi) at Brussels, June 5th, 1568. The building was greatly damaged in the bombardment by Louis XIV., and rebuilt in the style of that time. It has been recently restored according to the original design, so it is said, but all the character and history have been taken out of it, as so often happens with restorations. Four years later, Alva all but seized William by a night attack, in which he was saved by his little spaniel, who, hearing strange footsteps, woke his master by scratching his face and barking. Alva wreaked his vengeance on Mons and Malines, both of which he sacked, and the horrors perpetrated in the latter town would have been incredible if they had not been surpassed to-day. But even Alva did not wreak his vengeance on churches. It was reserved for the Germans to destroy the Cathedral and its wonderful tower of St. Rombauld, which was begun in 1452, but discontinued after the sack when it had reached only 320 ft. out of the 544 ft. which Jan Kelderman had intended it to have. The town hall was never finished from the same cause.

But Malines was not the only town which the Spaniards sacked. In 1576 for three days Antwerp was given over to what is still known as the Spanish Fury. More than 6,000 men, women, and children were butchered and 800 houses burnt. Antwerp had risen into importance when the silting up of the Zwyn had caused the decay of Bruges in the early fifteen hundreds, and consequently there are no very important buildings of a much earlier date. Also Antwerp suffered more than any other city from the image-breaking of the Calvinists in 1566. The Cathedral especially had been wrecked by them. It had been begun in 1352, and the tower had been carried as high as the first gallery by 1440. At the end of the sixteenth century the Keldermans planned a magnificent cathedral, but had only finished one tower when a fire destroyed all the material which they had collected and the funds had to be used for the rebuilding. The Town Hall, which is a fine specimen of the late Flemish style from which our Jacobean was derived, was built in 1561.

But let us return to Brussels. Comparatively little remains of the Brussels which saw the execution of Egmont and Horn, except the Town Hall, which is the finest of all the town halls in Belgium. Brussels had never been a manufacturing city like Ghent and Bruges, so its town hall was from the first really a town hall, not the abode of the guilds or four *nations* who arose much later at Brussels than elsewhere. The guilds had their separate houses which, picturesque as they are, date only from the beginning of the eighteenth century. They are those of the mercers, shippers, archers, carpenters, printers, and bakers. The town hall was begun in 1402, and by the middle of the century the east wing and tower were finished. The tower then stood as an angle tower on the north-west corner. The architect Van den Berg is said to have thrown himself from the top of the tower in 1431, because he found out then that he had not put it in the middle of the façade, but as the tower had not then been begun and the east wing was not finished till 1486, the legend lacks foundation. Some of the work is of the sixteen hundreds, more of the seventeens, after the bombardment. It was from Brussels and Louvain, with their constant repetition of similar bays, that Sir Charles Barry got his inspiration for the Houses of Parliament. Let us, therefore, now look at Louvain town hall, the only building which the Huns have left in that once beautiful city. The architect, Matt. de Layens, was appointed in 1448, on the death of John Kelderman, with a salary of thirty gold florins and enough cloth to make him a dress suit. He was to follow in the main the design of the Brussels Town Hall, which then consisted of only one wing and had no tower. Louvain was to surpass Brussels, and so it did, and perhaps that is why Brussels finished her tower and added another wing. "And yet one cannot but feel as one stands before this fascinating and fantastic structure with its crowd of statues, its dainty corbels, its

bristling roof and filigree niches, its pinnacles soaring to heaven like crystallised incense smoke, that it is less the triumph of the mason than of the sculptor; that architecture has ceased to reign; and that one of her handmaids has usurped her place." This is the character of all the late civic buildings of Belgium. And it is the more striking when we look at the churches, which are singularly plain in the interior as well as in the exteriors, which are hardly ever finished. To be fair, let us look at the Cathedral of St. Gudule. Nothing really is known of the saint, who is said to have lived about A.D. 712. Even her German biographer who wrote in 1047 tells nothing, because, with unusual candour, he says he thinks it a holier thing to keep silence than to tell lies—an opinion not shared by his descendants. It is a disappointing building, the exterior cold and dry with hard vertical lines; not for a moment can one think of it in the same line as Paris or Reims, or even Abbeville. The chancel dates from 1273; the nave was finished by 1446, and the towers by the beginning of the fifteen hundreds. The finest thing in the church is the late Renaissance work, and especially the stained glass. Nearly all the windows contain portraits of the later rulers of Brabant, and most of them were designed by Bernard van Orley.

Of the other buildings of Brussels, about the most interesting is the Church of Notre Dame du Sablon. It was originally, and indeed is still, the Chapel of the Guild of the Crossbowmen, the one guild which still survives in Brussels. The Calvinists would have destroyed it, but when they found it full of crossbowmen they retired, after relieving their feelings, according to the manner of crowds, by howling outside. It was begun in 1419, and took more than a century to build, but, as usual, the original plans were kept to throughout.

The chief cause of there being less to see in Brussels than in most of the other towns of Brabant is not only that, like them, it rose to importance at a later date than the Flemish towns, but that it was almost destroyed by Louis XIV., who bombarded it in 1695 with red-hot bullets and destroyed sixteen churches and over four thousand houses. He was in many respects the prototype of the Kaiser, and we English may take courage from the thought that though for fifty-two years he had never lost a battle nor failed to take a fortress, it was our William III., who had never till then won a battle nor taken a fortress, who in that year, by taking Namur, checked the career of that would-be world conqueror. It was in revenge for Namur that Louis bombarded Brussels—a truly Hunnish proceeding both in its barbarity and its utter futility, but less vile than the burning of Louvain.

But let us, before we leave the Brussels which he ruined as the Germans have ruined Louvain, go, as all tourists do, to Waterloo, and there, standing on the Lion Mount and gazing back over the history and the battlefields of Belgium, gain for ourselves an unswerving confidence in the justice of Him who ruleth over the kingdom of men and giveth it to whomsoever He will. Never yet has it been seized for long by a would-be world conqueror. All the nations of the world, not only the Jews, have been people chosen to carry out some work for Him—and time after time the work set to England has been to destroy the power of the Nebuchadnezzars of the modern world, not that she may ape their pride, but may learn the humility which they were taught—Philip II. and the Duke of Parma in the Armada; Louis XIV. at Namur and Audenarde; Napoleon at Waterloo—always on the battlefields of Belgium. Let us then, standing there, take good courage for the Future from the Past.

TRADE OF THE BAHREIN ISLANDS, 1915.

The statistics regarding movements of pearls and specie are very incomplete, as numbers of local pearl merchants, who travel to and from Bombay, and the foreign pearl merchants, carry large quantities of pearls and specie in their luggage or on their persons. There is no bank in Bahrein, and many lakhs of rupees are brought in every year by registered post in the form of Indian currency notes of 1,000 or 500 rupees. It is, of course, impossible to obtain statistics of all these sums. The effects of the upheaval in Europe began to be felt in Bahrein even before the commencement of hostilities. The pearl dealers, somewhat dazzled by the high prices ruling in 1912, in which year the catch had netted over £2,000,000, had been inclined to hold up their stocks for higher prices in 1913. The scale of living had also risen, and the commencement of the pearl season of 1914 found them with large stocks, but heavily indebted. The European pearl dealers who arrived in Bahrein Ramazan just before the Ramazan break in the fishing, were not inclined to pay high prices, and little business had been done when telegrams were received ordering them to cease buying owing to the strained relations between the Great Powers. As was natural, the depression affected most severely the improvident lower orders who depend on the pearl trade. The trade of the Bahrein Islands is to

a great extent in the hands of Hindu, Indian Mohammedan, and Persian merchants, who have been settled in these islands for a century, and thus by far the greater part of the trade is with India. Messrs. Gray, Paul & Co., the British India agents, are the only British firm. The one German firm in Bahrein has been closed. Shipping and communications have been naturally greatly upset by the war, and the Hamburg-Amerika line has, of course, ceased to run. Only 62 vessels entered the port during the year against 89 in the previous year. The total value of imports into Bahrein amounted to £758,418, as against £1,877,630, showing a decrease of £1,119,212, or 59·6 per cent. As has been already noted, the greatest decreases were in pearls and specie owing to the collapse of the European pearl market. The import of rice also fell by over 50 per cent. This was due during the early part of the war to the difficulty of the shipping, and latterly to capital being called in by Indian firms with branches in Bahrein.

The total value of exports fell from £1,740,008 to £461,624, a decrease of 73·4 per cent. It must be noted that, as exports are sent by native boats, no accurate statistics are available. The decreases are due to restrictions of markets owing to the war.

A SILK CAMP.

The *Pioneer Mail* has received the following from the Salvation Army headquarters at Simla:—

Perhaps the only mulberry forest in the world is to be found at Changa Manga, near Lahore. It is some 10,000 acres in extent, and has hitherto only been used for purposes of fuel and timber. It demonstrates that mulberry can be profitably grown by Government and private individuals for fuel and timber purposes, apart altogether from its great value in providing food for silkworms.

Some months ago Commissioner Booth Tucker asked the permission of the Punjab Government to take advantage of the immense supply of foliage in this forest to establish an annual silk camp during the months of February and March for the rearing of silkworms on a large scale, with a view to popularising the industry throughout the Punjab and other parts of India, and in order to demonstrate the best methods for rearing silkworms. The Lieutenant-Governor expressed his cordial approval of the scheme, and five acres have been assigned within the forest for the purposes of the silk camp.

Operations were commenced early in January, when a party was sent in advance to make the preliminary arrangements for erecting sheds and preparing accommodation for some two to three million silkworms.

As far back as May, 1915, a supply of disease-free eggs of the best varieties had been ordered from Europe. They reached the Simla Silk School in October, and were there hibernated in a special machine provided for the purpose.

This preparation for the silkworm industry is of recent introduction, but is an important link in the successful rearing of the best varieties. It helps to ensure a vigorous race of worms, which will produce cocoons rich in silk, and also protects them from disease.

Special hatching machines of a simple pattern have been utilised by the Salvation Army during the last three or four years. The use of these and their value for hatching purposes will be demonstrated. They insure uniform heat, and enable the eggs to hatch out simultaneously, thus avoiding much trouble, delay, and loss of eggs from chills.

Different systems will be demonstrated in the silk camp. The two chief dangers to be guarded against are excessive heat and excessive cold, with violent variation between the two. The various systems will be demonstrated, and the students, workers, and visitors will be allowed to judge for themselves which they consider best, or which will be most suitable for their own locality.

One large shed has been prepared on a system which guards both against cold and excessive heat. This has been introduced with great success at the Salvation Army silk farm at Moradabad. A trench is made about 100 ft. long, 12 ft. broad, and 3 ft. deep. The excavated earth makes a wall about 3 ft. high, with a thick thatched roof, and a doorway at each end. In a dugout of this character worms have been successfully reared in the hot weather.

The Persian system of a shed on poles raised above ground, where the air can freely percolate all round, and leaves can be stored underneath to get rid of extra moisture when there has been heavy rainfall, will also be demonstrated.

In Japan and Europe it is usual to rear the silkworms on shelves, carefully arranged, tier on tier. This economises space and gives the worms the best individual care. In Kashmir, and most parts of India, the worms are usually reared upon the ground, branchlets of mulberry twigs being heaped on top of each other. This ensures economy of labour, an important consideration. Instead of six or seven feedings during the twenty-four hours only two are necessary, morning and evening. The respective advantages of both systems will be demonstrated.

Besides the large sheds for the hatching of the worms, there are more than fifty tents for the accommodation of the workers and the staff, and for lectures and demonstration. The camp is already a hive of industry, with about 100 workers. It is intended to increase the number to 150, as the worms increase in size and need more attention.

GREECE (ZANTE).

The British Vice-Consul at Zante, writing with reference to the import trade of that island, states that even in so small a place as Zante there are indications that German traders are already making preparations to

resume business operations and to retrieve their position in trade, as soon as the war is over. It may not be amiss, therefore, for British traders to be advised to take the necessary steps to forestall this competition, and they should bear in mind that German exporters will spare no pains or expense in order to secure the desired object.

Prior to the war, imports from the United Kingdom into Zante had been gradually giving way before German competition. This was due to the energy and attractive methods of the German trader, such as extended terms of payment, rebates regulated according to the position of clients, advice as to selection, prompt despatch of goods to Zante, quotation of c.i.f. prices, and other facilities to which buyers all over Greece are now habituated.

With the exception of codfish, pickled fish and salmon, herrings, unwrought iron, sulphate of copper, soda ash, some textiles and yarns, etc., which are of British origin, most of the imports into Zante came from Germany and Austria. Imports from these latter countries comprised cutlery, hardware, glassware, enamelled ware, crockery, cotton and woollen manufactures, leather goods, lamps of all kinds, stationery and paper, domestic and household requisites, toys, dyes, drugs, medicines, brushes of all descriptions, etc.

If United Kingdom manufacturers will adapt their methods to the requirements of the Greek market, there is no reason why they should not secure the greater part of the trade in the goods hitherto supplied by Germany and Austria as soon as the war is over: a great advantage in their favour is the admitted superiority of British goods of all kinds.

RESOURCES OF THE SUNGPAN DISTRICT OF CHINA.

Sungpan is situated in the extreme north-western part of the Szechwan Province on the Min River very near to its source. While its population is about 4,000, it is an important distributing point for the Kokonor region of north-eastern Tibet and the border country north and north-west of Sungpan.

Sungpan as a commercial outlet for the region which it taps is most favourably situated. Not only can its exports be conveniently shipped by the Min River to Kwanhsien and thence to Chengtu, the provincial capital, but goods which are destined for Chungking and which eventually reach Shanghai and foreign countries enjoy the exceptional transportation facilities afforded by the Yangtze River and an important tributary that passes through Lunganfu, Tungchwan, and Hochow, and has its source near Sungpan.

The principal exports from Sungpan are sheepskins, wool, medicines, musk, fur, and hides. These are chiefly exchanged for tea, rice, and Chinese wine. Tea, which is largely consumed by the Tibetans and aboriginal tribes adjacent to the Sungpan district, is the principal article of import. The rice and Chinese wine are consumed by the comparatively small Chinese population of this region.

Most of the tea that figures in this trade is grown in the vicinity of Kwanhsien and Anhsien. The tea is of inferior quality; but since the beverage made from it usually contains butter, and the butter is very often rancid, the flavour of the tea is decidedly of secondary importance. Cheapness is the great desideratum. This requirement is successfully met, for the tea sells at Sungpan for less than 2*d.* per pound. Not only do the Tibetans use tea in making a beverage, but they also use it in preparing their principal article of food, which contains butter, salt and barley meal as well. This dish is known as "tsamba," and is generally consumed throughout Tibet.

Large quantities of the wool, medicines, musk, and hides from Sungpan finally reach the hands of foreign buyers. The wool is of somewhat inferior quality, and is used in the manufacture of carpets. Neither the quality nor the quantity of musk is equal to that obtained at Tachienlu. Medicines are the distinguishing feature of the trade of Sungpan; the most important from this district which are known to foreign markets are aconite, liquorice, and rhubarb. Many other herbs are employed for medicinal purposes, but they are mainly consumed in China.

According to a report by the United States Consul at Chungking, it is impossible to determine the value of the products which reach China by way of Sungpan. Mr. E. H. Wilson, the eminent naturalist who visited Sungpan on several occasions, estimated that this trade in 1910 amounted to about £120,000. However, since the commerce of Sungpan has considerably increased during recent years, it is probable that this figure represents only a part of the present trade.

The Sungpan district is poor agriculturally. The country is dry and mountainous and the few crops that are raised are very meagre. Wheat, oats, maize, barley, buckwheat, peas, beans, and Irish potatoes are grown to a certain extent. The area of cultivation, however, does not extend beyond an altitude of 12,000 ft. From 8,000 ft. to 10,500 ft., according to Mr. Wilson, represents the wheat-growing belt, while barley and buckwheat can be raised at a much higher altitude.

The country is not at all favourable to the cultivation of rice, this cereal, so highly prized by the Chinese, being imported into Sungpan for their use, as already mentioned. Most of the fruits that thrive in the north temperate zone are found in the vicinity of Sungpan, and some of them, particularly plums and peaches, are of

excellent quality. A fair variety of vegetables is also produced, and the potatoes, peas, and carrots compare favourably with similar vegetables in foreign countries.

There are few settled agriculturists or traders in the Sungpan district. Most of the people lead pastoral lives and many are nomadic. Their principal wealth consists of cattle, horses, and sheep. As the country is well adapted to raising these animals, there are great possibilities in this direction. The Chinese are beginning to realise this, and are trying to improve the breeds which they now have. They are already sending American sheep for this purpose to Sungpan, and hope to have a better quality of both wool and mutton.

With improved stock and the excellent grazing which the country affords, there is a good opportunity, in the opinion of the United States Consul, for the development of a large dairying industry. It is probable that this will be undertaken soon by the Chinese authorities at Chengtu, who are much interested in the industrial possibilities of the north-western part of the Szechwan Province. The future prosperity of Sungpan will no doubt depend in large degree upon the extent to which the pasture lands are utilised in producing an augmented quantity and a better quality of wool, hides, meat, butter, cheese, and other animal products, which could figure much more prominently than they do in the export trade of the district.

TRADE OF AUSTRALIA IN 1915.

In his report on the trade of Australia for 1915, H.M. Trade Commissioner in Australia (Mr. G. T. Milne) states that during the earlier part of the year the greater part of the country was still suffering from widespread drought. But when the long-looked-for rains arrived they were fairly general in character, and the resulting improvement in the pastures and crops brightened the outlook in all States with the exception of Queensland, which, having escaped in a large degree from drought when the rest of the country was suffering, was itself destined to suffer later. There was also a considerable area in New South Wales still affected by dry conditions till late in the year, but towards its close matters improved both in Queensland and in the parts of New South Wales alluded to. As a result of the abundant rainfall, there has been far more "feed" in many districts throughout Australia than could be used, the flocks and herds having become so seriously depleted in numbers. It is estimated that, owing to drought, the losses of sheep and lambs will exceed 15,000,000 in number, while the losses of cattle, including dairy stock, have also been serious. The situation will be reflected in the returns from the wool-growing industry, it being expected that there will be a diminution of 500,000 bales in the current season's clip, while there will also be a falling-off in the amount of meat available for export. High prices for these commodities will afford pastoralists partial compensation for their losses. The brightest feature both in retrospect and prospect is the wheat harvest, which is estimated to yield from 150,000,000 to 160,000,000 bushels—a figure about 50 per cent. in excess of any previous harvest. Over 100,000,000 bushels will be available for export, but the difficulty of procuring tonnage makes it doubtful whether the total crop can be shipped this year.

The effect of the war has been shown in various ways. The wealth of the community has been manifested in the extraordinarily generous contributions made to the various patriotic funds for which subscription lists were opened. Money is, of course, dearer, the cost of living is higher — this leading in turn to demands for increased wages—while taxation has increased. The withdrawal from their ordinary pursuits of the large numbers of men who joined the Australian Expeditionary Forces has affected the labour market to some extent. The heavy expenditure of loan money for war purposes has led to great activity in such local industries as were affected by the demand for equipment for the Expeditionary Forces. The diminution in the volume of the imports must be regarded as a reflection of the conditions created by the drought, as well as of those obtaining in the London money market, in consequence of which less loan money was available for expenditure on public works. The shortage of tonnage and consequent high freights are also war factors affecting both the export and import trades.

According to a statement in the Melbourne press towards the end of October, freight rates on most goods imported from the United Kingdom and the United States had increased by anything from 44 per cent. to 80 per cent. since the commencement of the war, and in the case of timber from Baltic ports the rates then operating had expanded by 180 per cent. For cased merchandise, such as soft goods, silk and apparel, rates by mail steamers to Melbourne increased from 70*s.* to 110*s.* per ton. It is estimated that the extra freights paid on 813,635 tons of merchandise from overseas imported into Melbourne between January and August of last year averaged 22*s.* 6*d.* per ton, and that the total amount of the increase passed on to the public was between £900,000 and £1,000,000.

Import Trade.—Preliminary figures put the total value of the import trade, inclusive of specie and bullion, during the year ended June 30th, 1915, at £64,431,837, as compared with £77,254,653 during the calendar year 1913. The value of the imports of "competitive merchandise" from all countries was £48,867,011, of which £31,732,974 represented imports from the

United Kingdom, £1,899,075 imports from British Possessions, and £7,430,170 imports from the United States.

Export Trade.—The value of the exports, inclusive of specie and bullion (£2,907,666), during the year ended June 30th, 1915, was £60,600,302, as against £78,571,769 in the calendar year 1913, the falling-off being due to the severe drought and to the dislocation of the wool and base metal industries and of shipping, owing to the war. Wool exports in 1915 amounted in value to £22,088,309.

Mining.—The decline in the gold production of the Commonwealth continued last year, the total output according to statistics furnished by the Mines Department (with the exception of Tasmania, for which the output is estimated) aggregating 1,942,835 fine oz., as against 2,048,905 oz. in 1914. As regards lead and zinc concentrates, mine owners have experienced considerable difficulty in disposing of their output of concentrates owing to the closure of the Continental markets for these metals, but of late large shipments have been made to American smelters, while Japanese buyers have also secured several shipments. Exports of coal from Newcastle, N.S.W., to other States and overseas during the calendar year 1915 amounted to 4,006,177 tons, valued at £2,108,057, as against 4,743,505 tons, valued at £2,488,449, for the corresponding period in the previous year.—*Board of Trade Journal.*

MATÉ, "TEA" PRODUCTION IN SOUTHERN BRAZIL.

Yerba maté, or Paraguay tea, constitutes one of the sources of wealth in Southern Brazil. It is the largest article of export from Parana and one of the largest from Rio Grande do Sul and Santa Catharina. The principal markets are Argentina, Uruguay, Chile, Paraguay, and Bolivia, in the order mentioned. In these countries maté is the popular drink of the people, almost to the exclusion of coffee and tea. It is supposed to have two great advantages over either coffee or tea—it is less stimulating and very much cheaper.

The maté tree is between 10 and 12 ft. in height, the leaves resembling those of a pear-tree. The grades of maté depend upon the amount of wood in the leaf. The following are the classifications: No. 1 maté, from Paraguay; No. 2, from Matto Grosso; No. 3, from Missoes Argentinas; No. 4, from Parana; No. 5, from Rio Grande and Santa Catharina.

According to a report by the United States Consul at São Paulo, the total consumption of maté in Argentina alone amounts to 50,000 tons annually, of which Parana furnishes 18,000 tons and Santa Catharina, 2,000 tons annually. Exact statistics are not available. The total exportation to all countries in 1913 was:—

Exporting State.	Amount.	Value.
	Tons.	£.
Parana	49,538	1,591,000
Santa Catharina	3,793	63,100
Rio Grande do Sul	2,174	139,700
Total	55,505	1,793,800

The exportations from Santa Catharina have fallen off very greatly during the past ten years, and the quality of the tea is not as good as that of the Parana maté.

Maté is prepared in the same way as tea, and may be taken with sugar and milk. In powder it is prepared by infusion, putting it into a small vessel (a *cuia*) and pouring thereon a sufficient amount of boiling water. As the dust does not sink to the bottom of the vessel the maté can be taken only by means of a "sucker"—that is, a tube terminating in a small hollow ball pierced with holes. Travellers to Argentina have doubtless noticed many quaint maté pots, of silver and other metals, lavishly ornamented.

The Germans in Curityba (the capital of the State of Parana) prepare it in the following manner. They heat the water, and when it is boiling add the maté. When the water begins to boil again they pour in a sufficient amount of cold water to stop the boiling. The dust then settles and the maté is taken pure.

The component parts of maté, compared with tea and coffee, as prepared by Dr. Caminhoa, Professor of the Faculty of Medicine at Rio de Janeiro, are as follows:—

In 1,000 parts.	Green Tea.	Black Tea.	Coffee.	Maté.
Essential oil	7·90	6·00	0·41	0·01
Chlorophyl	22·20	18·14	13·66	62·00
Resin	22·20	36·40	13·66	20·69
Tannin	178·00	128·80	16·39	12·28
Theine or caffeine	4·30	4·60	2·66	2·50
Extract and colouring matter	464·00	390·00	270·67	238·83
Fibers and cellulose	175·80	283·20	174·83	180·00
Ash	85·60	54·40	25·61	38·10

COCONUT CULTIVATION IN MALAYA.

In view of the rapidly-growing demand for copra and the produce of oil-yielding nuts of every description for the home manufacture of margarine and for other commercial purposes, any check to the growth of these nuts within the British Empire is to be deprecated.

Prices for copra during 1915 were 20 per cent. higher in the Singapore market than in 1914, yet the annual report of the Planters' Association of Malaya states that "during the year under review few extensions have been undertaken either by Europeans or natives. Natives (and in some cases Europeans) have been busy cutting out their coconuts to make room for the more attractive cultivation of rubber, which at the present time must needs claim the greater attention and capital." That the Government of the Federated Malay States is fully alive to the danger of limiting the forms of cultivation in their territory is borne out by the comments of Mr. E. S. Hose, Acting Director of Agriculture, in his report for 1915. In the Klang district of Selangor certain estates have been cutting out coconut trees in order to allow interplanted rubber trees to develop. On many small holdings also good bearing coconut trees have been cut out in order that rubber might be planted. "This practice on the part of small owners is highly inadvisable," writes Mr. Hose, "and the sub-inspectors of coconuts in Selangor have been instructed to persuade the owners to abandon it, if they can. During inspection work in Pahang it was observed that in many cases, especially in the Kuala Lipis district, no young trees had been planted for many years in the old kampongs to take the place of the very old trees which are gradually dying out. It is desirable that the importance of planting up young trees should be impressed on the owners. In addition, it appeared that more attention should be paid to manuring and cultivating the trees and to keeping newly-planted trees free from lalang."

The Malay States are especially favourable for coconut cultivation. During 1915 the growth of the trees in the coastal parts of Perak and Selangor was very satisfactory. Most trees commence flowering in the fifth year and bear nuts in the sixth. On one estate a 3½-year-old tree produced 550 nuts. In the second half of the year the crop of nuts on estates all over the Federated Malay States was short. There was a general belief that this was attributable to the absence of sunshine, as, though the rainfall had not been above the average, it was assumed (in the absence of scientific corroboration) that there had been a large percentage of cloudy days. It was considered that the nuts were present on the trees, but had not ripened.

The acreage under coconuts in the Federated Malay States on estates over 100 acres in extent was 54,822 against 58,027 in 1914. Appended is a comparison of the exports of copra for the past five years:—

	Tons.	Value.
1911	8,039	£151,000
1912	7,710	152,036
1913	9,347	211,042
1914	14,499	288,545
1915	13,937	214,492

Excluding the Straits Settlements (the statistics for which were not available when the report was compiled), but including the other Malay States under British protection, the acreage under coconuts on estates over 100 acres in extent was 82,250, Kelantan and Kedah having 18,201, Johore 1,621, and Trengganu 7,606.

In his report Mr. Hose sets out in detail the measures adopted by his Department for detecting and combating various beetle and ant pests attacking the coconut palms. The Chief Agricultural Inspector reported that rats were troublesome in Krian, Perak, and were also harmful around Sabak Bernam. In the Bagan Datoh district they were kept well under control and little harm was done. The Assistant Inspector of Coconut Plantations went to this district to supervise the destruction of the rats. Two thousand traps were issued to the Kampong owners, and a reward of c.1 per tail was offered. In addition 250 traps were lent to the manager of one estate. All the estates used traps and employed tin shields for young trees to some extent. On estates 206,375 rats, and on kampongs 34,196, making a total of 240,571, were destroyed between May 5th and the end of the year. This result was deemed satisfactory.

The Agricultural Department is engaged on experiments for the better cultivation of the coconut palm in Malaya. There is no doubt that valuable results might be obtained from a study of the various kinds of nuts, their yields, and the yields of artificial hybrids of the first generation.—*London and China Telegraph.*

COTTON IN RUSSIA.

According to the "Explanatory Memorandum" of the Russian Minister of Finance attached to the draft Budget of the Empire for 1916, there has been a remarkable increase in the cotton-growing and cotton-spinning and weaving industries of Russia during recent years. It is estimated that the 1915–16 crop of pure cotton fibre in Russia will be 18,750,000 poods (1,000 poods equal about 16 tons), as compared with 13,055,000 poods in 1912–13. The cotton grown in Russia, however, together with that imported from Persia, Afghanistan, and Kashgar, only meets about two-thirds of the requirements of Russian cotton-mills, and the balance is imported mainly from the United States and Egypt.

With regard to the cotton-spinning industry in Russia, the number of spindles in operation

in 1914 was 9,112,000, as compared with 8,950,000 in 1913, 7,350,683 in 1905, and 6,645,559 in 1900.

The development of the cotton-weaving industry has also been rapid. In 1900 the estimated number of looms in Russia was 151,306. By 1905 this figure had risen to 178,506; in 1910 it was 213,179; and in 1912 it was 224,411.

The output of textiles amounted to 19,589,229 poods in 1913, as compared with 12,520,495 poods in 1905, and 11,703,667 poods in 1900. As a result of the increased output of cotton textiles in Russia, there has been a reduction in imports of foreign goods.

NOTES ON BOOKS.

Welfare Work. By E. Dorothea Proud, B.A. (Adel.). With a foreword by the Right Hon. David Lloyd George, M.P. London: G. Bell & Sons, Ltd. 7*s.* 6*d.* net.

Although it is true, as Mr. Lloyd George says in the preface to this volume, that "Welfare Supervision is no new thing, either in this country, in the Dominions, or in America," still the conditions of labour in Great Britain during the last two years have been such that this matter has now acquired a fresh and striking importance. The sudden advent into munition works of men of all descriptions, and still more of women—many of them utterly unaccustomed to factory conditions—produced a great number of difficult and often delicate problems, and so necessary did it become to find a satisfactory solution of these, that a new Department was created at the Ministry itself, "charged with the general responsibility of securing a high standard of conditions for all workers in munition factories." Miss Proud has served in this Department since its creation, but, as her book was completed some time ago, it does not touch upon the work of the Department, but deals entirely with her experiences of factories under peace conditions in Australia, New Zealand, England, and Scotland. It would, no doubt, be extremely interesting to have an account of the work carried out by the Department; but this may perhaps form the subject of another volume from Miss Proud's pen.

Whatever the abuses of the factory system, there probably have always been numbers of manufacturers who realised that not only humanitarian considerations but personal interest should lead employers to provide for the welfare of their work-people. Thus we find Dale, whose factory was the model in 1792, "giving his money by shovelfuls" to his employees only to find that "God shovelled it back again." Owen bore witness to the financial success of his philanthropic experiments at New Lanark; and in 1835 Edward Baines, whose bias was towards the masters, remarked: "I believe the conviction is strengthening and spreading that it is eminently the *interest* of a manufacturer to have a moral, sober, well-informed, healthy, and comfortable body of workmen." This sentiment would probably sound far more of a truism to-day than when it was uttered eighty years ago; for while factory legislation has done much to mitigate the harsh conditions which were imposed at the beginning of the industrial revolution, many manufacturers nowadays take pride in doing for their employees a great deal more than is required by the law of the land. By no means the least beneficial of modern departures in this direction has been the institution of welfare workers in factories, and particularly is this the case in works where women are employed. Again and again it was found that a Lady Welfare Supervisor was able to relieve the management of a mass of minor but still important detail. To quote Mr. Lloyd George again: "She heard complaints and investigated dismissals. She supervised the canteen and other accommodation. She helped to engage new labour. The character and tone of the works depended largely upon her. The foreman referred to her in matters of discipline, slack work, or bad time-keeping. The workers brought their troubles to her. The management found that her presence conduced to smooth working and increased output. She became, not only the friend of the workers, but an essential part of the business organisation. Employers and workers alike wondered how they had done without her."

These few sentences sketch in broad outline the part to be filled by the welfare worker. The details (and these are numerous, including as they do such matters as cloak-rooms, mess-rooms, rest-rooms, wages and hours, health, recreation, food, baths, and gymnasia, housing and mental development) must be studied in Miss Proud's volume. It will be found full of value, not only to employers and lady superintendents and those who propose to enter on welfare work, but also to all members of the general public who take an interest in the conditions of life in our factories.

It should be added that this book is one (and by no means the least valuable) of the excellent series of monographs by writers connected with the London School of Economics.

The Microscopy of Vegetable Foods, with Special Reference to the Detection of Adulteration and the Diagnosis of Mixtures. By Drs. Andrew L. Winton, Josef Moeller, and Kate Barber Winton. Second Edition. New York: John Wiley & Sons, Inc.; London: Chapman & Hall, Ltd. 27*s.* 6*d.* net.

Microscopical examination has come to be recognised as of the greatest value in detecting the adulteration and sophistication of foods and

drugs. The authors of this work have been identified with this movement as State and Federal officials and as independent investigators, and many of the data collected in this way are incorporated in this second edition.

The book deals first with equipment, methods, and general principles, and then proceeds to consider the microscopic characters of various products, and their chief adulterants and impurities. In this manner are described different cereals, oil seeds and oil cakes, legumes, nuts, fruit and fruit products, vegetables, alkaloidal products and their substitutes, spices and condiments, and commercial starches.

A large number of fresh illustrations have been added to the first edition, so that the present text contains no fewer than 635 figures. A bibliography is appended to each section, and the whole work concludes with a full glossary and index.

GENERAL NOTES.

Victoria and Albert Museum.—The Duke of Buccleuch has generously lent for exhibition at the Victoria and Albert Museum the well-known collection of miniatures from Montagu House, Whitehall. This collection is one of the most important private collections in Great Britain, and is rich in works by all the great English miniaturists of the sixteenth, seventeenth, and early eighteenth centuries. From the historical point of view also it is of the greatest interest, containing as it does so many authentic portraits of members of the Royal Family and of the leading men of those days. Besides the miniatures of English origin there are also included in the collection numerous examples by French and other foreign artists and a considerable number of miniatures in oil. The exhibition is arranged in Room 83, adjoining the Picture Galleries, on the first floor, and access to it may be obtained most conveniently by the staircase at the east end o the Ironwork Gallery, running parallel with the Quadrangle. The collection was opened to the public on the 22nd inst., and will remain on exhibition until further notice.

British Leather Supply.—An informal conference with representatives of the leather trade has been held at the War Office, as a result of which it is hoped steps will be taken by the Government to see that when the war ends an ample supply of leather is available. Before the war probably 80 per cent. of the upper leather came (says the *Shoe and Leather News*) from abroad, and we were flooded with German box-calf. Unless our leather producers are making the necessary preparations and perfecting the box-calf trade we shall find ourselves when the war terminates in a worse position than ever. With every desire to buy in the home market, manufacturers will be obliged to take what they can get, and purchase leather from America, or even Germany, unless our leather traders are ready with the requisite goods.

Sulphate of Ammonia.—The Board of Agriculture are informed by the Sulphate of Ammonia Association that sulphate of ammonia (24½ per cent. ammonia) will be offered for sale from now till the end of September at 15*s.* per cwt. net cash, on condition that the quantities purchased at this reduced rate are removed from sellers' works by September 30th. After that date the price for home sales of sulphate of ammonia during the 1916-17 season will be 15*s.* 6*d.* per cwt. net cash. The goods will be delivered free on rail at makers' works in makers' bags, 3*d.* per cwt. being allowed if buyers supply their own bags. Farmers are strongly recommended by the Board to take advantage of the reduced terms offered by the association, as they will thereby facilitate delivery and also secure supplies which, owing to the increased requirements of the Ministry of Munitions, may not be so easily obtainable next year. Under favourable weather and soil conditions sulphate of ammonia is a very suitable autumn manure for cereal crops. Nitrogenous manures are most effective in increasing the yield of cereal crops, and are also of great use for most other crops, especially grasses, potatoes, mangels, turnips, and cabbages. Sulphate of ammonia, which is produced in this country, is now the cheapest and most available form of nitrogen for agricultural purposes. The quantity used by farmers in the United Kingdom could be doubled with profit to themselves and advantage to the State.

Mining in Mysore.—According to the Report of the Department of Mines and Geology, Mysore State, for 1914-15, the prospects of gold-producing companies on the Kolar Goldfield are distinctly encouraging. The output of gold during the year was 568,847 oz. of the approximate value of Rs. 3,26,76,516 against 559,832 oz. of the value of Rs. 3,23,53,731 in the year before the royalty was due to the Government. The dividends declared by the companies amounted to Rs. 18,95,740 in 1914-15 against Rs. 18,95,018 in 1913-14. During the year manganese was produced chiefly in the Kumsi mines in the Shimoga district, owned by the Workington Iron and Steel Company, Limited. The ore exported amounted to 19,629 tons, yielding a royalty of Rs. 4,907, against 5,953 tons in the preceding year on which a royalty of Rs. 1,461 was realised. Work in regard to other ores, chrome, asbestos, mica, iron ore, magnesite, corumbum, clay and copper is being carried on under prospecting licences, but progress was hindered considerably by the war. There was a considerable diminution in the number of mining accidents, the mortality therefrom falling from 4·38 per 1,000 in 1913 to 2·28 per 1,000 in 1914.

FOTHERGILL LECTURES.

HISTORIC BUILDINGS IN THE WESTERN WAR ZONE: THEIR BEAUTY AND THEIR RUIN.

By the Rev. G. Herbert West, D.D., A.R.I.B.A.,
Author of "Gothic Architecture in England and France."

Lecture II.—Delivered February 14th, 1916.

THE CATHEDRALS OF NORTH-EASTERN FRANCE.*

When the Roman Empire fell to pieces, in most large towns the Bishop, who generally had been appointed "Defensor Populi," gradually became the sole surviving representative of law and order; and his Cathedral took the place, in the eyes of the people, of the Prætor's Basilica, as being the abode not only of the worship of God, but of justice and liberty for the poor and oppressed. And when in the early twelfth century the rise of the Communes bound the citizens finally into one, their joy and enthusiasm found visible expression in rebuilding their ancient basilica under the guidance of their bishop, and his cathedral became also the symbol of their new-born national life, the centre of all its noblest energies.

The plans of these twelfth-century buildings, therefore, while deriving from that of the basilica, show that they were meant to be not only sanctuaries, places for the celebration of the sacred mysteries, but also for the assembling together of clergy and laity for any common purpose. The building is a vast hall with a small choir, and no solid screen between clergy and people.

But in England the cathedrals tell a very different tale. In quite early Saxon times the great Benedictine monasteries of the Continent had founded missionary daughter houses in our then heathen land. And even when, after the Norman Conquest, great churches sprang up on every side, they were all in the hands of monks, generally Benedictines, and if there was a bishop he might be abbot of the monastery whose church became his cathedral. Our cathedrals, therefore, generally stand apart from the cities to which they belong, in a separate enclosure, originally fortified, in which we find them still nestling amid the elms of their quiet close. Such contrasted views as those of Chartres and Lichfield, Wells and Rouen, sum up completely the stories of the two national churches and enable us to realise how completely the French cathedral was the centre of the life of the city; how entirely the English one was detached from it.

And instead of the great assembly hall of the early French cathedral, we find in Norman England a more purely basilican plan with a single or triple apse. Then, as the churches cease to be merely abbeys and become cathedrals also, and so have to serve a double purpose, the apse is replaced, as at Lincoln, by a greatly extended choir, which with the eastern transept and chapels formed the church of the monks, with a special approach from the cloister, while the western transept with its chapels and the immense nave were the cathedral and parish church cut off from that of the monks by a heavy stone screen—almost an iconostasis, with a central door and an altar on either side. Also, since the monks did not need a public procession path in their own church round the High Altar, we do not find an ambulatory as in France, but they reverted to the Saxon square east end, and obtained their procession path in sight of the people by placing another screen westwards of the Rood screen, with a central altar and a door on each side of it, and the Rood above.

We shall also find that whereas the builders of the French cathedrals handed down as craft

* For a full treatment of the subject of this lecture see the author's "Gothic Architecture in England and France." Bell & Sons. 1911. 6s.

secrets their learning and traditions, so that the constructional development of French Gothic is the result of the severest logical reasoning from first to last, the English cathedrals were frequently built under the direction of the monks, if not actually with their own hands, as at Gloucester. There is consequently a comparative absence of scientific tradition, much less coherence in purpose and expression, but more individuality and local originality. In France traditions grow stronger and more binding, as the art falls more and more into the hands of the great guilds and becomes less and less the expression of popular feeling, till it dies stifled by the swathing bands of invariable formulæ. But English architecture—less popular at first, but freer in its efforts and expression—comes always more and more into touch with the national sentiment and finally develops an entirely new form which never really died, but, adapting itself to the social evolution of the nation, gradually ceased to be chiefly ecclesiastical, and—passing on from the cathedral and the monastery to the village church and the crenelated manor—at last, under the Tudors, gave rise to the domestic architecture of that sturdy middle class which has always been the backbone of the English nation.

Thus while France was rearing Renaissance chateaux for her luxurious nobles whose power had not been broken as in England by civil war, the English squire and his tenants, still standing side by side as at Crécy, were going on building their country houses and farms on the old lines—adding a new aisle to the parish church, raising a grammar school in the village street, or providing a college at Oxford or Cambridge to receive their boys.

The general aspect of mediæval architecture in the two countries is therefore quite different, and the difference grows greater as time goes on, for English Gothic architecture was not introduced from or dependent on France. After the introduction of the Norman style just before and at the Conquest the influence of French art on English was very slight. Now and then an isolated case of importation appears, as in the earlier part of Canterbury, inspired by, but inferior to, Sens, and in Westminster, which is entirely French in plan but English in detail; but otherwise English Gothic is purely national from the very first. Indeed, national characteristics reappear directly after the Conquest, when Norman work was largely modified by the reappearance of Saxon traditions, the square east end, the high narrow lancets, the south porch, and the great length of the nave. Indeed, the influence was rather the other way, for it seems probable that, as Monsieur Enlart has suggested, flamboyant tracery and the ogee or reversed arch were introduced by the English into France during the Hundred Years' War, when native French architecture was almost at a standstill except in the districts occupied by the English.

It is indeed the essential difference in national character which reappears in national art. The one is logical, looking to the future; the other, opportunist, living in the present. French mediæval architecture of the Royal domain passes through a process of continuous evolution from its first appearance to its final decay. It took its origin in the district of Soissons as the result of the meeting of two streams of influence, one from the east given by the noble churches of the Rhine provinces where the traditions of the great art Renaissance of Charles the Great had developed into the grandest of all the Romanesque styles; the other from Burgundy in the south, where, at Dijon and Cluny, Lombard influence had combined with the classical memories of Provence, and had passed upwards through Champagne to north-eastern France. The story is fairly clear, though some of the links are already lost and few if any will be left after the war, as the whole district is in the hands, or within reach of the guns of the Germans. The earliest of these, Tournai, is one of the noblest Romanesque buildings left. It rises strikingly above the houses on the left bank of the Scheldt, and its five central towers and two western turrets form a grand group very like that of Spires.

The round-ended transepts are a distinctly Rhenish feature, which we find reproduced at Noyon, and with an aisle and extremely beautiful detail of an almost Gothic character at Soissons, of which but little is now left. Tournai belongs to the end of the eleventh century. Noyon, which was originally an abbey in the diocese of Tournai, was begun in 1131 by Bishop Beaudoin about ten years before his intimate friend Abbé Suger began the Abbey of St. Denis; and Notre Dame of Paris, which was largely influenced by St. Denis, was begun some twenty years later, about 1160. At Noyon the Lombard influence is clearly seen in the alternation of piers supporting three vaulting ribs, and columns which carry only the intermediate rib of the sexpartite vault. The choir of St. Remy of Reims and the nave of Laon are very like Notre Dame and Soissons, the sister church of St. Remy

but some fifteen years (1180) later is already suggestive of Amiens in the columns. Through them all runs the same principle gradually unfolding itself in strict logical sequence.

In England there is nothing like the same continuous development; there is no systematic logical pursuit of one distinct scientific and artistic ideal, no distinct rise, summit and fall as in France; no single scheme of vault construction giving unity to the drama; but the story is presented, as it were, in some seven independent tableaux connected together, but shown one after another, and threaded, not on the string of a continuous scientific principle, but on that of the varying religious and social history of the nation, and presented in succession by the dominant personality of the period. The Monk comes first and builds the great Norman abbeys, then the Noble, who enshrines himself in the floriated niches of the Decorated style, and lastly the Citizen who covers his churches, like his comfortable rooms, with Perpendicular panelling. Consequently no such classification as that of the seven periods of English Gothic is possible in France, where we pass gradually step by step from the stolid Romanesque of Tournai to the restless Flamboyant of Abbeville. The only sudden break is when Flamboyant tracery is introduced by the English at Amiens during the Hundred Years' War as one of the experiments which they were always making on window, vault, and wall surface, but never allowing to become frozen into routine, always passing on to some other idea which seemed more adapted to the requirements of the moment.

Thus much as to the influence of the history and national character of the two countries on their art. Let us now turn to its constructional development in each case, beginning with France.

From the time when Christian art began to revive in the eleventh century, the efforts of all builders in the ancient Roman provinces of Western Europe were centred in the attempt to do with small materials and a limited supply of unskilled labour what the Romans themselves had never even essayed with building resources such as the world had never before seen—to make the thin and isolated walls of the three-aisled basilica, which by long use had become the recognised form for the Christian church, carry the same stone or concrete arched roof or vault as the enormously thick walls of the Romans. The difficulty was this—"an arch never sleeps," and an arched roof, or tunnel vault, is always trying to thrust down the walls which carry it. Roman vaults were of two kinds, a continuous tunnel or barrel vault—and an intersecting vault, formed by dividing the plan of the building into squares and covering each square with two short tunnel vaults at right angles to each other and crossing in the middle where they form a projecting arris or groin on each diagonal. In this intersecting vault the outward thrust of the arch is not continuous, but is all concentrated on the four corners of the square, and if they are made strong enough, or sufficiently buttressed, the spaces under the arches on the four sides need not be walled in at all. This sort of vault could be managed by these early builders on a small scale as in the low and narrow aisles of a church, but it was beyond their power to put it over the high thin walls of the nave. At last, at Durham (between 1093 and 1133), and a little later at St. Denis (1140), the idea was hit upon of building two permanent stone arches or ribs diagonally from corner to corner of each square, instead of moveable wooden centrings—and of covering in the triangles between these with rows of smaller stones arched across from rib to rib.

Then the only thing needed was to prop up sufficiently the columns or piers which carry these cross ribs at each corner of the square. This prop or buttress must be brought to bear as nearly as possible at the springing of the ribs where the thrust is greatest, or a little above it, or better at both these points. This was done at Durham and at Caen by a complete stone arch thrown across the upper gallery or triforium at the back of each pier, and better at Gloucester by a quarter arch butting against the pier. But as the nave walls had to be much higher than the roof of the triforium gallery in order to get space for the windows of the clear-story, those buttressing arches came below the springing of the ribs, which is where they are really wanted, if they were kept under the roof of the triforium. So they were raised above the roof, and at Chartres and in all the beautiful later examples, as at Amiens, are made double, so as to buttress both the springing and a point above it. Then the wall between the buttresses being useless soon gave place to a mere screen of painted glass. It was a bad principle thus to leave all the important constructional parts of the building exposed to the weather, but if one excuses that, nothing can be more perfect in beauty than the Gothic cathedral. But, as always in the work of man, only for a moment did these stern reasoners and perfect artists rest

on the summit of their achievement. Beauvais is a literal example of that "vaulting ambition that o'erleaps itself." The chiefly passive role of the buttresses of Amiens in transmitting the vault-thrust must needs be exchanged at Beauvais for an active one which shall enable the main buttresses to be smaller, and the whole building lighter, though even higher than Amiens.

But while the vault thus dictated the exterior forms of the building, it affected the interior hardly less. The monocylindrical columns with great voluted capitals were soon felt to be unsuitable and illogical, as so much of their upper surface carried nothing. So in the later columns of Notre Dame the vaulting shafts stand on the one-coursed capital of a column of their own, standing in front of the main pier. Later still the vaulting shafts are carried down to the ground and their capital is at the point where they carry their load; the springing of the aisle vault and the nave arches have their columns with capitals of one course standing on either side of, and attached to, the main column which has a capital of two courses. This progress is well seen at Soissons and Amiens. We have thus the principle of continuity distinctly formulated—that every column must have its base on the ground and its capital at the springing of its arch and only there. Soon it was felt that every colonnette should have members corresponding to the mouldings of its arch, so, by a gradual transition which may be well traced at Notre Dame de l'Epine, it came to be thought that capitals had lost their meaning and that all mouldings of all arches should run down to a common base without a break, sometimes dying into one another on the way as at St. Maclon, Rouen, but reappearing below, even if their reappearance was marked only by the corners of their imaginary bases supposed to exist inside the main pier, but to have been turned round so that their corners project from the faces of the general base.

In England the story is very different. Although we were the first to make a real Gothic ribbed vault at Durham, we never allowed the determination to have a stone roof to our churches to influence the whole design—indeed, we were quite content with an open wooden roof, which the French never were. An English cathedral is always the Norman abbey church in essentials, even when the details have become Gothic. Now the Norman church consisted of three nearly equal stories set one upon the other with little or no vertical continuity, but with the chief beauty sought in horizontal perspective as at Wells, which forms a most striking contrast to such a church as Beauvais. In France the eye is led upward at once by the vaulting shafts to the vast height of the roof; in England eastward by the pier arches along the immense length of the nave. In England the vaulting shafts hardly ever run to the ground, but stop above the nave columns, which are designed to be beautiful in themselves and not as part of a whole. They are not in various groups or sizes so as to mark distinctly their various purposes, to correspond with the arches or ribs which they represent or carry, but so as to bring in the greatest number of detached or semi-detached shafts, some of which may even have nothing to carry, and since these whenever possible were of Purbeck marble, which could only be got in short lengths, circular bands had to be introduced and the abacus of the capital became circular also instead of square as in France.

The arch mouldings indeed are even adapted to the pier, instead of the pier to the arch mouldings. These mouldings also are more deeply cut than in France and enriched, so as to be in keeping by their strong contrasts with the black and white of the columns—very beautiful and well suited to our grey climate. But when the use of marble in the piers ceased, the mouldings became shallower arrangements in grey, frequently worked on the chamfer, in striking contrast to those of late French work, which are narrow deep hollows and sharp prismatic edges to catch the light, so as to distinguish the different ribs as they run down from the vault to the ground. Again, in contrast with the French, the wall which disappears with them till the incessant vertical lines give a sense of irritating restlessness to their later styles, is in English work everywhere visible, and its restful suggestion of strength and quiet repose most grateful, while the long-drawn-out perspectives of arcades and aisles give the special character to the whole which in France is found in the soaring elevation of each separate bay.

But the real glory of our English Gothic is to be found in its latest form. I said how in French vaults the triangles between the ribs are covered in by panels made of rows of arches of small stones thrown from one rib to the other. But as the diagonal ribs are of course much longer than the arches which form the sides of the square or oblong of the vault, the stones of these little arches must be much larger at the end resting on the diagonal than at the other, and if a straight joint is to be got

along the ridge this difference must be distributed over all the little arches by carefully shaping each stone for its place in laying it. Only skilled workmen could do this properly. To the practical, rule-of-thumb Englishman it seemed much simpler to cover in his triangles with rows of stones all of the same size like planks. But the result of this was a joggle or dovetail along the ridge instead of the straight joint of the French vault. This could not support itself, but needed a rib for the ends of the stones to rest on. Also this system gave a flat surface instead of an arched one between the ribs, which if of any size needed another rib or tierceron to support it in the middle, or rather to give an extra bearing so that the rows of stones could be shorter. The effect was thought so pleasing that more intermediate ribs were added until we reach such a beautiful form as Exeter.

But a difficulty arose with these "tierceröns." They varied greatly in length, according to their position, and were all much shorter than the diagonals. Either, therefore, the ridge could not be kept level, or the curves of these ribs must be changed, "fudged," half-way. At the point where the curve changed a short crosspiece, or lierne, was put, and then as it was difficult to get a tidy-looking mitre of the mouldings, a little carved boss was placed at the intersection as at Canterbury, Lincoln and Winchester, and soon star patterns and all sorts of fanciful arrangements of the ribs were indulged in as at Tewkesbury, and the practical result became a ribbed barrel vault with intersections as in Winchester nave and Gloucester choir.

Soon the number of similar ribs springing from one capital gave the idea of making them into a perfect cone, called Fan vaulting, a very silly name. If the curve of the ribs is a single simple one, as at Gloucester, a flat ceiling must come between the cones, or if a regular vault with a ridge is wanted, the curve must be altered to provide for the different lengths of the ribs, and so the four-centred arch arose, which is characteristic of our later styles, and which naturally, as had happened previously with the pointed arch, was taken from being a mere necessity of construction to become the chief decorative feature of the building.

Having got this cone of ribs it was ingenious to bring it out from the wall and spring it from a pendant as centre, as at Oxford Cathedral, or even to bring it out so far as to complete the cone and let it meet another half cone springing from the wall as in the Divinity School, Oxford, or that final masterpiece, Henry VII.'s Chapel, so easy to criticise, so impossible not to admire. It is curious that in these latest vaults the true use of the ribs has entirely disappeared and the ribs and panels are all cut out of large blocks of stone, and we have got back to the Roman barrel vault with its continuous thrust, a strange result to arrive at from merely altering the system of covering in the triangles between the ribs. It is rendered all the more striking by the fact that the French, who kept to their original system, never arrived at these rich vaults. Many of their later vaults, as at Gisors and Abbeville, have little pendant bosses, and occasionally, as at St. Ricquier, a lierne vault may be found copied from the English ones, but anything elaborate like Rue is a mere piece of fanciful decoration.

Having now traced out the causes, historical, racial and constructional, which influenced the development of Gothic art in England and France, let us look again at the results at which the two nations arrived in their great cathedrals. There could hardly be a greater contrast than that between the two. In the exterior of the French cathedral—which is generally obviously the result of one great effort, begun with vast enthusiasm but never finished as intended, if at all—the walls have "formed fours" and are standing in slices at right angles to the building which they support but do not enclose, towering high above it, and seeming to push and thrust with all their power to keep up its enormous height. It is very wonderful and very beautiful, but leaves a sense of constant effort to overcome difficulties after all only partially vanquished. But till the other day, one cathedral—Reims—did show us almost perfectly the ideal which was aimed at and with very little of that sense of effort, standing now, alas! merely a shell, wrecked by the Huns—and the French rightly propose to leave it as it is, a monument to their enemy's eternal infamy.

How beautiful is the peace of the long low English cathedral, with its insignificant buttresses and unambitious lines, with no traceried canopies or wealth of sculpture, and, except for the upward pointing of its central spire, seeming content to remain quietly on earth; telling generally in its unequal parts and varied styles—not of a mighty impulse which faltered all too soon, of a lofty enthusiasm which died down to mere mechanical dexterity, but of successive generations of commonplace yet earnest men, each bringing its little stone and saying—

Add this to the rest.
Take it and try its worth, Here dies another day.

The French cathedral was the most perfect work of art imaginable, more complete even than the Greek temple, for not only was it a perfect combination of all the arts, architecture, painting, sculpture, more inseparable and more perfectly co-ordinated, but it was the expression of a higher, fuller ideal as coming later in the history of the human race and the work of a people as idealistic, as highly strung as the Greek. This artistic expression is found most in that part of the cathedral which was the least fully worked out, the great west front. There is not one of them which is not open to criticism as to proportion, adaptation to its purpose, disposition of lines and parts—yet there is not one which is not beautiful and inspiring.

The original type is in that strange rugged building, the Cathedral of Laon, now within the German lines, perched on its precipitous rock, fit emblem of the turbulent race who built it. The towers and triple porch, the great rose window and arcaded gallery reaching across are features which become invariable. But the point about Laon which impressed itself on the artists of that time, as we know from the sketches of Willars de Honnecourt, and through them on all subsequent buildings, and especially on Reims, was the towers. The way in which the diagonal pinnacles are carried on the angle buttresses with a rich cornice and just the right amount of horizontal lines, forms, perhaps, the best transition in existence from the towers to the spires which were to have crowned them.

There is a beautiful legend about the bold and original figures of oxen and peasants which look over the balustrades of these towers. The peasants who, as at Chartres, were dragging the stones up the hill, found the load beyond their strength, so the oxen in the fields around came of their own accord to be harnessed to the carts. In the homage given by these striking figures to the patience and strength of the docile creatures who thus helped to build the house of God, is a touching expression of gratitude and justice.

The break in the gallery is a defect avoided at Notre Dame. The horizontal lines there are, perhaps, too strong, and it is too much cut up into squares, but what restfulness in the wall spaces, what noble proportion and sense of scale! The Arc de l'Etoile is exactly the same size and looks about half. Put Wells by the side of it; the sculpture there is glorious, but is independent of the poor and monotonous design, with its mouse-holes for doors and columns like scaffold poles all over the front. Or set Amiens by the side of Lichfield with its shopful of statues put away on brackets, or even Peterborough by the side of Reims, far and away the most glorious of them all. Reims has defects and serious ones; the carrying forward of the statues round the buttresses destroys the necessary vertical lines; the towers, inspired by Laon, come out of the façade without apparent connection with it, and there is such a crowd of sculpture and galleries and fretted gables that it is not easy to understand how they are carried on the mass of colonnettes and pinnacles, open work, and carving. And not one cathedral is complete. They all lack their spires. The towers of Amiens were cut in half down the middle for lack of funds, and finished in a hurry when the first impulse had died out. Reims was set back on its ground floor and finished flimsily for the same reason. But what noble gateways to the heavenly Jerusalem as the builders of St. Ouen called their church. Never was a glorious dream more marvellously transmuted into stone than in those triple-storied portals, compassing about those passing in to worship, with so great a cloud of witnesses, and bidding them as they enter look up to Jesus, the author and finisher of their faith, their Judge that shall be at the last.

And in the interior also the story is the same. In the English church we may trace the stolid acceptance of existing facts which preserves all that has gone before, however imperfect, and, adding here and changing there, makes up a building, humble-minded as it were, with a wooden roof perhaps, content to suffice for the needs of the present, telling in every corner of the makeshifts of the past, with no sign of anxious unrealised ambition for the future, incapable of perfection because begun and ended incessantly and most often without continuous design, yet breathing out an indescribable charm of sympathy, almost human in its loving reverence for the results of all the past efforts of the bygone generations.

But in the other, the soaring lines which guide the eye upward ever to the vault of stone poised miraculously on its walls of painted glass, seem to tell of those whom

> God whispers in the ear
> For whom earth had attained to heaven—there was no more far nor near—

of those who, greatly daring in their implacable logic would sweep ruthlessly away all that had gone before, for they had dreamed to raise a structure complete and harmonious all through, the absolute expression of one over-mastering ideal of future perfection, but bound to remain

incomplete at the last from the weakness of all human means and efforts, for they had aimed

> At the high that proved too high, the heroic for earth too hard.

Yet therein lies its undying power. While our cathedrals tell of the strong consciousness of the historical continuity of the nation, which has made of the English a governing and imperial race, the mediæval architecture of France is the expression of that logical and artistic nature which has made the French through all European history the originators of the noblest social ideals, and the exponents of their highest expression in art. And here it is that the French art towers far above the English. Put Lincoln and Reims side by side. The latter seems far more the expression of the nation's soul. So far as a building only makes use of its materials dexterously, appropriately, beautifully even, with limbs and fingers only, it falls short of the highest; so far as it lays open the soul of the man or of the race, it reaches it.

Let me sum up. I have tried to bring before you not mere differences of style founded on details of moulding or tracery, things interesting but of little real importance, but to show you how English and French mediæval architecture are, each of them, the outcome of the character of the race, the result of the history of the nation, the expression of the people's faith and ideal.

The same national characteristic of "drift" for which we are paying so awful a price to-day, which has always taken us muddling along with no definite aim or plan for the future, and which led Edward III. in his blundering rush across Northern France till he was brought to bay on the hillside of Crécy, led also the workmen of his time to close their vaulting panels just any-how provided they got them closed; the same sturdy common sense and determination to stand shoulder to shoulder in whatever they undertook, which made the King dismount his knights and place them side by side with the peasants, row over row on the terraces thrown up on that gentle slope and which gave to them all when thus united the power

> to turn to flight on that famed Picard field
> Bohemia's plume and Genoa's bow and Cæsar's eagle shield;

made them also build their walls always thick enough to carry the vaults, or else rest satisfied with a wooden roof, and caused them in like manner to be content to mend and patch their heritage from the past rather than sweep it all away in the hope of replacing it by some marvel of quite unattainable perfection in the future—till in the end the gradual blending of classes and of their aspirations made itself felt in their art as in their social life, and the architecture of the cathedral, the monastery and the castle found its last expression in the village church, the manor house, and the farm. In art, as in empire, the English race has ever been the same—opportunist, realistic, almost incapable in material matters of ever formulating an aim much beyond the present moment, yet blundering half unconsciously, in spite of themselves, into marvellous results in art and empire—and, let us hope, in war.

And so with France. It was the same chivalrous devotion to an ideal which inspired St. Louis to build the Sainte Chapelle to receive the Crown of Thorns, which drove to death the knights at Crécy and Poitiers and Agincourt, which also inspired the burghers of the Communes with their wild enthusiasm for liberty and with their resolve to find for their thankfulness a visible expression in their vast cathedrals. It was the same pitiless logic and thirst for an ideal which dictated the unswerving policy of Louis XI. and of Richelieu, and which later made the nation sweep away all its past in a torrent of blood, in the vain hope of bringing back the golden age, which also in art inspired the reasoning and the artistic sense whereby the builders of St. Denis and of Chartres were led on from Notre Dame through the perfection of Amiens, the magnificence of Reims, the lovely folly of Beauvais, and the ruinous unfinished beauty of Abbeville, to the last wire-drawn skeleton of a sixteenth-century church. Through it all, up to the very end, these builders were true artists aiming at expressing a something higher than themselves which should draw up into sympathy with them all that was best and noblest in their fellow men.

And their descendants have not changed. How strikingly these characteristics are coming out in this dreadful war! What a contrast between the silent uprising and stern devotion of France, all in a moment, when the Germans were once again outside the gates of Paris, her self-consecration to the one single aim of beating back the enemy, and our vacillating, shrieking, discordant methods, culminating, however, in spite of it all, in a vague sense of national duty and purpose, which will lead us on to victory, please God, not less surely, but much less impressively than the spiritual determination of our infinitely noble and loveable Ally.

COALS AND OTHER MINERALS IN JAPAN.

By WATSON SMITH.

COAL MINES.

The existence of coal in the Miike district or thereabouts was known for many years back, as the seam crops out in one direction, and although there is no authentic record of the date when the coal was first mined, local tradition assigns the date as about the year 1468. The extent of the old workings most certainly shows that mining operations of some sort must have been carried on at a very early date, and there is positive information that before the revolution mining was systematically pursued, one part of the district having been worked by the Daimio of Miike, Lord Tachibana, and another by Ono, the chief retainer of the Daimio of Yanagawa. The coal so mined was used for salt-works on the shores of the Inland Sea and Shimabara Gulf, and is still in great request for that industry because of the great heat it easily develops owing to its highly bituminous nature, with the consequent rapid evaporation of the brine.

Of course the method of mining was of a very primitive nature, the coal having been worked from the outcrop on the side of the hill; and when the Japanese Government purchased the mine in 1873 from the then proprietors for some 40,000 yen the same simple system of mining was followed. Pumping was done only by the native tread-wheel, and draining was effected by gullies, but at the time when the Government purchased the mine, water had nearly drowned out the workings, and an immense amount of this simple pump-work had to be gone through before any quantity of coal could be mined. Convict labour alone was used for mining, and the purchase of the mine by the Government seems to have been influenced first and foremost by the object of thus finding occupation for the convicts. In 1876, the Government handed over the management of the Miike mine to Mitsui & Co., and that firm, rightly thinking that much more might be done with the mine, set vigorously to work to improve matters. They were also appointed sole agents for the sale of the coal, and under the name of the Mitsui Bussan Kaisha branch offices were opened at Shanghai and the principal Japanese ports, and subsequently sub-agencies in Hong-Kong, Singapore, etc. At the time when the Mitsui Bussan Kaisha took charge as aforesaid, the output was only some 300 tons per diem, the coal being obtained from the Oura mine, the site of the ancient workings, and carried to the surface in baskets on men's shoulders. The most important work was that of sinking a shaft at Nanoura, a spot to the south-east of the Oura mine. This was commenced in July, 1879, and completed in June, 1882, coal having been struck at a depth of 240 ft. There was great influx of water in completing this shaft, and hence much delay, but the difficulties of pumping it out were overcome, and this Nanoura mine became, and is, the most productive. The Oura, Miyanoura, and Nanoura mines were in full work in 1888, and the output had been increased to 1,200 tons a day, when the Government came to the conclusion that the Miike mine should be sold to some private purchaser if the reserve price of 4,000,000 dollars could be obtained, and on January 1st, 1889, the entire property was transferred to Mitsui for the sum of 4,550,000 dollars, and the sole control and working came into the hands of the Mitsui Bussan Kaisha.

As regards quality, I have already shown, in conjunction with Chorley and Baly, that Miike coal is quite equal to the best Lancashire coal (see *Journal of the Society of Chemical Industry*, 1891, pp. 975-980). Now as regards labour, this, too, being a period when we in this country are suffering for lack of it—the bulk of the mining labour is carried on by convicts. Years ago the demand for this labour had so much increased that the Government built a large convict prison in the neighbourhood of the Nanoura mine in 1882, capable of accommodating 1,600 prisoners, and when the Miike mine was sold to Mitsui it was stipulated by the Government that convict labour should be employed as hitherto, the Government receiving a fixed price for the work done. All the convicts immured in this prison are undergoing long sentences, none being in for less than twelve years, and nearly 400 for life. On first entrance the convicts are kept at labour in solitary confinement, or are put to work of a more or less rough nature until their character is determined in some measure. The refractory obtain no indulgencies, but are kept to solitary confinement and exercise, and when necessary there is the dark cell for punishment. All are dressed in cinnamon-coloured cotton garments, and those well conducted earn diamond-shaped blue badges, which are worn upon the left arm. When a prisoner has attained five of these good-conduct marks he is entitled to a ticket-of-leave, or a special pardon, and the good-mark men are allowed the privilege of better food once, twice, thrice, or four times a week, according to the number of good-conduct badges they have won.

Those not physically capable of working in the mine, and who have conducted themselves well, are permitted to work at various industries, such as mat-making, basket-making, weaving, shoemaking, etc., and a certain task for the day is allotted to each man. If this is accomplished, the Government takes seven-tenths of the value of such work, and sets aside three-tenths for the worker, and for all that is done over and above the allotted task the scale is reversed—the Government taking three-tenths, and according seven-tenths to the worker. The same system is observed with mining labour, and as more extra money can be made by this work, all are eager to be sent to the mine, especially as when underground they necessarily enjoy a certain degree of liberty. All the prisoners' clothing is made on the premises, and there is a large demand from Kobe for the matting made by the convicts. The utmost order and

cleanliness rule in the prison, and the food supplied is ample and good. There seems to be very little serious illness among the prisoners, and most cases under the doctors' care are from slight colds or injury to the eyes. Those in hospital are well cared for, and are allowed to while away the time by reading. An ingenious contrivance is used in all the buildings in which the prison cells are situated. A turn of an iron wheel simultaneously opens a door in each cell, so that in case of fire the prisoners can at once escape.

Roughly speaking, the Miike coalfield extends over 18 square miles, as defined in 1893, and the area of deposit was estimated to extend over some 3,758 acres, containing near 85,444,000 tons of coal. Several seams of coal occur in the Miike coalfield, but the first and second only are capable of being economically worked. The first seam averages 8 feet in thickness of pure, solid coal, without any interstratified bands of shale, as frequently found in most of the Japanese coal-seams. So far, the mines here are extraordinarily free from explosive gases, so that naked lights are invariably used and with impunity. The second seam lies only from 6 to 10 ft. below the first, and its thickness averages 6 ft. near the outcrops, though more irregular and uncertain in the deeper portions. The coal here is free-burning and non-caking, but its quality is inferior to the coal from the 8-ft. seam, and it is now worked only on a limited scale for local consumption.

One great disadvantage peculiar to the Miike coalfield, is the entire absence of shale in the strata overlying the coal. The strata, being composed of different kinds of sandstone more or less coarse, porous, or fissured, allow an easy passage to water from the surface to the coal-seam, thus rendering the process of mining expensive, and dangerous from flooding. On the other hand, the dip is comparatively gentle (about 5°), the roof is firm and strong, and no faults worth consideration are found. One of the strata contains fossil shells in great abundance. The output from 1877 to 1892 was—

1877	54,589 tons	1885	248,137 tons
1878	78,207 „	1886	277,718 „
1879	120,186 „	1887	317,717 „
1880	118,211 „	1888	368,109 „
1881	168,899 „	1889	462,271 „
1882	156,430 „	1890	487,641 „
1883	158,592 „	1891	574,330 „
1884	209,775 „	1892	468,831 „

From 1904 to 1913 the annual production and exports were—

Year.	Output (tons).	Amount exported (tons).	Percentages of export.
1904	1,236,639	668,637	54·07
1905	1,301,126	678,785	52·17
1906	1,455,469	493,297	33·89
1907	1,469,429	640,174	43·57
1908	1,525,480	601,526	39·43
1909	1,539,030	609,326	39·59
1910	1,785,206	733,342	41·08
1911	2,036,024	834,594	40·99
1912	2,039,807	1,051,675	51·56
1913	2,156,954	959,510	44·50

Coal, Coke, and By-products from Coking.—The coal has a brownish lustre, and is highly bituminous. Owing to its great steaming power, high heating value, and uniform quality, it has acquired the reputation of being the standard coal on the Asiatic markets. The average evaporating power of the lump coal is 9·72 lb., water evaporated at 212° F. by 1 lb. The fine coal is peculiarly fitted for forging purposes, and commands a wide market both at home and in Chinese ports. The gas-producing power of Miike coal has long been recognised by the gasworks of Japan and China. It cakes easily, and coke of excellent quality is made in Kopper's regenerative coke-ovens, with a by-product plant installed at the colliery. The average results are—

Per Ton of Miike Coal.

Coke produced	1,500 lb.
Gas produced	11,000 cub. ft.
Coal tar produced	166 lb.
Ammonium sulphate produced	21·3 lb.

There are at the Miike colliery 92 Kopper's regenerative coke-ovens with a by-product recovery plant producing over 100,000 tons of coke, and 1,420 tons of ammonium sulphate per annum, besides coal-tar products by distillation of the tar.

Mine-workers, etc.—The mine-workers number 14,240 in all, including underground and surface hands. They are comfortably housed, and rice and other necessaries of life are supplied at the canteens at cost prices, and special reduction is made, even from these, for long-service miners. All the miners are required to save from 5 to 10 per cent. of their earnings, so as to provide against contingencies. Liberal rewards are given for regular attendance. The colliery even provides three nurseries for the care of infants during the mothers' absence at work.

Education.—The education of mine-workers' children is receiving close attention. There are five elementary schools at the mines with an aggregate attendance of over 1,000 children. Besides these, day and evening classes are opened for boys in the service of the colliery offices and works, giving them opportunities to pursue higher studies and so qualify themselves for posts of responsibility. With the object of turning out competent foremen and assistants in the fields of mining and engineering, a special institution, with the name of the Mitsui Technical School, was established in 1907 near Omuta, under the patronage of the Mitsui families, for the benefit of the public. There are three departments, viz. mining, mechanical, and electrical engineering. One of the special characteristics of the school is that the whole of the colliery works are thrown open to the students, and there, in addition to the regular curriculum, practical training is given them under the guidance of engineers and foremen.

Hospital Accommodation.—The Miike colliery maintains a well-equipped hospital in Omuta intended exclusively for the colliery employees and their families. At present, the hospital has a

staff of 19 physicians, 36 nurses, and a number of attendants. The hospital can accommodate 80 patients. It has a branch at each mine, and also at the Miike harbour.

Foreign Markets.—The chief foreign markets for the Miike coal are Shanghai, Hong-Kong, Singapore, Manila, and Java.

Other large collieries are those of Tagawa, output 980,114 tons in 1913; Yamano, output 407,952 tons in 1913; Hondo, output 380,884 tons in 1913; Noborikawa, output 100,678 tons in 1913. In all these, as in the Miike mine, the welfare of the workers and their children is zealously seen to.

GOLD AND SILVER MINES.

The Kushikino Mine.

This mine is situated in the province of Satsuma, the southern extremity of Kyushu. It is said to have been first opened a few centuries ago. The Mitsuis purchased some part of it in 1906, and the remainder in 1911. The present metallurgical works were completed in 1913. The concession comprised a surface of 1,823,294 tsubo (1,489 acres). The ores are mined by means of the pneumatic drill as well as by hand. Explosives are also applied as required. Drainage is effected by means of electrically-driven turbine pumps. Formerly the gold and silver were extracted in the main by amalgamation, yielding only 60 per cent. of the gold and 25 per cent. of the silver contained in the ore, but since the Mitsuis took over the mine the all-sliming cyanide process was adopted, and extensive plant was completed in 1913. The extraction rate for gold attained 90 per cent., and for silver 80 per cent. of that contained in the ore.

Motive Power.—To obtain electric power for various purposes, an electric central power-station is established, consisting of four sets of vertical gas-engines, each developing 318 B.H.P. driven by producer gas.

Mine-workers and their Treatment.—The mine-workers, including underground and surface hands, number about 660. The mine is provided with a hospital with staff of medical men.

Kamioka-Kushikino-Kongo.

The Kamioka Zinc, Lead and Silver Mine.

This mine is situated in Central Japan, and is said to have been first opened some twelve centuries ago, and different portions of the mine were worked on a small scale by independent proprietors until the Mitsuis amalgamated the mines in 1888, when a modern and extensive system of development was begun. The area of concession covered 8,638,495 tsubo (7,057 acres). The ores are chiefly silver-bearing galena and zinc blende. They occur in irregular deposits, the largest ranging from 50 ft. to 60 ft. by 300 ft. or so, and the depth known by actual mining is over 1,000 ft. The metals produced at Kamioka are zinc, lead, and silver, besides some copper, gold, bismuth, and arsenious oxide. The output of ores and metals in each of the ten years ending in 1913 is as follows:—

Year.	Gold.	Silver.	Copper.	Lead.	Zinc concentrates.	Bismuth.	Zinc dust.	Zinc.	Arsenious oxide.	Argentiferous copper.	Refined lead.

Mining.—The prospecting of the body of ore is carried on by driving levels at different altitudes. In case of massive deposits, the ore occurs mostly at the intersection of veins. The mining is mostly effected by overhand stoping and in rare cases by underhand stoping. Explosives are applied wherever required. Drainage is effected principally by levels driven in from the surface, as the workings lie high up the mountain, and wherever mechanical drainage is required water-jet pumps are used. The higher parts of the mine above water-level are naturally ventilated, and the lower parts are ventilated by mechanical fans.

Concentration and Smelting.—All kinds of ore here contain considerable amounts of zinc. Two concentration plants have been established. Part of the zinc concentrate is sent to Miike, where ten recuperative furnaces, each capable of treating five tons of ore per day, are installed, and spelter of 99·9 per cent. of pure zinc is obtained. The lead concentrates are roasted in reverberatory furnaces

and pots, and then smelted in a blast-furnace with suitable fluxes, thus producing rich lead, matte, and slag. After liquation and softening, the lead is desilvered by zinc. The zinc scum is distilled, the resulting zinc being used again for desilvering, whilst rich lead is cupelled. The desilvered lead is refined, cast in ingots, and sent to market. The matte is repeatedly roasted and smelted for lead, and the concentrated matte is subjected to oxidising smelting for copper. As lead contains about 0·2 per cent. of bismuth, the Pattinson Rozan desilvering plant is installed.

Motive Power.—Water power is used, and the motors are mostly of the Pelton type. The horse-power developed amounts to 688 h.p. Besides this, 220 h.p. of electric power are consumed for various purposes in zinc refining at Miike.

Mine-workers and their Treatment.—The mine-workers, including underground and surface hands in the Kamioka mine, and the employees in the zinc refinery at Miike, number over 3,000. There are three elementary schools, and a hospital at the mine. All the mine-workers are supplied with necessaries of life at a canteen established for their exclusive use.

Kongo Tungsten Mine.

This mine is situated in the Kongo mountain range in Korea, famous for its scenic grandeur. The extent of the concession is 564,600 tsubo (461 acres). The mine appears to have been first opened by a Japanese in 1912, and the Mitsui Mining Company purchased it in 1914. The output of tungsten ores in the last two years is as follows—

Year.	Tungsten ore.	WO_3 content.
1912	11·8 tons	65 per cent.
1913	16·9 ,,	68 ,,

The ore is wolframite, occurring in quartz veins found in granite; also a small amount of cassiterite and molybdenite; gold and silver is found in quartz veins. To concentrate, the ores are crushed and sorted by manual labour. The concentrate contains from 60 to 68 per cent. of WO_3. It is expected, however, that this strength will be improved up to 72 per cent., when the concentration plant now in preparation is completed. As regards the mining, this is effected by the open cuts, and explosives are applied as required. The total length of excavation attains 4,000 ft. and the average depth is 15 ft. Underground mining by overhand stoping will in the future be adopted. The number of miners is about sixty.

Sulphur Mines.

Iwaonobori Sulphur Mine.—This mine is in the province of Shiribeshi, Hokkaido. It has been worked by the Mitsui firm since 1886, and the area of concession covers 560,724 tsubo (458 acres). The output of ore and refined sulphur during the last ten years is as follows—

Year.	Ore produced.	Sulphur refined.
1904	11,297 tons	2,250 tons.
1905	10,532 ,,	2,184 ,,
1906	10,463 ,,	2,039 ,,
1907	17,465 tons	1,590 tons.
1908	17,038 ,,	3,026 ,,
1909	22,387 ,,	3,041 ,,
1910	32,527 ,,	4,865 ,,
1911	43,607 ,,	7,671 ,,
1912	37,104 ,,	8,363 ,,
1913	44,341 ,,	9,072 ,,

The sulphur ore is found mostly in beds mixed with clay and partly as impregnation in volcanic rocks. It is mined almost exclusively in open workings, and the main portion of the mined ore is refined by steam liquation, and a small portion by sublimation. The refined sulphur contains over 99·5 per cent. of pure sulphur, and is largely exported to San Francisco, Australia, China, etc. The crude ore generally contains 60 to 70 per cent. of sulphur, and is partly sold direct to sulphuric acid and fertiliser manufacturers in various parts of Japan.

Owing to the deep snow of winter, mining is suspended for about six months, usually from the middle of November.

Kobui Sulphur Mine.—Situated in the province of Oshima in Hokkaido, the deposit was discovered fifty-one years ago, and was purchased by the Mitsui firm in 1911, the area of concession being 1,352,772 tsubo (1,105 acres). The production during 1912 and 1913 has been—

Year.	Sulphur refined. Tons.
1912	11,195
1913	10,046

The sulphur ore is found in deposits amongst volcanic rocks. The method of mining is given as the "long-wall working." Ventilation is by natural draught, and drainage by natural flow. The mined ore is refined by simple sublimation, and the refined product contains 99 per cent. of pure sulphur. It is largely exported to Australia, New Zealand and the Pacific coast of America. The raw mineral and the refined sulphur are chiefly conveyed by horse tramway from mine to shore. The mine-workers, underground and surface hands, number about 680.

The Itava Sulphur Mine is in the northern part of the main island of Japan. It has been worked by the Mitsui firm since 1914. The area of concession is 526,157 tsubo (430 acres), and the output of mineral and refined sulphur in 1913, was—

Mineral (ore) produced	4,769 tons.
Sulphur refined	390 ,,

The mineral is found as sulphur impregnating volcanic tuff, and the method of mining is described as the "pillar-and-stall" and "long-wall" systems. Explosives are used as required. The mined ore is refined in the modified "Gill's furnaces," or by sublimation. The refined sulphur contains on an average 99·62 per cent. of pure sulphur and is largely exported to the United States and Australia. The mine-workers, underground and surface, number about 130.

ENGINEERING NOTES.

The Rocky Mountain Division of the Chicago, Milwaukee and St. Paul Railway.—With reference to the electrical tests of the above railway given in one of the Engineering Notes of March 9th, this line has now undergone a six months' trial, and certain advantages appear to have been demonstrated. One of these is a material reduction in running time. On one 21-mile 1 in 50 gradient alone the time for passenger trains has been reduced from 1 hour 5 minutes to approximately 40 minutes. In the goods service it has been found that where steam locomotives have required from ten to twelve hours to make 115 miles, electric locomotives can meet a schedule time of from seven to eight hours for the same distance. The capacity of the new locomotives has been thoroughly tested. Trains of 3,000 tons have been hauled east and 2,800 tons west, an assistant engine being used on the heavy grades. On some of the runs, where the grades are less than 1 in 100, trains of as many as 130 trucks and as heavy as 4,000 tons have been hauled by a single locomotive. It has been shown that much heavier trains can be hauled with the electric locomotives than by steam, and furthermore the capabilities of the electric equipment are not impaired by bad weather. During a series of record-breaking temperatures last December, Mallet engines were frozen up at several points and were rescued, with their trains, by electric locomotives. Through passenger trains of 650 tons are hauled 220 miles by a single electric locomotive. Steam operation required a change of engines midway. Local passenger trains are handled by a half unit. The regenerative braking has proved an easy solution to a difficult problem on the long mountain grades. Electric goods trains usually descend the maximum grades at 17 miles per hour, but half that speed can be maintained if desired. In case there are no other trains between the substations to absorb the power generated by a descending train, the power passes through the substation machinery, and is readily absorbed by the extensive system of the power company. There are forty-four electric locomotives on the division, twelve passenger, thirty goods and two switching. They operate on the 3,000-volt direct-current system, being the first to use so high a direct-current potential. For a distance of 440 miles this railway has been electrified, the first unit of 115 miles being already in actual operation. The full East to West sweep of the Rocky Mountains is traversed, and the electrical line runs across the three principal mountain ranges. This is believed to be the longest section of electric railway service in existence. The immense electrical energy required is obtained by water power from mountain waterfalls, and the power is transmitted over long distances with the greatest efficiency. It may be mentioned that the full mileage of the Chicago, Milwaukee, and St. Paul Railway is to-day more than 10,000, and on its lines are situated nearly 1,000 cities and towns of commercial significance. The entire work of electrification cost approximately £2,500,000, and has required three years to complete. Some of the above particulars are extracted from the *Engineering Record* of New York.

Progress of New Southwark Bridge.—This bridge, which will have five spans instead of the three of the old bridge, is being erected on four piers and has been designed to give a head-room of 26 ft. above Trinity high water. According to the *Times*, the centre span is 140 ft. 6 in., the intermediate spans 131 ft. 9 in., and the two shore spans 123 ft. The arches will be composed of seven steel ribs placed as regards the two outside ones at 5 ft. centres, and as regards the others at 8 ft. 9 in. centres. Beyond the outer ribs cantilever arms will project for a distance of 6 ft. 5 in., and on these a portion of the footpath will be carried. The roadway will be 35 ft. wide and the footways 10 ft. wide, giving a total width of 55 ft., as compared with 42 ft. 6 in. of the old bridge. The present position of the work, which is being carried out by Sir William Arrol & Co., is that the pier on the City side of the river has been completed up to road level, while that on the south side is rapidly approaching a similar state. The sinking of the permanent caisson for the foundation of the second pier from the City side has reached a point within a few feet of foundation level, which is 50 ft. below high water, while in the case of the fourth permanent caisson the building of the steel work is in an advanced state. The caissons are remarkable for their size, measuring 102 ft. by 30 ft., whereas those of the Forth Bridge, which are circular, are of 70 ft. diameter. They are sunk into the river in the ordinary way by means of compressed air, the pressure employed being 22 lb. per square inch, but one or two special features are presented by the method employed by the contractors. At the beginning the caissons are placed between temporary guide-posts and lowered until they float in the water. At this stage, the caisson body being filled with concrete and the building of the masonry for the piers started, the pier is thrust downwards by the pressure of the superimposed weight regulated by the air pressure and the excavation carried out within the working chamber. At a point halfway between high and low water the masonry work is stopped for the time being, and the work of putting the foundation steelwork in position is continued under the compressed air method of excavation. On the foundation caissons reaching the predetermined foundation level, the interior working chamber is filled up solid with mass concrete, the air pressure released, and the building of the upper courses of masonry proceeded with.

Fire Prevention at Sea.—The need for perfect fire-fighting plant on land is urgent enough; how much more so, then, at sea. With the object of bringing the subject prominently before the notice of those concerned, the British Fire Prevention Committee have just issued, as Red Book No. 203, some important suggestions on fire protection for passenger ships of 1,000 tons gross register and over. These may be classified under the headings: (*a*) Ship fires and fire records; (*b*) preventable causes of fire on board ship; (*c*) discovery of fires on board ship; (*d*) first-aid fire appliances on board ship; (*c*) main fire appliances on board ship; and (*f*) ship's fire service. Other sections in the Red Book, copies of which are obtainable at the committee's offices, give extracts from the International Convention as to safety of life at sea, the Board of Trade's War Emergency Notice of 1915, and the Merchant Shipping Advisory Committee's recommendations on the subject of fire protection. The main fire appliances on board ship should be based on a good hydrant service on both sides and on all decks—a primary essential that should be compulsory. It is recommended that hydrants should always be kept under moderate pressure from steam-pumps installed in or near the main engine-room, and in the same watertight compartment as the main steam generating plant; and that there should be on no passenger ship of more than 1,000 tons register less than two such steam-pumps, such pumps being interchangeable and serviceable for the entire hydrant system, so that water under pressure may be obtainable at all times, even if one of the pumps breaks down or is out of working order. Supplementary to the hydrant system, the committee urges that it should be compulsory that a ship should have a certain number of independent steam fire-engines—*i.e.* fire-engines entirely independent of the steam supply of the ship, and should also have a certain number of manual fire-engines. Certainly if ships were generally equipped with fire-fighting plant on these lines there would be far less chance of hearing of that most terrible of all maritime disasters—a ship on fire at sea.

Combination Steam and Gas Engine. — The following abridged account of this engine is from the *Engineer.* Power-generating equipment of a very novel and remarkable character has been adopted for the large automobile works of the Ford Motor Company at Detroit. It comprises electric generators driven by a combination of gas and steam engines, with boilers and gas producers, and regenerators to utilise the waste heat. There will be six main units, each with a capacity of 6,000 horse-power, at a speed of eighty revolutions per minute. The arrangement resembles that of a horizontal twin tandem compound steam-engine unit, but one side consists of a two-cylinder tandem gas-engine, and the other side consists of a two-cylinder tandem compound steam-engine. The engines are connected to opposite ends of a shaft, upon which is mounted a generator of 4,000 kilowatts for 250-volt continuous current. The gas-engines have water-cooled cylinders 42 in. by 72 in., and are of the four-cycle double-acting type. The gas exhaust is utilised in a steam superheater on the steam main between the high-pressure and low-pressure cylinders of the steam-engine. A portion of the exhaust gas is passed through the jacket of the high-pressure cylinder in order to reduce heat loss. Finally, the exhaust gases are utilised in the feed-water heaters for the boilers. This water has already passed through the cylinder jacket of the gas-engine, and has thus been heated to about 160° F. or 180° F. before it enters the heater, in which the exhaust gas raises the temperature to about 250° F. for the feed. The gas-steam unit is designed to combine the economy of a gas-engine under constant load with the reliability of a steam-engine under varying load. A gas-engine operates to best advantage, as a rule, under full load and constant load, but under such conditions there is practically no overload capacity. The general practice, therefore, is to run the engine rather underloaded. This produces wire-drawing of the gas through the valves and ports, which tends to cause a precipitation of tarry matter. Such trouble does not occur with the engine running under full load. With the combination gas-steam unit the gas-engine does not come into service until there is at least something more than half load on the unit, so this engine will be normally under full load. The steam-engine does all the governing and can meet fluctuations in the load. The only governing on the gas-engine is to prevent excessive speed. In case of trouble with the gas side of the unit, the steam side can handle the full load by giving a late cut-off. The electric generator weighs 105 tons and has an armature 16 ft. diameter, weighing 45 tons. The field frame is 21 ft. high and 26 ft. wide across the projecting feet which support it upon its foundations. Considerable trouble has been experienced in completing and adjusting the units so that they will operate in service in the manner designed. There has been trouble also with the gas-producer plant. Taken altogether there appears to be some scepticism among American engineers as to the economical and efficient operation of the combination units, and especially as to the reliability and freedom from operating troubles which is such a desideratum for the power equipment of manufacturing establishments. The first units were installed by the end of 1915; it is hoped to have the entire installation completed shortly, and it will be interesting to hear how the engines work.

Simmer Pan Electric Power Station, Transvaal.—The Victoria Falls and Transvaal Power Company issue the following particulars with respect to the above scheme. The generating plant at Simmer Pan comprises six 4,000 k.v.a. turbo-alternators, and two additional turbines in course of erection. Both of these, together with the new boiler plant, were put in operation early last year. Each of these generators is of 11,000 kw. (15,700 k.v.a.) capacity, the alternators being of the totally-enclosed type. There are three single-phase transformers operating in conjunction with each of the above alternators (one in each phase), and stepping up from 5,000 volts to either 42,000 or 10,500 volts. These transformers were made by the American General Electric Company in Schenectady, and are of the oil-insulated water-cooled type, contained in circular cases, with the high-tension leads entering the top. The existing boiler-house at Simmer Pan was enlarged, and eight Babcock and Wilcox standard marine-type boilers, with chain-grate stokers of their latest design were added. Each of these boilers is of 33,000 lb. to 38,000 lb. per hour rated capacity, with internal superheater. Regarding extensions at the company's other stations, it may be mentioned that last summer the work of installing at the Brakpan station of two further three-phase turbo-alternators, each of 12,000 kw. capacity, and ten boilers similar to those already put into commission at Simmer Pan, was completed, and the plant was brought into use. At Rosherville eight boilers of 33,000 lb. capacity were installed, and three further turbo air compressors, each of about 10,000 h.p. capacity. Under normal conditions, the four stations (*i.e.* Vereeniging, Brakpan, Simmer Pan, and Rosherville) are operated in parallel, and the average load during the heaviest hour of an average day reaches 100,000 kw. This should not be confounded with the peak loads, which may be considerably higher. The total generating capacity of the four power stations is now more than 137,000 kw. The present business (inclusive of the supply of compressed air) closely approaches 600,000,000 units sold per annum, and the extensions of plant will enable this figure to be considerably increased in the near future.

GENERAL NOTES.

Science and Modern Languages.—In pursuance of the arrangements which the Government have made for reviewing the system of education as a whole, the Prime Minister has appointed two committees to inquire into the position of science and modern languages respectively in the system of education in Great Britain. (1) The terms of reference and constitution of the Science Committee are as follows: To inquire into the position occupied by Natural Science in the educational system of Great Britain, especially in secondary schools and universities; and to advise what measures are needed to promote its study, regard being had to the requirements of a liberal education, to the advancement of pure science, and to the interests of the trades, industries, and professions which particularly depend upon Applied Science. Sir J. J. Thomson, O.M., D.Sc. (Chairman); the Right Hon. F. D. Acland, M.P.; Professor H. B. Baker, D.Sc., F.R.S.; Mr. Graham Balfour; Sir William Beardmore, Bt.; Sir G. H. Claughton, Bt.; Mr. C. W. Crook; Miss E. R. Gwatkin; Sir Henry Hibbert, M.P.; Mr. William Neagle; Mr. F. G. Ogilvie, C.B.; Dr. Michael Sadler, C.B.; Professor E. H. Starling, M.D., F.R.S.; Mr. W. W. Vaughan; secretary, Mr. F. B. Stead, H.M. Inspector of Schools. (2) The terms of reference and constitution of the Modern Languages Committee are as follows: To inquire into the position occupied by the study of modern languages in the educational system of Great Britain, especially in secondary schools and universities, and to advise what measures are required to promote their study, regard being had to the requirements of a liberal education, including an appreciation of the history, literature, and civilisation of other countries, and to the interests of commerce and public service. Mr. Stanley Leathes, C.B. (Chairman); Mr. C. A. Montague Barlow, M.P.; Mr. E. Bullough; the Right Hon. Sir Maurice de Bunsen, P.C., G.C.M.G., G.C.V.O.; Mr. A. G. Coffin; Dr. H. A. L. Fisher; Mr. H. C. Gooch; Mr. J. W. Headlam; Mr. L. D. Holt; Dr. Walter Leaf; Dr. G. Macdonald, F.B.A.; Mr. A. Mansbridge; Mr. Nowell Smith; Miss M. J. Tuke; Sir James Yoxall, M.P.; secretary, Mr. A. E. Twentyman.

Iron and Steel Institute.—The autumn meeting of the Institute will be held at the Institution of Civil Engineers, Great George Street, Westminster, on Thursday and Friday, September 21st and 22nd, 1916. The following is the list of papers that are expected to be submitted for reading and discussion:—(1) H. Brearley, "Some Properties of Ingots"; (2) Professor E. D. Campbell, "Influence of Heat-Treatment on the Thermo-Electric Properties and Specific Resistance of Carbon Steels"; (3) Dr. H. M. Howe and A. G. Levy, "Heat Treatment of Eutectoid Carbon Steels"; (4) J. N. Kilby, "Steel Ingot Defects"; (5) Herbert K. Scott, "Manganese Ores of the Bukowina, Austria"; (6) Dr. J. E. Stead, F.R.S., "Influence of Elements on the Properties of Steel"; (7) Dr. J. E. Stead, F.R.S., "Notes on (*a*) Nickel Steel Scale, (*b*) On the Reduction of Solid Nickel and Copper Oxides by Solid Iron, (*c*) On Effect of Blast Furnace Gases on Wrought Iron"; (8) G. F. Zimmer, "Use of Meteoric Iron by Primitive Man."

London: Printed by William Clowes & Sons, Ltd., Duke Street, Stamford Street, S.E., and published for the Royal Society of Arts by G. Bell & Sons, Ltd., York House, Portugal Street, W.C., in the Parish of St. Clement Danes, in the City of Westminster.—September 1, 1916.

Journal of the Royal Society of Arts.

No. 3,329. VOL. LXIV.

FRIDAY, SEPTEMBER 8, 1916.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICE.

CANTOR LECTURES.

The Cantor Lectures on "Optical Glass," by Dr. Walter Rosenhain, F.R.S., Superintendent of the Metallurgy Department, National Physical Laboratory, have been reprinted from the *Journal*, and the pamphlet (price one shilling) can be obtained on application to the Secretary, Royal Society of Arts, John Street, Adelphi, London, W.C.

A full list of the Cantor and Howard Lectures which have been published separately, and are still on sale, can also be obtained on application.

PROCEEDINGS OF THE SOCIETY.

FOTHERGILL LECTURES.

HISTORIC BUILDINGS IN THE WESTERN WAR ZONE: THEIR BEAUTY AND THEIR RUIN.

By the Rev. G. Herbert West, D.D., A.R.I.B.A.,

Author of "Gothic Architecture in England and France."

Lecture III.—Delivered February 21st, 1916.

FRENCH MEDIÆVAL SCULPTURE.

The history of mediæval Christian sculpture is complicated in its earlier stages by its being the expression of a vigorous new society coming to life amidst, or upon, the dying embers of the civilisation of an effete race. This is curiously illustrated even so late as the eleventh century in the sculptural art of Southern France, where, as at Vezelay and Autun, over the stiff foliage of fairly correctly carved Corinthian capitals may be seen wandering strange, uncouth, northern figures which tell some Scripture story such as the expulsion from Eden or the sacrifice of Isaac. Yet pure classical traditions lingered on, especially in Provence, the only part of the empire where any of the old life was left. Although, as everywhere, there is a great gap between the eighth century and the eleventh, yet it is impossible not to see these traditions reappearing in such remarkable compositions as the great porches of St. Trophime at Arles and St. Gilles (about 1200). In the cloister at Arles there are clear traces of Byzantine influence, but it is not that which preponderates in the porch. Fine as the compositions are as a whole, with good proportions and beautiful detail, yet there is no promise in them, they are lacking in life, in expression—the work is that of an art which is dying, not of one which is being born. This is clearly seen if it is compared with such a contemporary work as the tympanum of the Cathedral of Cahors. Grotesque as that may appear to us now, it is full of the power and life and promise which the other lacks. Like the rather later north door in the front of Chartres, it represents the Ascension. The figure of Christ is dignified and full of expression. The folds of the drapery are free and ample, with very little trace of Byzantine stiffness. There is a roundness and modelling about the figures superior to the flat, fret-sawlike work of the great door at Vezelay, which is of about the same date (1104).

Several schools of sculpture arose in France during the eleventh and twelfth centuries. That which was the first to free itself from classical limitations was the Burgundian. Its chief characteristic is breadth and firmness. It avoids the dryness of Byzantine work and shows a wonderful imaginative power. The Burgundians were already Christians and good workmen when they crossed the Jura, and from their great Abbey of Cluny, founded in the tenth century, issued an extraordinary artistic influence. The abbey itself was destroyed in the Revolution, but we may form some idea of it from Vezelay, the main door of which is one of the most remarkable works left us. It dates from the end of the eleventh century. The upper part of the tympanum represents the Day of Pentecost.

The drapery of the Christ and that of the Apostles is tossed about by the rushing mighty wind, and beams of fire from His hands touch the brows of each. The eight square compartments round represent possibly the seven Churches, the bottom one on the left being the Apostle writing under the dictation of the Saviour. There is a life and expression in these figures vastly in advance of the monotony of those of Arles; for example, in the two figures of St. Peter and another Apostle on the right-hand pillar there can be no doubt that St. Peter is gravely rebuking the other, who is listening attentively. The subject of the lintel is unknown. It is perhaps the "Apport," the people of all the earth, as in Acts ii., bringing contributions to the abbey, or it may be an allegorical representation of the Last Judgment, the saved being represented by the Israelites entering Canaan, the lost by the representation of the different vices, Pride being the little man getting on horseback by a ladder; Falsehood and Slander the people with ears reaching down to their feet.

The classical influence is still very strong, especially in the ornamental details, and in the two outer orders of the arch. But it is almost more visible in a somewhat later (*c.* 1140) but inferior work, the Last Judgment tympanum at Autun, of which we shall speak later. Yet, in spite of this inheritance of the past, one cannot but recognise the promise of the future in the strong dramatic feeling of the whole. At Autun Roman remains were very numerous, and the design of the cathedral is copied from the Roman Porte d'Arroux. The classical influence is most marked in the central pier, where one can see, not only Byzantine, but pure Greek influence. Let me, before passing on, give one or two more examples of how a classical spirit is occasionally to be found almost to the end of the Gothic period. The beautiful twelfth-century figure of St. Stephen, so dear to the people of Sens that they preserved it even through the Revolution, shows it strongly, and the ornament on the sides of the piers is pure Roman.

But the most remarkable instance is the late thirteenth and early fourteenth century work at Auxerre. It is quite noticeable in the treatment of the nude figure of Bathsheba, and in all the draperies, but especially in the exquisite figures of the Seven Arts, which are worthy of being placed with the Tanagra statuettes, and also in a sleeping Cupid and many of the smaller figures.

We will now rapidly pass on through the semi-classical Burgundian Romanesque of the twelfth century to the fully-developed thirteenth-century work of the Île de France and Champagne.

North of Burgundy, round Bourges, a school of sculpture arose in the twelfth century, in which we find a mixture of many influences, Gallo-Roman, Byzantine, and above all northern Romanesque. This last is specially marked by the elaborate ornamental detail. It is curious how these northern races begin by covering every inch of their buildings with mechanical ornament, much as the South Sea islander covers his paddle. Only gradually do they learn the value of the plain surface and of the concentration of ornament on certain points. On the old side doorways of Bourges, as in the rather earlier work of Avallon, we find the germ of the glorious porches of the Île de France with statues placed among the columns. But as they are rightly felt to be part of the architecture, they are made longer than nature. It was not ignorance but true artistic feeling which dictated their proportions. This is still more noticeable in the wonderful west portal of Chartres, dated from 1140, which was moved forward when the cathedral was lengthened in the thirteenth century. The statues are strongly individual portraits of living persons, not, as was the case later, brought into conformity with an ideal type. The dignified kings and queens with the mysterious smile are those mentioned in St. Matthew's genealogy; but unfortunately statues of kings on the cathedrals were taken in the Revolution to be kings of France, and ruthlessly destroyed, so that much of the early history of French sculpture is lost.

The capitals of the columns are still covered with stories from the Old and New Testament, and their true carrying function is not clearly marked, nor had the complete scheme of sculpture yet been fixed. Thus we still find Christ in the tympanum surrounded by the emblems of the four evangelists, as at Bourges, instead of the Christ in Judgment, which becomes the rule later. The left-hand door represents the Ascension and is worth comparing with the earlier work at Cahors, by which it was perhaps inspired. The right-hand door is the Virgin's door, as became usual in the fully-developed scheme of iconography, of which the first idea is to be found at Laon, and which, during the thirteenth century, furnished a more or less fixed programme to all the great cathedrals. Starting with the three great portals, the central door gives us Christ on the pier as the Judge of the

world, with the Last Judgment on the tympanum above Him, and with His assessors, the Twelve Apostles standing on either side of Him, each with his emblem beneath his feet, or, in the earlier examples, seated on the lintel below Him; while on the jambs of the door itself are the wise virgins who entered with the Bridegroom, while "the door was shut" against the foolish ones "who stood without, crying, 'Lord Lord, open to us.'" Could any scheme of decoration be more solemnly appropriate to the entrance of the House of God in the arches, patriarchs, saints and angels? The second door, that in the place of honour on the right, was consecrated to the life of the Blessed Virgin, and the third, or the side doors, to the histories of some local saints—St. Firmin at Amiens, St. Sixtus, St. Nicaise or St. Remy at Reims, St. Marcel at Paris. Other doors were consecrated to saints, some of whose relics were amongst the treasures of the Church, St. Anne at Chartres, St. Thomas at Semur, St. Stephen at Paris. Between the doors at Paris, on the great buttresses, were two large figures carrying the line of sculpture across from door to door, the synagogue on the left of our Lord with the eyes blindfolded and the Book shut, the Church with open eyes and open Book on the right, and above, in the great gallery, the statues of the kings of Judah, ancestors of the Blessed Virgin.

The thirteenth century was the age of encyclopædias. Thomas Aquinas summed up all theology, Jacobus de Voragine collected all the legends of the saints in the Golden Legend, Durandus epitomised all writers on the liturgy, and Vincent of Beauvais attempted to embrace universal knowledge. It was on his work, as M. Male* has shown us, that the whole artistic scheme of the great cathedrals was based, and it was the Cathedral of Laon which first gave the pages on which the story was to be written.

That story is arranged as in de Beauvais' "Speculum" in the four chapters or mirrors of Nature, of Instruction, of Morals, and of History—that is, of the history of the Church. We have then (1) the Signs of the Zodiac in the heavens, the work of Creation on earth, leading up to the creation of man; (2) *Instruction to Salvation*—the story of the Fall of Man and of his redemption, the Labours of the Months, the liberal Arts; (3) *In Morals*—the Virtues and Vices, the Active and the Contemplative life; (4) *The History of the Old Testament as leading up to the New*—prophets, patriarchs and the kings of Judah, the legendary story of the Blessed Virgin, the Saints and their legends, all leading up to Christ and the Final Judgment and finding its centre there.

The façade of Laon is too early, and that of Paris is so largely a modern restoration, that we had better go for our chief example to the great north and south porches of Chartres, which were finished in the last quarter of the thirteenth century, about forty years later than Notre Dame. That on the north, which is the richer and the more perfect in design, loses by never getting full sun, and must have lost even more at first when they both were painted and gilt. The south porch also gains greatly by being raised on a flight of steps. In no buildings, not even in the Parthenon, is there so perfect a union between architecture and sculpture as in these two porches. Let us begin with the south porch. It is less elaborate than the north, and the square piers adorned with bas-reliefs between the columns are much less effective in their light and shade than the narrow arches and statues of the other. The large statues are, however, even finer, the heads noble and full of character and suggestion of moral beauty, the draperies almost classic in their simple grandeur. Since there is no arcade for the kings of Judah on the west front, they are placed here, six on each side of the porch and three on either side of the central archway.

Since the twelfth-century sculptures of the west front were already given to the glorification of Christ, the central door here is the Judgment door. Christ is in the centre showing His wounds, the Virgin and St. John on either side, pleading for sinners, and six angels with the instruments of the Passion, the two lower ones with the lance, the pillar and scourge, the upper ones holding the nails, the crown of thorns and the Cross, which seems to have no arms. On the central pillar is Christ, a very beautiful figure, standing on the lion and the dragon. There are six Apostles on either side standing on their executioners, and in the five orders of the arch the nine choirs of angels.

As specimens of the statues, we may take those of the right-hand door, beginning on the left. (1) St. Leo Pope with a conical tiara; on the pedestal three heads. (2) St. Ambrose pushing the end of his crozier into the mouth of a figure on the pedestal—Maximus, who made himself Emperor in opposition to Valentinian. (3) St. Nicholas, Archbishop of Myra. The man on the pedestal (without a head) is the

* "French Thirteenth Century Sculpture," Male. Dent & Co.; and "The Sculptures of Chartres," Marriage. Camb. Univ. Press.

innkeeper who murdered and salted down three boys, according to the western legend, the real story being that St. Nicholas delivered three officers of the Emperor Constantine from prison. They are shown in the east as three little figures looking out of the top of the prison tower; in the west they were taken for three children in a tub, and the story invented accordingly.

On the right we have (1) St. Martin, the wonder-worker of the west, as St. Nicholas was of the east—a very fine statue. His soul shines in his face, active and severe. Beneath his feet are two dogs whom he stopped from pursuing a hare. (2) St. Jerome, with the Vulgate. Beneath on the pedestal a woman with her eyes bandaged (the Synagogue), with the roll of the Old Testament, which the saint is taking from her: she is trying to hold on her crown, which is falling off. (3) St. Gregory with the conical tiara. He used to dictate to his secretary from behind a curtain. One day his secretary drew back the curtain and saw a dove sitting on his shoulder and whispering to the saint. He is peeping out from the pedestal.

Between the columns on each of the square piers are panels giving the virtues and the corresponding vices, or lives of saints.

In the north porch the most beautiful of the larger statues are—on the central pillar, St. Anne carrying the infant Virgin, a beautiful figure of an old woman; Solomon, a type of Christ, a fine head with the technical skill of the later sculptors and the force of the earlier ones; and next him the Queen of Sheba, a type of the Church, as she came from the ends of the earth to hear the wisdom of Solomon, and is therein a type of the Magi—she is standing on a slave. Judith, a type of the Virgin as deliverer of her people, standing on a dog—the emblem of fidelity. Above, in the voussoirs of the arch, are scenes from the story of Judith, and next her the story of Gideon who was a type of Christ, because "Tau"—T the Greek for 300—is the sign of the Cross, and so his victory represented Christ's.

In the outside mouldings of the arch are the labours of the months and the signs of the Zodiac. April, a man holding ears of corn; October, a man knocking down acorns for pigs; January, a man with two heads, cutting bread and with a bowl of wine on the table. These, though better executed, are much less vigorous and full of life than the corresponding earlier series on the west front; compare, for instance, the He-Goat.

But the most beautiful figure in the north porch, perhaps in the whole cathedral, is that on the north-western angle of St. Modesta, the daughter of the Governor Quirinus. She was converted by the martyr St. Potentian, who stands next her; she was martyred, as is shown on the pedestal, by being thrown into a well. The figure is one of exquisite grace and modesty, and the face touchingly sweet and maidenly.

Time would fail us if we attempted to pass in review all the sculpture of the great French cathedrals; but before passing on to Reims, the crown of them all, we must just glance at Amiens, which offers us the model of the perfect union of sculpture and architecture. The wonderful porches of Chartres are additions to the church; the scale is not always perfect. At Paris nearly all the statues are modern and there is some lack of richness, and at Reims there is overmuch. At Amiens the two are perfectly combined, and the statues are almost all as fine as possible in life and individual expression, which is rather lacking at Chartres, and perhaps a little too marked at Reims, and also in scale of the great statues of the kings of Judah in the gallery and of the prophets at the entrance. The colossal statues of the kings are perfectly adapted to their position—the heads are bold, detail is sacrificed to the general effect to be got from below, the eyes prominent and looking down, the detachment of the nostrils from the cheeks exaggerated; they would not look beautiful in a museum, they are perfect in their place. The opposite would have to be said of much modern work, and even of some of that of the Greeks. The details of the figures in the pediment of the Parthenon, such as those of the Fates, would have been hardly visible from below, and parts of the seated and lying figures would have been hidden by the cornice.

As we have seen at Chartres and Paris, the figure of Christ is on the central pier, above Him the Judgment, and on either side the twelve Apostles. The great door of Amiens is the finest of all in the beauty of the figure of Christ, the nobility of the statues, and the spiritual beauty of their faces. Radiant with the light of the Holy Spirit, they gaze before them with profound serenity. At Chartres and at Reims some of the statues are poor works of art: at Amiens hardly one falls below the general level of excellence. On the right of Christ are: (1) St. Peter with the keys and Cross; (2) St. Andrew with a Latin Cross; (3) St. James the Great with a sword and the scallop shells of a pilgrim; (4) St. John holding the poisoned cup which Aristodemus gave him to drink; the

next is probably St. Philip; then comes St. Bartholomew, who should be holding the knife with which he was flayed alive (the axe is modern).

On the left of Christ come—(1) St. Paul with a sword; (2) St. James the Less with a club; St. Thomas with a T-square; and the others must be Matthew, Jude and Simon, and beyond them prophets beginning with Ezekiel.

St. Thomas has a T-square because he is said to have been an architect, and at Semur-en-Auxois we have his legend, which may serve us as a type of many of the mediæval legends. In the tympanum of the north door at Semur, beginning on the left, we see him—(1) Putting his hand into Christ's side; (2) The Provost of Gundoforus, King of India, meeting him in the market-place at Cæsarea and engaging him to go to India to build his master a palace; (3) St. Thomas and a disciple going in a boat to India.

Line 2, from right, shows Thomas arriving during the wedding feast of the king's daughter, where a dancer is walking on her hands. St. Thomas has just cursed the king's cupbearer who tried to prevent his entering; so dogs had eaten him, and one is running in with his hand in his mouth. St. Thomas receives orders and money for the palace from the king, who is going off to war. He gives the money to two beggars, one on a stool, the other, a negro, holding a calabash. St. Thomas is put in prison, but escapes and tells the king, who is kneeling before him, that a more beautiful palace awaits him in heaven if he will be baptised.

These apocryphal legends are much commoner in the cathedral carvings than the true Bible stories; but they are sometimes mixed with them as at Rouen, where on the north door the death of John the Baptist is shown on the lintel and Salome is shown tumbling as at Semur. In the upper part disciples are shown gazing into an empty tomb, the story being that St. John the Evangelist had a grave dug in front of the altar, lay down in it, in a dazzling light, and when the light had faded the grave was filled with sweet smelling manna in place of the body of the Apostle.

But the most perfectly executed of these stories, whether true or imaginary, are to be found in Paris in the story of St. Stephen on the south door, and in that of St. Theodore.

There is also a wonderful set of panels (of about 1275) on the south side of Notre Dame which represent either the life of some unknown saint, or perhaps, though it is less likely, scenes from the turbulent life of the students of the University of Paris in the thirteenth century. If that is so, we have (1) the students quietly taking notes of a lecture; (2) standing round a professor, who is addressing them from a high dais; (3) probably a riot amongst the students; (4) the young men being hauled up by the Proctor before the Vice-Chancellor and taking an oath to behave themselves better in future.

The plinth of Amiens is covered with quatrefoils, in which are the Virtues and Vices and the Labours of the Months, and in the other porches and on the buttresses where the statues represent the prophets a little scene is given from the book of each. Thus Ezekiel sits before a little wheel. They are pretty enough, but probably the sculptors had never read the books themselves.

Let us now pass to what was the crown of beauty of French mediæval art—Reims.

The whole interior of the west wall is covered by seven rows of niches, divided by panels of most beautiful foliage and each containing a statue. The drapery of these figures is of the most masterly design and execution, with large ample flowing folds. The Communion of the Knight is sometimes called Melchisedek and Abraham, and I believe that is right, and that it was not ignorance that represented them as figures of the time, but the wish to bring home to the people the fact that the great teaching of God's Word is for all time. In our modern efforts to represent sacred scenes as they were we often lose the spiritual lesson. In some of these figures, however, as in that of Joachim, there is an exaggerated inclination to bend and turn the figures.

The whole exterior was an inexhaustible mine of glorious sculpture. On the buttresses of the apse are figures of adoring angels, all different, invariably beautiful, graceful in attitude and noble in proportion, young and gracious, with a calm and holy joy, intelligent, delighting in their work; and the great statues in the buttresses on the south side are not less admirable. By the rose on the north transept is a charming Eve. She appears, however, to have made a pet of the dragon which she is carrying and stroking. But the west front is the glory of Reims. On the centre porch, the artist has given his figures a life and interest as well as beauty not found even at Amiens. They are combined in groups—the Annunciation, the Visitation, the Presentation. The way in which they turn to each other has in it much of the graceful action of intimate home life. In the

Annunciation the angel is turning with extreme grace to the Virgin, and in the Presentation the venerable Simeon is stretching out his arms with gentle kindliness to receive the infant Christ. The drapery again is masterly in its contrast of grand "sweepy garments vast and bold," with delicate folds on other figures, such as the aged Elizabeth. The northern portal is hardly less fine: the two angels on the left-hand side nodding confidingly to St. Nicaise between them were delightful. Now, alas! they are ruined for ever.

The centre gable represents the Coronation of the Virgin, the northern one the Crucifixion, but both were badly restored in the eighteenth century.

In the north transept are two doors. On the centre one we have the life of St. Nicaise, beheaded by the Vandals, with his sister, St. Eutropia, at his side and on the left, kneeling carrying his head, with an angel censing, and another behind. The whole scene is quite perfect in design and execution.

I propose now to take two subjects and sets of statues and trace them down through the centuries as represented in French sculpture—The Life, Death and Coronation of the Blessed Virgin and her statues; the Last Judgment and the figures of our Lord.

At Senlis is the earliest representation of the complete legend of the Coronation. The Apostles who were dispersed through the world suddenly felt themselves drawn together by a mysterious force which brought them into Mary's room where she lay awaiting death. In the third hour of the night Christ came with sweet melody and song, and in the morning her soul issued out of her body and fled up in the arms of her Son. After the burial of the body the Apostles watched by the tomb three days. On the third day Christ, with a multitude of angels, came to raise the body of His mother, and her soul came again. Thus at Senlis and Notre Dame we see the angels, trembling with reverence, gently bear up the body, which is too sacred for them to touch, on a long veil. Then follows the Assumption, and when borne by angels Mary reaches heaven, Christ seats her on the throne at His right hand and places a crown on her head.

At Laon we have an almost similar but inferior treatment of the same subject, probably copied from Senlis.

Next comes the south doorway of Notre Dame, which was in the old cathedral and replaced, slightly altered, when the cathedral was rebuilt. It is of late twelfth century date. When rebuilt it was raised and a new lintel added. It gives the history of St. Anne and St. Joachim, but a good deal mixed up with that of the Virgin and St. Joseph. Above is the Virgin enthroned. with the Child on her knees. Very Byzantine in character, she is seated, and the Child. standing on her lap with His hand upraised in blessing, is the chief and most conspicuous figure. On her left is a king, probably Louis VII., father of Philip Augustus, kneeling. On her right a bishop, standing, probably Maurice de Sully, the founder of the present Church. The elongated figure on the pier is St. Marcel.

The later north door, the Virgin's door, is perhaps the most perfect work left us by the thirteenth century. On the centre pier is the figure of the Virgin restored, but from the original which had been preserved at St. Denis. She stands on the dragon, with Adam and Eve and the Tree of Knowledge. Above her head is the Arch of Alliance, a name given to her in many mediæval litanies, as she is the link between the old and new dispensations. On the lintel are three prophets, who foretold her coming; three kings, her ancestors, on the left; on the first four voussoirs, angels censing. On the second tier comes her resurrection, treated as at Senlis. Two angels, trembling with reverence, lift her from her tomb and bear her gently on a veil; Christ, standing by the side of the tomb, is calling her to Himself, and the pensive Apostles meditate on the mystery. Above is an angel placing a crown on her head, and Christ with His hand raised in blessing. The attitudes are perfectly natural and graceful, the faces expressive and calm.

As a rule, the Blessed Virgin Mary is treated as a Queen throughout the thirteenth century, and all the emblems which are given her are those of majesty and mystery; she stands on the Burning Bush at Chartres, sits beneath the Arch of Alliance at Paris, and carries in her hand the rod which budded. But gradually this idea seems to remove her too far from sinful men who needed help. At Amiens, in the older of the two statues, she is carrying the Child on her left arm like an ordinary baby, though He holds the sphere in His left hand and is still blessing with the right: she is less the queen than a noble lady holding out her right hand as if granting a request. The other statue, the Vierge Dorée, is a charming mother playing with her Child, Who is looking at her, not out on to the world; the sphere has become a ball held in both His hands. This is perhaps the finest of all the statues of her—the modelling

of the head is perfect, the hands beautifully carved, the draperies grand in their broad simple folds. A little later, as in the Vierge de Riom, the idea of divinity seems almost to have disappeared in the laughing mother playing with the lively romping Child, and later still she becomes simply the young girl-mother looking lovingly at her little swaddled baby, as in the Virgin of Autun.*

Yet, at the same time, the sense of the infinite suffering of the mother of the Lord was growing, and on the remains of the eighteenth-century choir screen of Chartres, in the scene of the Nativity, she is represented leaning over and timidly touching the Child Who is laid, not in a manger, but on an altar in front of her. In the scene of the Presentation the dignity of the whole group is very striking, and the exquisite expression in the hand of Joseph guiding her from behind makes one feel more angry than ever with the barbarism of the eighteenth-century clergy who broke up this masterpiece and used it as paving stones.

Later still, in the fourteenth century, the time of the Hundred Years' War, the Jacquerie and the Black Death, life became unbearably sad, and the mother of the Lord became the Mater Dolorosa, Our Lady of the Seven Dolors, the Martyr of Martyrs. So in the last great works of French sculpture, the fifteenth-century groups at Solesmes, melancholy is the prevailing expression of all the faces, exquisitely beautiful but full of heart-rending grief.

Let us end by seeing, in a similar way, how the thought of judgment and the idea of the Saviour passes away from the terrors of the Apocalypse to express the divine love of the infinitely sad Saviour of mankind. At Autun the Christ who presides at the Judgment is not yet "The Son of Man." By His side is an angel weighing the souls, and a devil waiting for the lost, while an angel with a large sword keeps them off from the elect. In the lintel is the Resurrection, the saved clothed and looking up to heaven, the lost naked and weeping. Above, an angel is passing the souls of the blessed, one by one, through a window into a palace which represents Paradise. Barbarous as it is, it is full of life and dramatic feeling.

Laon, a later work, is crowded and confused and much less vigorous; but here for the first time Christ is not only Judge but the Saviour, showing His wounds.

The door of the north transept at Reims shows an immense advance. The figure of the enthroned Saviour is solemn and grand, and the drapery truly antique in its arrangement; St. John and the Blessed Virgin Mary on either side are raising their hands in humble supplication, and two angels with emblems of the Passion are kneeling behind them. The Resurrection of the Dead is depicted in two strips of relief with such life and variety that the twenty-nine little figures, in different and often very naive positions, express at once, with the utmost skill and perfect reverence, the act of raising the coffin lid and clambering out of the tomb, and at the same time astonishment, fear, pious resignation, and earnest prayer. Below are seated figures of blessed saints on the right of the Saviour; on the left the lost—partly destroyed. Below again, the lost souls are being dragged away by Satan, and the saved souls being presented to Abraham by angels, two of whom, in the most delightful way, are presenting two souls on a pair of napkins.

But finer than this in its original state was that at Paris. The lintel is modern, but the rest, though restored, is the original work. The expressions, especially the terror and despair of the lost, are very finely rendered. In the upper part is Christ, showing His wounds; the two angels with the instruments of the Passion, the Virgin, and St. John on their knees. The grouping of the figures at the top is perfect. Christ, larger than the others, is in the centre, two angels stand by His side holding the implements of the Passion, and the kneeling figures of St. John and the Virgin fill the corner spaces; but the most wonderful thing is the filling of the tiers of arches. Note the calm and breadth of the work, especially of the angels, and with the heavenly calm of the blessed contrast the rush and whirl of the other side. Note especially the horsemen of the Apocalypse, famine, and, most of all, Death. He who rides on the pale horse is here shown as a woman with blindfolded eyes. She has leaped in front of a man and stabbed him with a huge knife, so that he has fallen backward over the horse, dead and limp, while she, clinging tightly to the creature's neck, is making him rush on with outstretched head in an agony of terror.

True as the Judgment scene of Amiens is, it is confused and crowded, and does not come anywhere near the simpler beauty of that of the north transept of Reims, still less to the perfection of Paris. One alteration in particular is far from being an improvement on either. At Reims the two angels and St. John and St. Mary

* In the collection of M. Rerolles, to whom I am indebted for a photograph.

are all kneeling; at Paris the angels are standing, and St. John and St. Mary are beyond. It did not seem right for the angels to be kneeling in the former, and the two intercessors seemed too far removed from the judge in the latter. So the sculptor of Amiens placed them with outstretched arms on either side of Christ that their intercession might be irresistible. The innovation was affecting, but not happy from the point of view of art, for it was necessary to reduce the height of the angels to get them within the arch, and the result is a straight line, instead of the pyramidal arrangement which was needed to fill the triangle.

Here, first, we have the figure of St. Michael prominent. He weighs the good actions of the soul waiting by his side in one scale, its sins in another. But here, to teach the lesson that it is salvation by Christ and not man's own good works that save him, the Lamb is in one scale, in the other the head of a demon, while another demon is trying to push up the good scale.

That which is usually reckoned as the finest is the great west door of Bourges, but it has the fault of Amiens of being too crowded. The St. Michael is a charming figure, and so is the whole group of the elect making their way to the Gate of Paradise where St. Peter is sitting, representing the Church which alone has the power through the Sacraments to admit men to eternal life. Here, as at Amiens, the first to enter is a Franciscan with his triple knotted cord; the next, a king carrying the flower of a saintly life, St. Francis of Assisi, and Louis IX., slender as a knight and beautiful as an angel, who had just died. This tendency to confusion goes on increasing. We see it in the Cathedral at Rouen, and still more at St. Maclou, where, however, there is a marvellous piece of imagination described by Ruskin in the figure of the flying angel driving the lost before him, right out of the tympanum into the niches which are represented as all on fire, with a little demon in the roof of each grinning down on the lost soul below.*

Never was the soul of a people so revealed as in the great cathedrals of the Middle Ages and their marvellous sculpture. To the men of the time they spoke with a thousand voices. In them the creative power of the artist made a garland of all living things to adorn the house of God. Plants, animals, all these beautiful creatures that awaken curiosity and tenderness in the heart of the simple and the child, there grew beneath his magic touch. And there was given the key to the riddle of life, its conflict, its struggle with Nature through the labours of the months, the constant battle in the heart of every man between the evil and the good, the teaching of the prophets, the salvation through Christ, the final Judgment, and to those who have fought a good fight the angels of the heavens above hold out crowns. Conviction and faith pervade the cathedral from end to end and tell their story with a thousand tongues. Even the widest of us moderns must hear some echo of those silent voices, see some of the wondrous visions which they saw and left carved in the stone for us to learn by.

Just a few words of that lesson I have tried to set before you in hopes that you may dip further into the deeper thoughts which lie there. You will have noticed the steady change which takes place in the representations of the Blessed Virgin, of the Last Judgment, and of Our Lord—how from being only the Queen of Heaven crowned by her Son, she becomes the Majestic Matron, then the Human Mother rejoicing over her Child; in the fourteenth century the Mater Dolorosa; and, finally, in the fifteenth century and in Italian Pietás the desolate widow carrying the dead body of Christ. In the Last Judgment, and in the figures of our Lord, the stern Judge of the Apocalypse of Autun becomes the Christ showing His wounds of Laon, then the severe but pitiful Saviour of Chartres and Amiens, and the purely loving and gentle Beau Dieu of Reims, which is a work of such beauty that it may reckon as the most perfect of the most perfect period of mediæval art. It shows admirable understanding and execution of the whole form in faultless proportions, and there is such beauty in the mild calm expression of the face, that it is even finer because stronger in expression and attitude than Leonardo da Vinci's.

But gradually, as in the case of the Blessed Virgin Mary, the figures grow sadder, and later the Saviour is generally represented on the Cross, as His mother is with His dead body on her knee. But, as a transition to that, the last stage, one of the most beautiful but saddest figures of the Saviour that I know is at Troyes. What is the secret of all this? I think it is this. When the Roman world was crumbling to pieces, St. Augustine bade the suffering people look up from the perishing City of Man to the eternal City of God. They needed the assurance of the justice of God overruling the injustice and cruelty of man, that there was a divine and lasting order over and behind the shifting

* Ruskin, "Seven Lamps of Architecture."

anarchy of the world. So the idea of the great Judge and trust in the stable organisation and all-embracing knowledge of the Church were what appealed to them most. The answer to that appeal was given. That is what we find in the earlier work, in the all-embracing encyclopædic sculpture of the Church, and in the great picture in St. Croce of the Feudal Empire and the Church ruling the world side by side.

But as the world settled down and life became orderly and joyful once again, and the tenderer, womanly side of human nature was able to show itself, the love of the Virgin Mother and of the Saviour wounded for our transgressions were what found the readiest echo in the hearts of men and women. But with the fourteenth century the joy of life was clouded over again, and the sadness of the Mother for the dead or dying Son became the pity for which each individual soul was crying out, and the sorrow of the Crucified One was most in touch with the sadness of man—men no longer wanted to point, Lo here or Lo there is the orderly Kingdom of God; each man wanted to feel for himself the Kingdom of God was within him, and to have the Saviour for his very own. It was in answer to that sense of personal need that the great upheaval of the Reformation came about, and the outward material message made visible in the beauty of art became the inner invisible spiritual voice speaking in the soul of every man.

THE WORKMAN'S SHARE OF PROFITS.*

The workman says that he should have his share of the profits. What is his share under the present state of things? The average capital expended in an engineering works per individual employed is about £200. An investigation the writer made some years ago gave this figure, and it was confirmed by an investigation of shipbuilding yards, which gave £185, and of the Census of Production, which gives a capital of £1,500,000,000 for 7,000,000 workers, or £214 per man. An investigation of the dividends paid shows them to be about 4 per cent. on the capital employed. Here it must be remembered that firms paying 10 to 15 per cent. on their ordinary capital have often a large preference and debenture capital, on which a much lower rate of interest is paid, and also that often part of the ordinary capital was issued at a premium. Also account has to be taken of the large number of companies that do not pay any dividend on their ordinary stock, and often none on their preference. Little is as a rule heard of the finances of such companies; it is the ones paying good dividends that public attention is drawn to.

It thus means that the shareholders get about £8 per year per individual employed.

On the other hand, the average wages for men and boys, skilled and unskilled, is about £70 per annum in normal times. This means that the worker gets between eight and nine times as much as the capitalist, and shows on what a very small margin the capitalist works. And without the capitalist, under our present system of individualism, there would be no factories erected and run, and therefore no work for the working-man—a thing it is well for him to remember—and also that without profits the capitalist will not invest in engineering and other works in this country, but will seek for a more profitable field for his capital elsewhere. Every £200 invested in this country in a factory means work and livelihood for one British working-man.

At the same time I am sorry to say the employer does not look after the welfare of his workmen as he might. In a small factory the head of the firm, as a rule, knows all the leading men among the workmen, many of them having been with him for years. As the place grows he loses touch with his men, and as an actual fact knows fewer of those under him when he has 1,000 or more employees than he did when he had 400 or under. This state of things gets worse when the place is turned into a limited liability company, as nearly all large places are at present. The result is that a most deplorable state of things has come to pass. The workman says, "Put not thy trust in employers"; the master says, "Put not thy trust in workmen"; and the official who is between the master and the workman says, "Put not thy trust in either."

It is difficult to say what is to be done to remedy this state of things, but one cannot help feeling much might have been done in the past to have prevented such a regrettable state of affairs as there is at present. Much of this trouble might have been avoided if employers had shown more consideration for the welfare of their workmen. Of course, there are some notable exceptions, but they are few and far between. An example is the necessity of the Factory Acts to ensure proper light and air and other arrangements necessary for the health of the workmen. But much more should be done. Why is it that canteens are being rushed up all over the country, and why were there so few before? In many works to this day the provisions for getting food and drink warmed are most primitive and inefficient, and as to getting anything to eat if one has to work overtime unexpectedly, it is in most works impossible. As a rule, the only thing available was a drink at the public house outside the gates, and even this is now closed at five o'clock. Why, if a man works overtime, should he also starve? And how can efficient work be expected under such conditions?

* Extracted from the address to the Engineering Section of the British Association at Newcastle-on-Tyne by Gerald Stoney, B.A.I. (Dublin), F.R.S., M.Inst.C.E., President of the Section.

Why also should there not be provision for drying clothes after walking to work on a wet morning, and each man be provided with a cupboard where he could keep a change of boots? Why are not sanitary arrangements decently private, and why are they not kept clean and wholesome. They are often in a disgraceful state. These are only a few samples of the directions in which much might be done.

The adjustment of the wages to be paid to the workman is a most difficult one. There are three principal ways of paying workmen—on time, on piece, and on bonus.

On time is the only way of paying a man who is on various classes of work, where the fair time required for each job is not known, and in many cases the most highly skilled men are on such work and as a result only make time wages. This results often in the highly skilled man making less money than the less skilled man who is on repetition work and as a consequence is working on piece or bonus, and this is obviously unfair. For example, a man may have the setting up and adjusting of a number of machines on repetition work, and he often makes less money than the less skilled men under him who are on piece or bonus, although their nominal rate of wages is less than his.

Again, highly skilled erectors who go outside the works to erect machinery, often worth thousands of pounds, and set it to work, are only paid on time, and often make less money than their fellows who are on piece inside the works.

The adjusting of piece prices is a most difficult one. They should be adjusted so as to be fair both to master and man, but too often such fixing of prices is left to subordinate officials who have in many cases their own axe to grind. There should in every works be a special department for such fixing of prices, and once a price is fixed it should not be altered without good reason. The practice of cutting prices by the masters in the past is, in the opinion of the writer, largely responsible for the present limitation of output by the men about which we hear so much. There is a rule that if a man makes more than time and half or time and third the price of the job is to be cut. If the price has been fairly fixed why should it be reduced because the man makes large wages due to his skill and industry? The larger the output from his vice or lathe the better for the master, as he is getting a larger output from his plant with a certain capital expenditure, and thereby establishment charges are reduced. This is especially the case in machine work, as the hourly value of the machine employed often far exceeds the wages of the workman employed.

A fair rating for machine tools is 4*d.* per hour per £100 value, and as the time rating of the man is generally about 9*d.* it is easily seen that if the average value of the machine tools exceed £225, machine charges exceed time wages, and the average value of machine tools is generally largely in excess of this figure, in fact often about double it. It is therefore obvious that it is much more important to get large output than to pay small wages.

The result of this "time and half" rule is that a good man by working up to the limit of his capacity "spoils the job" for the next man who comes along, and may not be of the same calibre as the first man. It has therefore been found advisable and necessary by the workmen to limit the output of all men to a certain standard, and this results in the end by the pace being set by the slowest man on a particular job.

A fair bonus system is perhaps the ideal way of paying men; but here, again, although the times for a job are supposed to be fixed and unalterable, in too many cases they have been altered by various devices, and as a result the system is looked on with suspicion by the workman.

Gradually bit by bit the pernicious doctrine that the less work done by a man the more employment there will be has grown up, he not seeing that the cheaper an article can be produced the larger will be the sale for it and the better it will be able to compete with the products, not only of other producers in this country but of those abroad. And also that very cheapness, combined with good quality, induces the sale for such articles to be large.

Laziness is inherent in man, and *on an average* no man will work unless compelled to do so, and still less will work his best unless there is a great inducement. This is true not only of the working-man but of all other classes. Therefore the policy of "Ca' canny" has been only too readily adopted on the ground not only that it was pleasant for the man himself; but also he believed that it tended to the welfare of his fellow-workmen.

The writer has very reluctantly come to the conclusion that the workman of to-day is not doing as much work as was done some thirty years ago when he was in the shops, and not only this, but that timekeeping is not as good. In this connection, however, it must be remembered that excessive overtime inevitably leads to bad time-keeping.

FUR FARMING IN CANADA.

Attention was drawn in the *Journal* of March 21st, 1913, to a new industry which had sprung up in Prince Edward Island, viz., the breeding of silver foxes for their pelts. Some striking figures were quoted as to the value of the animals—*e.g.*, in 1911 prices rose to £1,000 a pair, and towards the time of littering in 1912 one pair sold for £4,000, while in the closing months of 1912 the prices had risen even higher. Further particulars of this industry are now given in "Canada, the Country of the Twentieth Century," a book published by the Department of Trade and Commerce, Ottawa. Owing to the value of the pelts, the demand for silver fox pups became so great that prices

steadily increased, and at the time when the war broke out five months' old pups of the best Prince Edward Island stock were selling at from $12,000 to $16,000 per pair, while old stock of proved fecundity realised as much as $35,000 per pair. When the pups could be bought at prices ranging from $1,000 to $4,000 per pair a number of farmers started fox ranches, but when the price rose to $10,000 and more it became impossible for the ordinary individual farmer to embark on the industry, and joint-stock companies were started. In April, 1914, there were in the island 194 joint-stock companies which had been organised for the purpose of breeding fur-bearing animals, chiefly silver-black foxes. These companies had an authorised capital of $31,232,700, but a number of them have not yet been floated, and probably not more than half the stock has been actually issued. Besides these companies, about three hundred individual farmers are registered as having ranches for breeding fur-bearing animals. Karakul sheep, from which the well-known Persian lamb skins are obtained, have been imported into the island by some of the fur farmers, and promise to do well. The breeding of red foxes, crosses between silvers and reds, blue foxes, minks, otters, and skunks, is also being undertaken by some farmers who cannot afford the high prices demanded for pure silver fox breeding stock.

Very few silver fox pelts have been sold in the island in recent years, owing to the great demand for breeding stock; but it is generally agreed that as the foxes on the ranches are rapidly increasing, the industry will come down to a pelt basis in a few years. It has been estimated that if prices keep up long enough to enable farmers to get back the money they have invested in fox-breeding, they could afterwards make good profits by raising silver foxes for pelts if the price of pelts should fall as low as $60. As regards the prices of silver fox skins in 1914, Mr. J. Walter Jones, who was selected by the Canadian Commission of Conservation to make a special study of the whole question of fur farming, writes: "At the present time the average price of wild silver fox skins in London is about two hundred dollars, and for ranch foxes, such as are found with the best ranchers, twelve hundred dollars. Wild silver fox skins are not always prime, and they are frequently shot, chewed, mangled and poorly dressed, while ranch foxes are usually killed when their fur is in prime condition. The highest price ever paid at the London sales for a silver fox skin was $2,900. It is said that this skin was sold by a Paris firm which had bought it at a previous sale for $1,950, and that it was from a ranched fox from Prince Edward Island. The next highest price was $2,700, and half a dozen have sold for $2,500 or more, all being from Prince Edward Island ranches. A remarkable sale was made in March, 1912, when a pelt from a fox that died in James Rayner's ranch at Kildare, Prince Edward Island, on October 12th, 1911, brought the highest price, $2,050, although the skin would not have been fully prime before December."

The fox-breeders of Prince Edward Island claim that the climate of this district is more favourable to foxes than any other known locality, and the prices realised at London auction sales would seem to bear out their contention. Other provinces in Canada, however, are following the example of the island. Up to April, 1914, Nova Scotia had issued fur farming permits to 205 individuals, 36 partnerships, and nine joint-stock companies, while 46 joint-stock fur farming companies had been incorporated in the province. At the same date 42 joint-stock fur farming companies had been incorporated in New Brunswick, and 27 permits had been issued to individual farmers. In Quebec Province fur farming permits had been issued to 21 firms and companies. In Ontario 30 fur farmers were registered; in Alberta nine fur farming companies had been incorporated; in British Columbia, two; and in Manitoba, one.

HORTICULTURE ON THE NILGIRIS.

The Annual Administration Report of the Government Botanic Gardens and Parks on the Nilgiris for the last official year contains some interesting information regarding efforts that are being made to improve fruit-growing on the hills. Surprise has often been expressed that the Nilgiris, which possess a climate so admirably adapted for the growing of all varieties of fruit—those of temperate regions as well as sub-tropical varieties—should be less well known for its fruit-growing than many places in one respect or another less favoured, such as Saharanpur, the Kulu Valley and Quetta. The reason for this seems to be that the efforts of the past have been mostly those made by private enterprise; they were spasmodic and uncontrolled, so that a promising start was not maintained. In course of time deterioration and degeneration set in, because little or no attempt was made to renew stocks, to introduce new varieties, or by plant-breeding to improve existing varieties. This applies both to the English fruit and vegetables for which Ootacamund and Coonoor and the other Nilgiri stations were once reputed. For instance, the jargonelle pears many years ago were large, luscious and delicious, and the same might be said of the two varieties of plum grown on these hills. Recent specimens of these fruits, says the *Madras Weekly Mail*, prove how they have degenerated. The Nilgiri Horticultural Exhibitions have done much to encourage horticulture and agriculture on the hills, but a great deal remains to be done.

According to the report, several choice

varieties of apple trees have been imported from South Australia, and ninety of these have been planted in the orchard in the Government Botanic Gardens, where they are thriving. The remainder were either sold to the public or planted in the orchard in Sims' Park at Coonoor. For this purpose the plantation in this park had to be cleared to provide more orchard land. In addition to the cherimoyer and the Chinese guava plots which have already produced fruit, these orchards will contain the apple trees already mentioned, peaches of several choice varieties, pears, oranges and almonds. This stocking has been going on for the past three or four years, and the experiment seems promising. When we get to the Burliar and Kullar experimental gardens, we reach a zone where the temperate climate fruits and plants give place to the tropical and sub-tropical varieties. Burliar is already known to fame as the first place in Asia, outside the Malayan archipelago, where the mangosteen and the nutmeg have prospered and produced fruit. The mangosteen crop during the year under report was a poor one, but an excellent crop of nutmegs was harvested. As there was no market for these in India, they were sent to England for sale; but the profit on the consignment was almost nil owing to high freight and other incidental charges. For the first time after its introduction in 1898 the durian has fruited. It produced a single ripe fruit of good quality. The durian trees in the gardens have flowered on several occasions, but have never set their fruit before.

PROPOSED NEW RUSSIAN RAILWAY.

The *Board of Trade Journal* contains some particulars of the proposed Obi-Ural-Bielomorsky Railway, which has been projected by the Minister of Finance and the Minister of Ways of Communication, and approved by the Russian Council of Ministers. Starting from Archangel, the line will be built to Pinega, and traverse the Ukhtinsky district, crossing the River Petchora, near the village of Troitzko-Petshersk, and will thence proceed to the port on the Obi River, in the vicinity of the Chemashevsky settlement. After the railway has crossed to the eastern slopes of the Ural Mountains, a branch line will be built from one of the stations to the Nadeshdinsky works of the Bogoslovsky Railway. The total length of the line will be about 1,000 miles.

As the railway will pass through the dense forest districts of the basins of the Mezen, Petchora, and Obi Rivers, it will greatly facilitate the exploitation of these parts, and will thereby increase the revenue of the Forestry Department, as well as promote the export trade in timber. It will also provide a cheaper route for the exports of raw materials, chiefly grain, from Siberia; and it will connect the mining districts of the north-eastern slopes of the Ural Mountains with newly-discovered rich deposits of iron ore and mineral fuel. By opening up a route to a country so rich in natural resources, but hitherto almost inaccessible, the new line will make it possible to establish factories in this territory, so that many articles now imported may be manufactured within the district.

TANNING MATERIALS IN MALAYA AND NORTH BORNEO.

A correspondent, writing in the Imperial and Foreign Trade Supplement of the *Times*, says it is a mistake to suppose that the quebracho tanning extract produced in Argentina and Paraguay, largely under German auspices, is indispensable to the British tanning industry. Quebracho extract is a very good and useful tan, and possibly some tanners in this country who are accustomed to use it would object strongly to any obstacle being placed in the way of its importation; but the fact is that the British Empire is quite capable of producing within its own borders sufficient tanning substances for its own requirements, and many excellent opportunities exist for the employment of capital and energy in the manufacture of tanning extracts at the places where the raw material grows.

The Malay Peninsula, which has come much into public notice in the last ten years, could contribute largely to the world's requirements of tanning materials. For example, on the coast of the States of Perak and Selangor there is an area of about 250 square miles of mangrove forest. At present this is a Government reserve forest and is worked for firewood only. It contains six species of mangrove suitable for the production of cutch or extract, and the bark is so far a waste product, with the exception of a small quantity used locally for dressing fishing nets and sails. The Governments of the Straits Settlements and Federated Malay States are ready to encourage the starting of new industries, and a good opening is here presented for the establishment of a mangrove extract factory.

Good progress is being made in the manufacture of mangrove cutch in British North Borneo, and the exports of extract have expanded both in quantity and value during the past year. In Borneo, as in other tropical countries, supplies of mangrove bark are practically inexhaustible, and factories erected in suitable localities can obtain their requirements of bark from the immediate neighbourhood for many years without depleting the supplies. The process used in Borneo for preparing mangrove cutch is simple. The freshly gathered bark is tied in small bundles and boiled in vats until the soluble matter has been extracted, which is ascertained by determining the density of the decoction. The spent bark is taken out, allowed

to dry in the open, and used as fuel. Concentration of the extract by evaporation is carried out in vacuum pans similar to those used in sugar manufacture. The extract is concentrated to a syrup, which on cooling hardens to a resin-like solid.

ARTS AND CRAFTS.

The Design and Industries Association.—The Design and Industries Association is showing further signs that it is an organisation which has come to stay. It has just issued its fourth pamphlet, "A Modern Creed of Work," by Mr. A. Clutton Brock; and in "The Beginnings of a Journal of the Design and Industries Association" it has published the "forerunner" of a regular periodical dealing with the doings of the Association. This, in war time, is no mean achievement on the part of a body which was only inaugurated in May, 1915. Further, Mr. Clutton Brock's paper is a statement of the aims of the Association, not only written as we should expect him to write it, but embodying a singularly sane, sensible, and at the same time noble, ideal, and pleading not merely for the joy of handwork (such pleas have been abundant in recent years), but for recognition of the fact that to do any piece of work really well is in itself a joy. What is wanted is not so much any particular form of work as a spirit of adventure and of life running through the work of the community. It is surely a recognition of the possibilities of the machine at least as much as a revival of home and peasant handicrafts towards which all lovers of art ought to turn their faces to-day. That there is a charm and a quality about good handwork which is lacking in goods produced by machinery is indeed true. But the best machine-made wares have also certain qualities of their own, and at the present moment there is a fairly plentiful supply of objects which hide under the convenient cloak of peasant art a deal of bad craftsmanship. Further, there is a certain amount of aping of handmade characteristics in machine-made goods which is truly reprehensible. In the face of all this, it is cheering to see that a society, which sets before itself the aim of harmonising "right design and manufacturing efficiency, accepting the machine in its proper place . . . as a device to be guided and controlled, not merely boycotted, by those interested in the production of worthier and more beautiful things," is making good progress. The announcement that the Arts and Crafts Exhibition Society have placed a space at the disposal of the Design and Industries Association at their forthcoming exhibition at Burlington House, and that the Association proposes to show a collection of domestic pottery and china is a very welcome piece of news. The Arts and Crafts Society has not always been noted for the judicious selection and arrangement of its pottery exhibits, and the Design and Industries Association includes amongst its members one or two men at least who should be able to ensure that the proposed show of ceramics will be up to a high standard as pottery no less than as art. Perhaps there is no branch of manufacture in which the cry for handmade or hand-finished work has led to more unsatisfactory results. This is peculiarly unfortunate, as the pottery trade, besides being an important British industry, is also one which does a considerable export business, not only with Europe but also with America.

Handweaving and Embroidery.—Handweaving and embroidery have been much talked about lately. For some time past, of course, they have been in the forefront of the industries associated with the Home Arts and Industries Association and the Peasant Arts Association, and weaving has, further, been suggested and tried with some success as a suitable form of employment for the crippled and the blind. Now it is being further urged that hand-loom weaving is an excellent occupation for girls who have made shipwreck of their lives, and that embroidery offers a good opening for wounded sailors and soldiers, many of whom are wonderfully skilful with their fingers. There is, no doubt, a great deal of truth in all this. The two crafts are obviously within the capacities of those who it is suggested should be encouraged to practise them, and there is, moreover, a certain demand for such work. On the other hand, there seems to be a very reasonable doubt whether that demand is capable of very much growth, or whether even it may not be slightly artificial—the outcome of a desire, sincere enough but not necessarily very strong or persistent, to help forward some pet scheme or other, rather than to possess or use hand-woven or hand-embroidered fabrics. We have to bear in mind that such materials are, in the twentieth century and in this country, rather in the nature of luxuries. They are bought, not because they wear longer than machine-made goods, but because to some people they are more pleasing, and therefore worth paying more for. At the moment people are willing in the interests of a cause to buy them, but it seems doubtful whether, with increased taxation and the higher cost of living, this state of mind can go on indefinitely. It is still more improbable that it will spread to larger sections of the community. Again, we have to remember that it is not only the conditions of life in our own country which have to be considered. Before the war there was enough interchange between the various countries of Europe for Russian, Scandinavian, Italian, and other peasant work to find a market in this country. The little exhibition held in June at Cromwell Road, of the work

done by the Serbian refugees at Corfu, which consisted for the most part of very interesting and characteristic peasant embroidery, served to remind us that after the war we shall in all probability be confronted with work from the Balkan States. Again, Transylvania and some of the Slav districts of Austro-Hungary, though comparatively few English people seem to realise it, are extraordinarily strong in peasant embroidery, and in all these lands labour is comparatively cheap. There may possibly be an increasing opening in this country for the practice of hand-loom weaving and embroidery, but there is certainly the danger that such work will tend to be paid at a rate which will bring it within measurable distance of sweated labour. It is to be hoped that philanthropic folk will pause and consider the possibilities before they encourage any considerable number of people to turn their attention to these occupations.

GENERAL NOTES.

The Institute of Metals.—The annual autumn meeting of the Institute of Metals will be held on Wednesday, September 20th, commencing at 4 p.m., in the rooms of the Chemical Society, Burlington House, Piccadilly, London. Sir George T. Beilby, F.R.S., LL.D., will preside, and a number of important metallurgical papers will be presented and discussed. These include: (1) "The Allotropy of Silver," by Dr. W. D. Helderman (Utrecht University, Holland); (2) Note on "Cadmium in Spelter," by W. R. Ingalls (New York, U.S.A.); (3) "The Annealing of Arsenical Brass containing 61 and 62·5 per cent. of Copper. A Study of the Structure and Properties Developed by Varying the Rate of Cooling within the Transformation Range," by C. H. Mathewson and E. M. Thalheimer (Yale University, U.S.A.); (4) "The Development of the Spelter Industry," by Ernest A. Smith, A.R.S.M. (Sheffield).

The "Englishwoman" Exhibition of Arts and Handicrafts.—This Exhibition will be held at the Central Hall, Westminster, from November 15th to 25th. There will be exhibits of hand-weaving, wood-carving, stained glass, embroidery, lingerie, enamelled glass, pottery, statuettes, water-colour drawings, etchings, calligraphy and illuminating, miniatures, jewellery, pewter, lace, toys, model buildings, leather work, Armenian needlework, silver and metal work, feather work, antiques, gardening, dressed dolls, Chinese lacquer, bookbinding, tapestry rugs, hospital supplies, basket work, bead work, hand-painted buttons, artificial flowers, bread-making, war relics, sweets, needlework, stencilling, artistic dress, etc.

A Tree-felling Steam-saw.—A description is given in the *Engineer* of a tree-felling steam-saw made by Messrs. A. Ransome & Co. It consists of a steam cylinder 5 in. in diameter and 19 in. stroke. It is pivotally attached to a light wrought-iron frame of triangular shape, so that the saw can be fed up to its work by means of a hand-wheel worm and quadrant, the latter being attached to the cylinder. The saw-blade is fixed to the piston-rod and the teeth are designed to cut on the inward stroke only. During some tests recently conducted steam at 100 lb. pressure was obtained from a portable 2 ft. 9 in. by 6 ft. 3 in. Spencer-Hopwood water-tube boiler, through the medium of flexible metallic tubing, covered with felt and canvas to minimise condensation. Some Scotch fir trees were selected, of about 24 in. in diameter. The process of felling each tree occupied only some three or four minutes, and it is claimed that one machine, attended by a gang of four men, will do more work than thirty woodmen.

Cement in Malaysia.—In his annual report on mining in the Federated Malay States, Mr. W. Eyre Kenny, Senior Warden of Mines, expresses regret that more cement is not manufactured locally, as excellent materials are available. This fact should be noted by those who are seeking an outlet for the employment of capital after the war, for with plenty of raw material within easy access, first-class transport facilities, relatively cheap labour, and a ready market throughout the Far East, it should not be a difficult matter to establish a profitable industry within a short space of time. The Batu Caves Cement Works, in Selangor, quarried 8,825 tons of limestone in 1915, and manufactured 5,725 tons of cement, all used locally, with the exception of 712 tons exported. The statistics of the Federated Malay States show that cement to the value of £40,000 was imported in 1915; but this was much below the average, owing to the restrictions imposed by war conditions on public works. In 1914 the value of imported cement into these States was £89,846, and in 1913 £91,674. A reference to the trade statistics of the Straits Settlements, however, gives a better idea of the requirements of this region, and from these it is found that the imports of cement were valued at £226,450 in 1912, £248,150 in 1913, £194,714 in 1914, and £210,253 in 1915.

Correction.—Mr. James Watt points out an error in the figures for the proportions of theine or caffeine in green tea, black tea, coffee, and maté, quoted on p. 701 of the *Journal* of August 25th. The figures, viz., 4·30, 4·60, 2·66, and 2·30 were given as parts in 1,000 on the authority of the report of the United States Consul at São Paulo, but they should have been given as percentages.

PROCEEDINGS OF THE SOCIETY.

FOTHERGILL LECTURES.

SURVEYING, PAST AND PRESENT.

By Edward A. Reeves, F.R.A.S., F.R.G.S.,
Map Curator and Instructor in Surveying to the Royal Geographical Society.

Lecture I.—Delivered March 27th, 1916.

HISTORICAL SKETCH.

When I was asked to come here and talk to you about surveying, I at first hesitated, chiefly because it seemed impossible to deal with the subject in a few lectures in a way that would be profitable or interesting. But upon further consideration I came to the conclusion that, after all, there were aspects of the subject which are not usually dealt with in text-books, and as my somewhat lengthy connection with the Royal Geographical Society has necessarily afforded me exceptional opportunities for coming into contact with travellers and geographical surveyors from many parts of the world, perhaps I ought to be in a position to say something not to be readily found elsewhere—so finally I decided to accept the honour of addressing you.

Surveying is a large subject, and one of which there are many branches. There is ordinary land surveying with the object of producing plans of property, or cadastral maps, for revenue purposes; railway and road surveying; mine surveying, and other departments of the subject which are generally limited to comparatively small areas, and are undertaken by the civil engineer in connection with some special work he has to carry out. But there is also geographical surveying, which has for its object the fixing of positions on the earth's surface, and the production of maps, often of previously little-known regions, giving a representation of the general geographical features.

It would be useless to attempt to deal with all of these in the space of three short lectures, and I therefore propose to restrict myself almost entirely to the latter with which I am more intimately connected, and to treat the subject in a general way without going at all into details.

In these three lectures I propose (1) to give a brief historical sketch of the way in which geographical surveying was done in early times, and the methods and instruments of the surveyors and explorers of those bygone days; then (2) to consider the present survey basis upon which maps of various parts of the world depend, the progress made in recent years, and the work remaining to be done; and finally (3) to give some account of present-day survey instruments and methods.

The acquirement of all knowledge has been progressive, sometimes moving slowly, at others more rapidly, but ever advancing; and this is specially true of the subject we have to consider. Our present knowledge of the earth's form, size, the configuration of its surface features, their measurement and representation on maps, is the result of many centuries of strenuous endeavour and conquest over obstacles, and at times over apparently insurmountable difficulties, the record of which constitutes a striking monument to indomitable courage and perseverance such as cannot be excelled in the history of mankind.

Of all branches of human research and discovery, that of geographical exploration and the measurement and representation, in some fashion, of the surface features of the earth is doubtless one of the oldest—in fact, it is difficult to imagine a time in the history of intelligent man when it did not in some manner exist, however rough and crude the attempts may have been.

The earth's surface is the present dwelling-place of man, and however high or far he may soar in imagination and thought, as to his bodily presence he is restricted to the surface of the comparatively small planet he inhabits. By his very nature he is an adventurer and a restless wanderer; and since his physical constitution does not permit of his travelling more than a very short distance vertically,

his only chance of expansion is horizontally or laterally, and geographical investigation and measurement was a natural consequence.

From the very earliest days there would arise the need of some sort of maps, and boundary questions, and limits of pasture lands and of irrigation rights would have to be settled; so that it is quite impossible to say when surveying commenced. From the rudest and most elementary beginnings it has, like all other departments of knowledge, slowly advanced as the centuries have passed and greater accuracy was required, until it has reached the refinement and exactitude which characterises it at the present day.

Probably the earliest attempts were those which naturally resulted from the necessity of representing in some sort of plan the limits of a man's private property, and an interesting example of this is the plan of an ancient Egyptian villa, evidently made from measurements, taken from a Theban tomb of the eighteenth dynasty, and given in Maspero's "Dawn of Civilisation." This must have been constructed more than 3,000 years ago, and is partly a plan and partly a perspective view. Another very old plan is that preserved at Turin, which represents the Wadi Alaiki, where the Nubian gold mines were situated, possibly dating back to about 1370 B.C.

A careful reader of the account of the dividing of the land of Canaan among the various tribes of Israel can hardly fail to come to the conclusion that Joshua had some sort of a map of the land before him when he proceeded to apportion the various districts, the boundaries of which are so minutely and carefully described; and it is also more than probable that he and the others who had been sent beforehand to spy out the land, as Gore says in his "Geodesy," "had in view quantity as well as quality," which implies some kind of rough survey and sketch map.

However this may have been, it is clear that at the period of their wandering in the wilderness the Israelites were familiar with measurement and planning; for the account given of the construction of the Tabernacle, with the details of its dimensions and the measurement of the land it was to occupy, with that of the surrounding encampment, is clear evidence that this was no new subject even at that time. How far this knowledge was obtained from the Egyptians or from some other source, and exactly what instruments and methods were employed, it would be interesting to learn.

At a later period we have the vision of "the man that had the measuring line in his hand," measuring out his thousands of cubits apparently much as a chainman does his work to-day.

So long as the district concerned was of no great extent, there could have been little difficulty about making a rough plan or map of it. For linear measurements of distance, the most natural units would be the lengths of various parts of the human body. The cubit, the pace, the foot, and the span were evidently amongst the earliest standards of all; and most of these have remained in use until to-day. With these, and an elementary knowledge of some of the simpler geometrical figures, it would be easy for quite useful plans to be constructed, as we know was the case. The longer distances were reckoned in time—the number of hours it took to travel between places, days' journeys, etc.; and later on in other measures such as the Greek stadium, of which it is generally understood there were 600 to a degree.

For comparatively short distances, when distinctive features were visible, there would be little difficulty in mapping roughly a route travelled, much as a man at the present day can make an approximate sketch to show any journey he has taken, without a compass or other instruments, or the Esquimo and other natives have drawn rough sketch maps to explain to explorers the direction any coastline follows.

A good example of this is the rough map of part of the west coast of Greenland, drawn by one of the Esquimos from his own knowledge and from that gathered from other natives on board H.M.S. "Assistance" during the winter of 1850–51; and a more recent example of the same kind of thing is a map of the tributaries of a river in Papua, sketched in the sand by a native chief for Mr. Beaver, who was exploring this region.

It is easy to understand that by following round coastlines, after repeated voyages, quite passable charts would be made by early navigators, as indeed we know was the case.

Long before the magnetic compass was known, at any rate in Europe, navigators and travellers had to find their way somehow, often through little-known regions; and when they had no landmarks to direct them they would have to seek some other means of guidance. Early nomad people of the desert would soon become acquainted with the heavenly bodies and their general movements and positions, and would naturally turn to these for the direction they sought. Their positions at certain seasons would, through being continually observed, become quite familiar, and so doubtless before

any instrumental astronomical observations were made men learned to march and steer their ships by the sun by day and the stars by night; and by such means routes would be roughly sketched on maps, and the tracks of vessels and coastlines of newly discovered lands laid down.

The heavenly bodies are the natural guides of the traveller, and the accuracy by which a path through the trackless desert can be found by natives accustomed to using them is often astonishing. Travellers in modern times have frequently borne testimony to this.

It is interesting to note that marching by stars is now receiving increased attention, and during the present war has proved invaluable to those who have taken the trouble to learn a little about it beforehand.

So long ago as the seventh century B.C., Thales, the Greek philosopher, had taught the Ionian sailors to use the stars and to steer by the Little Bear, as did the Phœnicians. According to Herodotus, the Phocæans were the first Greeks to undertake long voyages, and one of the most important exploring expeditions of ancient times was that of Pytheas, the discoverer of Britain in the fourth century B.C., who had not only learnt to sail by the stars, but to determine the latitude of points throughout the voyage by astronomical observations made with a gnomon or sort of sundial. The gnomon in its earliest form consisted of an upright rod, and was used for roughly determining time and the distance of any place from the equator, or the latitude. At the summer solstice, when the sun reached its greatest declination, at any place on the Tropic of Cancer the sun would be vertical at noon, and no shadow would be cast; hence the distance from the equator to the place where no shadow was cast was the same as the declination of the sun, or $23\frac{1}{2}°$ N. The distance to anyplace north or south of this position on the earth could then be computed from the length of the shadow cast by the gnomon. The invention of the gnomon is often ascribed to Anaximander, who was born in 612 B.C.; but it appears to have been in use among the Chaldeans long before this time, and probably all he did was to introduce it into Greece.

The gnomon used by Pytheas was doubtless of the simple form; but Aristarchus in the third century B.C. introduced a decided improvement in its design as an instrument for determining latitude, called the scaph, which deserves to be borne in mind by all surveyors, since it seems to have been the first instrument by which angles could be measured directly without computation. He substituted for the flat disc or plate a hemispherical bowl, in the centre of which an upright rod was fixed equal in length to the radius of the bowl. Concentric equidistant semicircles were drawn on the interior of the bowl, and these became a scale for the measurement of angles of altitude as indicated by the shadow of the rod or gnomon.

The voyage of Pytheas is of special importance, since it shows that even at that early date serious attempts were made at carrying out geographical surveys or exploring expeditions by sea on scientific lines. Sir Clements Markham gave an interesting paper on the voyage in Vol. I. of the *Geographical Journal*, which I would recommend anyone wishing to learn more of the subject to read.

In early days the earth was supposed to be divided into parallel zones within any of which the day was taken to be of the same length—one zone from twelve to thirteen hours, the next thirteen to fourteen hours and so on. These zones were called climates, from the Greek word "klima," a slope. From the comparative length of the day at any stated time of the year, such as the summer or winter solstice, the distance of the place north or south of the equator could be roughly computed. This was the usual method of determining latitude, and the one which Pytheas seems to have frequently followed; but in determining the latitude of Massilia (Marseilles) as a starting-point for his voyage he worked on improved lines. At the longest day, when the sun would be vertical at noon in the latitude of the Tropic of Cancer, and so no shadow would be cast on the dial, he found that the shadow of the gnomon measured $41\frac{4}{5}$ divisions of the 120 divisions which he had marked on the gnomon from which, by proportion, the altitude of the sun could be deduced as 70° 47′ 50″. When the semidiameter and the proper declination are applied this meridian altitude gives practically the true latitude of Marseilles, which is certainly remarkable, considering the roughness of the method, and must be more by chance than anything else.

Leaving Marseilles Pytheas sailed through the Straits of Gibraltar, round the coasts of Spain and Portugal, France, Belgium and Holland, thence up the east coasts of England and Scotland as far as the Orkney Islands. Latitude observations were taken at a number of places, and the expedition added a vast amount of new geographical information, and greatly improved the maps of the time.

The first record of anything that could be considered as geodetic surveying was the well-known attempt of Eratosthenes to ascertain the size of the earth by the measurement of an arc of the meridian. This wonderful old philosopher was born in Cyrene in 276 B.C., and was so noted for his learning that he was put in charge of the famous library of Alexandria.

The method he adopted was much the same in principle as that upon which geodesists work at the present time. Two places north and south of each other must necessarily be on the same great circle passing round the earth, and the task Eratosthenes set himself was to find the circumference of this great circle.

Supposing Alexandria and Syene (Assouan) to be exactly on the same meridian, he found that the difference of the angle cast by the shadow of the gnomon at midday at the two places at the time of the summer solstice was 7° 12′, and taking the linear distance between the two places to be 5,000 stadia, and multiplying this by 50, which was the proportion of the measured arc to the whole circle, he obtained 250,000 stadia as the circumference of the earth.

As there is a question as to the length of the stadium used by Eratosthenes, it is impossible to say what the degree of accuracy was; but if, as some have supposed, it was $\frac{1}{700}$ part of a degree, the circumference obtained would be only about 200 miles in error; but if, as is more likely, the ordinary Greek stadium was used, the error would be much greater. Apart from the rough method of measurement, there were many sources of error, one of which was that of assuming Alexandria and Syene to be exactly on the same meridian, so that no real accuracy was possible; but that at such an early date an attempt of the kind was made at all, and on lines similar in principle to those of the present time, is most remarkable.

This was the beginning of other attempts; and about 200 years later Posidonius undertook the solution of the problem by measuring an arc of the meridian between Rhodes and Alexandria, using the star Canopus instead of the sun, which ought to have given a better result; but as so few particulars are now obtainable, it is not possible to say with certainty how near to the true measure the result was.

The subject of the true figure and dimensions of the earth is a most important one in many respects, and greatly affects survey questions, since it must form the basis of all exact measurement on the earth's surface. Right on to the present day geodesists have been working at it, and although they have brought down the probable error in the measurements to what must be almost a minimum, yet even now the question is not finally settled.

As regards the maps of very early dates, it has always been a question as to how far they were the outcome of vague information collected by travellers without any attempt at instrumental measurement, and how far they were based upon some kind of route surveying and astronomical determinations.

At sea, as has been shown, occasional observations were made to determine the latitude, but the actual charting of the coastline, it is more than probable, was sketched in in the roughest possible manner, with little or no assistance from any kind of instruments.

After repeated voyages the navigators would naturally obtain a fair acquaintance with the general configuration of the coastlines with their bays and headlands, and be able to draw a fairly accurate chart. These rough sketches were sent from one to another and copied by hand by cartographers; so in course of time quite a fair representation was produced. It is indeed remarkable how good some of these old charts were.

As might be expected, now and then serious mistakes were made in the fitting together of various sections of charts received from different sources. This was probably due to the fact that in many cases they were rough copies from other copies of the originals, and with no proper means of settling the orientation the chart would be likely to be fitted on to another at quite a wrong angle. This is doubtless the explanation of some of the grosser errors in many of the old maps. For instance, in the early editions of Ptolemy (1472–1490), to the north of England there is a remarkable mass of land running something like east and west, and projecting a long way in the former direction. This is doubtless meant to be Scotland, but it is difficult to see how it could have got so wrongly drawn. Yet if we suppose the whole mass turned round at right angles, so that the part that projects to the east is placed to the north, we get a much better representation. There seems little doubt that somehow or other the whole thing has got wrongly joined on to England. In later editions this error has to a great extent been corrected.

Much of the same kind of thing frequently happens even at the present time, and one of the chief difficulties that a cartographer has to contend with is this question of orientation

A man makes a compass traverse of his route, or of some new river, which may be fairly accurate in itself, but through some mistake in his azimuth observation, or the compass variation, when it is fitted to existing work it gets turned round the wrong way.

A rough latitude could always be obtained from observation, but it was quite another thing with regard to longitude. Even at the present day there is far more uncertainty about a longitude observation than a latitude, and in early days, before the construction of accurate chronometers, to obtain the difference of longitude (or time) between two places accurately was a problem which could not be properly solved with the rough instruments and tables available, although the principle may have been understood. Consequently the longitudes on early maps were generally very wrong. The tendency was to sketch out the maps too far in an east and west direction, as the distances travelled were, as a rule, overestimated owing to the windings of the course and the unevenness of the ground not being properly allowed for. The same difficulty still holds good in all route traverses uncontrolled by fixed points, and almost invariably the distances given are too long. Still, it should always be remembered that but for the spreading out of the continent of Asia far too much to the east, Columbus might never have been led to suppose that he could reach the Indies by sailing west, and so not have undertaken his famous voyage across the Atlantic.

It has been a much disputed point as to whether Ptolemy's great geographical work, in its original form, had any maps at all. It was written somewhere about A.D. 150–160; but the first edition that we are acquainted with, with the maps, is of a date long subsequent, late in the thirteenth century A.D.

The original work contained long lists of latitudes and longitudes of places which have frequently led to the overestimating of the accuracy of their determination, and to the conclusion that quite a large amount of astronomical fixings and instrumental surveying had been done, even in the most out-of-the-way parts of the world, so long ago as that early date; but, in truth, there seems to have been nothing of the sort. Ptolemy collected what information he could at Alexandria from travellers in all parts of the world, and from the data thus obtained he drew maps which were no doubt far superior to others up to that time. It is then supposed that he drew latitude and longitude lines of a sort on maps, and afterwards made his tables of the positions of places from these, for ready reference and the use of other geographers.

Still, Ptolemy was fully alive to the importance of astronomical observations for the fixing of places, as (quoting from Nordenskiöld's Facsimile Atlas), he says in his geography (second chapter): "In the first place it is advisable to procure access to the journals of intelligent travellers who have visited distant countries. Their observations may be only of a geometrical character, *i.e.* only giving distances between different places, or they may be founded on observations made of celestial bodies by means of instruments for the measurement of the

FIG. 1.—ASTROLABE.

altitude of stars, and the length of the shadow of the gnomon. It is only with the aid of such instruments that the bearings and distances between different places can be determined."

The best known of all the old instruments is the astrolabe (Fig. 1), which is generally supposed to have been invented by Hipparchus about 150 B.C. Ptolemy and many others introduced modifications in it, some of which were doubtless improvements, while others, as is the case with many so-called improvements to surveying instruments of recent times, were of doubtful value, or merely unnecessary encumbrances.

In the hands of the Arab geographers specially the astrolabe became a most complicated affair, and contained much that was more concerned with astrology than astronomy. It remained in some form or other the principal instrument for astronomical observation and

determining of positions until the time of the great Portuguese navigations of the fifteenth century. The famous Portuguese "Junta," or committee appointed to consider the question of instruments and methods, very wisely decided to clear off all these unnecessary encumbrances, and finally produced an astrolabe much simpler in form and more generally suited for the work it had to do.

I have always admired the action of the Junta in clearing away the useless accretions that had gradually grown to the astrolabe and making it a more practical instrument, and often feel that it would not be a bad thing if some such committee could be found to deal in a similar way with modern instruments, for in the case of many of them there is much that rather tends to encumber than facilitate operations when put to a practical test. My experience has been that an instrument that is supposed to do many different things does nothing at all properly, and that the simpler a thing is the better.

Divested of all elaborations the astrolabe consisted of a somewhat heavy metal disc, varying in size from a few inches to over 2 ft. in diameter, suspended by a ring from the thumb, or, in the case of the larger instruments, hung on some sort of tripod arrangement. Pivoted at the centre was the movable sighting ruler or alidade, through the two ends of which the sun or stars were sighted; and the altitude was measured off on the graduated circle round the circumference of the disc. There was, of course, no vernier, and since the circle was only divided into degrees it was merely by estimation that readings closer than a degree could be obtained. There were on many of the astrolabes scales called the Umbra Recta and Umbra Versa, by means of which heights and distances of terrestrial objects could be approximately obtained.

These consisted of two scales, one at right angles to the other. The scales were divided into 100 equal parts. When the distance was known and the number of divisions on the vertical scale or Umbra Recta measured by the alidade, the height could be roughly computed by proportion. In the same way the distance could be found, when the height was known, by using the Umbra Versa, or horizontal scale. This was really a rough method of the trigonometrical computation of the present day, and when the angles subtended were not more than a few degrees, the fact that the divisions on the scales were all equal instead of being tangents would not introduce any very serious error.

Triangulation, as we understand it, that is the computation of the lengths of sides of triangles from a known base-line and measured angles, so far as is known did not come into use until the beginning of the seventeenth century, when Willebrord Snell, a mathematician of Amsterdam, carried out the computation of his arc of the meridian; but from the days of the Greek philosophers there seems to have been some sort of graphic triangulation in general use for land surveying; indeed, it would be difficult to believe otherwise when we remember the great advance that had been made in all matters connected with geometry. As to the instruments used for this very little definite information is available.

By some the diopter is supposed to have served some such purpose, but no one really seems to know now what this old instrument was like, although it probably resembled in its main features the diagrammatic sketch which is given in Laussedet's "Recherches sur les Instruments."

An interesting instrument, known in later times as Ptolemy's rods, was of very early date, certainly going back to the time of the famous Alexandrian geographer and astronomer, if not before; it deserves some attention, since it was used for obtaining the altitudes of heavenly bodies, and so the latitude. It consisted of three rods or rulers, one of which was held vertical, another directed towards the object whose zenith distance was to be measured, whilst the third gave the distance between the fixed points on the other two.

During the mediæval ages things were at a standstill, or rather went back, as regards all scientific pursuits, at any rate in Europe. This in a special manner affected geography and map-making. The advance that had been made by the Greeks was arrested, and the knowledge they had gained was lost sight of; so that instead of the maps being improved by more accurate surveys of explorers and travellers they were frequently drawn in monasteries by monks from imagination distorted by religious bigotry. The very idea of the spherical form of the earth was considered contrary to Scriptural teaching; Jerusalem was placed in the centre and other cities and countries at a distance and in positions assigned more at the will of the draughtsman than from any idea of geographical accuracy. The interiors of the least known parts, such as Africa, were filled by mythical monsters, and the whole became so crude and misleading that, instead of marking

any progress in geographical discovery, they are only interesting to the student as curiosities.

Map-making fared somewhat better in the hands of the Arabs, as will be seen from the Edrisi map of the world of 1154 A.D.; but many of their maps seem to have been made under the fixed impression that the outlines of all parts of the world must be formed by straight lines and arcs of circles drawn with a ruler and compass. An example of this is the Istakhri map of the world of 930 A.D. As time went on things began to improve, and some of the maps were quite creditable productions for the time.

It was not until the latter part of the fifteenth century, the time of the great Portuguese and Spanish discoveries, that there was any real advance, but then Europe seemed to awake out of a long sleep, and a grand new start was made.

It is no part of my plan in this lecture to attempt to describe the Portuguese voyages which resulted in the circumnavigation of Africa and the opening up of the sea route to India and the Far East, and I refer to them only in connection with the improvements that they called forth in the construction of instruments and methods of determining positions on the earth's surface.

One of the first acts of King John II. of Portugal (1481–1495), whose memory deserves to be equally held in respect with that of his great-uncle Prince Henry, was to bring together the "Junta," a committee of men noted for their learning in astronomy and navigation, to consider the best means of finding the latitude when the Pole Star got too low to be of service, and to decide upon the most suitable form of instrument for taking meridian altitudes. One of its members was the remarkable Martin Behaim, who is chiefly noted for his famous 1492 globe.

A learned Jew (converted to Christianity) named Abraham Zacuto, formerly professor of astronomy at Salamanca, came to Portugal about this time, bringing with him a work in Hebrew entitled "Almanac Perpetuum," which contained tables of the sun's declination required in the computation of the latitude. This almanac was translated into Latin by one Moses José, an eminent member of the Junta, and was published in Leiria in 1496. It perhaps deserves to be called the first "Nautical Almanac," and was of the greatest service on these early exploring voyages, since by its use far more accurate results could be obtained than was hitherto possible.

But equally important was the astrolabe, which has already been referred to. All the unnecessary elaborations were cleared away, and a simplified instrument much more suitable for the measure of altitudes was provided.

Equipped with the new tables and the improved astrolabe, the Portuguese navigators started on their famous voyages with a much better chance of accurately fixing positions of places than their predecessors.

The vernier had not yet been invented, and the difficulty of obtaining accurate readings of the circles was still considerable. To overcome this difficulty it was decided to construct astrolabes with very large circles, and the instrument carried by Vasco da Gama on his famous voyage round the Cape in 1497 was over 2 ft. in diameter. The size of the instrument certainly made it unwieldy and awkward to use, and it was found necessary to suspend it from some sort of stand, which meant that it could not have been used with much success on board ship. Vasco da Gama seems to have been fully alive to this, and so we find him, when he arrived at St. Helena Bay, not far from the Cape, bringing his instrument on shore. His observation and method of obtaining the latitude of this spot is of considerable interest. The sun's altitude measured 76° 20′, which gave a zenith distance of 13° 40′. He then turned to tables, and found that the sun was in 26° of the sign Scorpio, to which corresponded a declination of 19° 21′ S., so by adding this to the zenith distance he found the latitude, which he took to be 33° 0′ S.

I have recently tried to find out how near this result was to the truth, but it seems to be difficult to say exactly where the instrument was erected. If we take the head of the bay as the spot the error seems to be 13′, since this point as given on the latest Admiralty chart is 32° 47′ 0″ S. This error appears somewhat larger than might have been expected, but still, taking all things into consideration, it was not so bad after all. The possibilities of error from such instruments and methods are many, and it is an interesting question as to what sort of a result might reasonably be expected. To try and arrive at some conclusion as to this matter, on several occasions I have made altitude observations with rough home-made instruments of the astrolabe type, and have found that with care it is possible to get a latitude with an error of something like 5′ to 7′, taking the mean of several readings. With a circle divided only into degrees it is, of course, necessary to estimate

the subdivisions; but if several observations are taken in rapid succession it is possible to obtain a fair idea of the sun's meridian altitude, even with very rough instruments of the clinometer type.

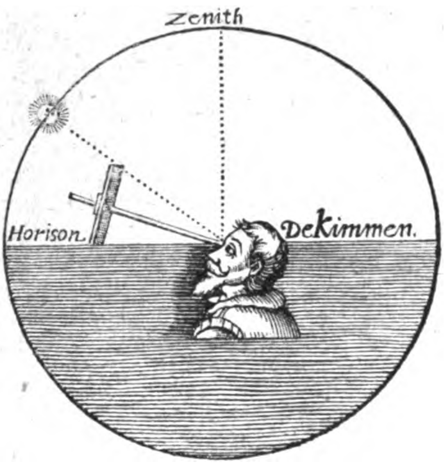

FIG. 2.—CROSS STAFF.

I have frequently heard surprise expressed at the accuracy of the results obtained by early navigators and explorers; but I feel sure that most of us, with a little practice, could have done what they did in this matter.

The old cross staff, shown in Fig. 2, was certainly an ingenious instrument, although the altitudes obtained with it must have been decidedly rough.

It consisted of two rods or pieces of wood at right angles to each other. The shorter piece had a hole in the centre, and was made to slide along the other. The eye was placed at the end of the long piece, and the sliding piece, or cross, was moved until one end of it cut the sea horizon and the other the sun. The degree of altitude was then read off on the longer rod, which was graduated and numbered. This appears to have been an instrument in common use by navigators in the sixteenth and seventeenth centuries, and even before that. The earliest known description of it is by Levi ben Gerson, a Babylonian Jew, in 1342 A.D., but whether he was really the inventor appears to be uncertain. Fig. 2, of the cross staff, is taken from Peter Goos' "Sea-Mirror" of 1658. The man using the instrument appears to be up to his eyes in water; but this is doubtless only an attempt to show the horizon line level with the eye—at any rate, we will hope that it was not really necessary to have a cold bath of this kind to use the instrument. It was not only for observing vertical angles that the cross staff was used, but for measuring horizontal and oblique angles as well.

The famous old British navigator and Arctic explorer, Captain John Davis, of the sixteenth century, constructed an instrument which was a decided improvement on the cross staff, which was used for years after and was known generally as the back staff. The great advantage of this instrument was that it enabled a man to take an altitude with his back to the sun instead of facing it. It certainly must have been no easy matter to have observed at all accurately with the sun shining in the face. Fig. 3 is a view of Davis's back staff, or quadrant, by which name it was also known. It consisted of a combination of two arcs, or a chord and an arc, upon each of which was a movable sight. The sight on the small arc was set to any convenient angle, say 30° or 60°, and then, with his back to the sun, the observer looked through the lower arc at the horizon line, at the same time adjusting the sight until he saw the sun's rays through the sight on the upper arc cutting the horizon line.

With such rough instruments all the early survey work was done. Captain John Davis, the daring old navigator who ventured far into the Arctic regions of America and discovered the Strait that still bears his name, deserves to be held in high esteem by geographical surveyors of all times; for not only did he improve the instruments of his day, but wrote a work, entitled "The Seaman's Secrets,"

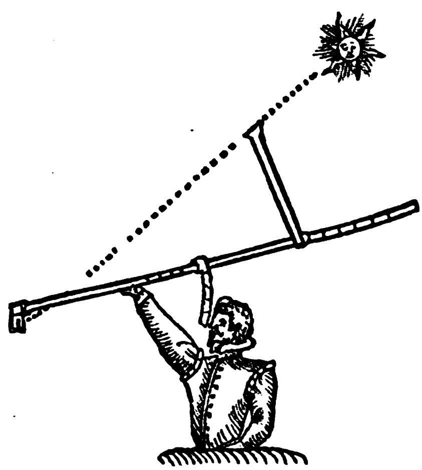

FIG. 3.—DAVIS BACK STAFF.

which was for a long time one of the principal guides to the subject of navigation and practical astronomy. He was also the first to introduce into this country the method of determining

longitude by lunar distances — a method that was most valuable before the perfecting of the chronometer, since it gave the Greenwich time. Captain J. Cook used it extensively on his surveys; and when the reflecting sextant came into use and better lunar tables were published, it was possible by this means to get a longitude at sea with greater accuracy than by any other. In fact, until quite recently it has been employed; but now, like all such methods, it has become obsolete, and for some years past the lunar distance tables, which used to form such a conspicuous part of the Nautical Almanac, have ceased to appear, although the method is still referred to, and directions given for working by it, if anyone wishes to do so.

The coming into general use of the magnetic compass not only made a wonderful difference to navigation and exploration by sea, by enabling the navigator to launch out boldly into the unknown with confidence, but soon began to leave its mark on land surveying and geographical exploration generally. Much has been written on the invention of the compass, and many have been the disputes on the subject; but it was certainly in use in the Mediterranean countries of Europe as early as the twelfth and thirteenth centuries. The date when it was first used for land surveying is not exactly known, but it was doubtless earlier than the sixteenth century.

FIG. 4.—PART OF SAXTON'S MAP OF SUSSEX, SURREY, AND KENT.

The magnetic compass in some form or another has perhaps done more for rough exploratory surveying than any other instrument; and is, of course, still extensively used when it is impossible to carry out a more accurate survey.

As regards land surveying, it was impossible to obtain anything approaching accuracy according to modern standards before the introduction of triangulation. Independent astronomical determinations are all very well, but cannot approach the accuracy of stations fixed by a regular triangulation, when the base-line and angles have been properly measured, and the whole work is carefully adjusted.

The early maps, even of our own country, were often very erroneous, and were based upon the measurement of distances along roads by some form of surveyor's perambulator, or by pacing. Many road-books appeared from the time of the "Itinerary" of John Leland, 1535-43, and all maps of the British Isles up to the date of the first Ordnance Survey at the end of the eighteenth century, were based almost entirely on itineraries and other rough surveying of private individuals. These were carried out with more or less care by the measurement of distances from place to place, and these distances were frequently given in tabular form or written on the maps. Sir George Fordham has devoted considerable attention to these early road maps, and has within the last few years published some interesting accounts of them.

The atlas of Christopher Saxton, published in 1577, during the reign of Queen Elizabeth, marked a great improvement in the maps of

England and Wales, and is generally taken to be the earliest collection of maps based upon regular surveys of some sort issued in this country. Fig. 4 shows a part of one of the maps from this atlas. As you see, it gives the South London district, with the counties of Kent, Surrey and Sussex.

Sometimes a man having a special knowledge of a certain locality or county would bring out a map as a private enterprise of his own, which would be a great improvement on any previously published. A good example of this is the map of Kent by Phil Symington which bears the date 1596. As regards accuracy, this map is much superior to others of the period, including that of Saxton. A comparison of the two would soon show this, and it is evident that it is based on fairly good surveys.

An idea of the sort of surveying carried on in this country in the early part of the seventeenth century may be obtained from the account given by Richard Norden of his attempt at measuring an arc of the meridian in 1633 between London and York. After describing how he took meridian altitudes of the sun with "a sextant of more than 5 ft. semidiameter," he goes on to state how he made the linear measurements of the distance between the two places. He says: "I measured (for the most part) the way from thence (York) to London, and where I measured not I paced (wherein through custom I usually come very near the truth), observing all the way as I came with a circumferator all the principal angles of position or windings of the way, with convenient allowance for other lesser windings, ascents and descents, so that I may affirm the experiment to be near the truth." I do not know what our present geodesists would think of obtaining the distance between two points for the measuring of an arc of the meridian by pacing. This piece of work was carried out by Norden eighteen years after Snell had shown the correct way of doing it by triangulation; so it was rather a retrograde step.

There are some interesting remarks in the preface to Ogilby's "Britannia" of 1675, on the surveys upon which the maps in that work were based, which also incidentally show that rivalry between surveyors and map-makers existed in that day as well as this. The wording is so quaint that I think it may be worth while to quote some part of it here. After stating that the maps were from "actual dimensuration," he goes on to say that the maps of "Bleau, Sanson, and the rest, so eminent for the curious performances of the graver" were even the most accurate of them; "but so many guess plans and their perambulated projections, as those of our own country compiled by Mr. Saxton, and more and more vitiated since by transcribers and copiers, much inferior to what might have been done by a strict dimensuration . . . We may adjoyn a word or two of dimensurators or measuring instruments, whereof the most usual has been the chain, and the common length for English measure, 4 poles, as answering indifferently to the English mile and acre. We have been facilitated, therefore, in this great work by the Wheel Dimensurator, which for ease and accurateness infinitely surpasses the chain, as being manageable by a single person, measuring even the smallest deviation of the way, and finishing a revolution but once in ten miles. We . . . commend rather the foot-wheel here mentioned, of half a pole circumference with the Way-Wizars as they are now regulated, than any such like coach or chariot measurer whatever." (Ogilby's "Britannia," Vol. I., preface, 1675.)

The "Wheel Dimensurator" was much the same as the ordinary survey perambulator, which measures the number of revolutions on a dial.

Triangulation holds such an important place in all accurate surveying, since it furnishes the control points to which the topographical details can be adjusted, that a brief notice of the first recorded occasion of its being employed will doubtless be of interest.

It is supposed that Ptolemy was fully alive to the fact that it was not necessary actually to measure the whole length of an arc of the meridian, but that some parts could be computed, or perhaps graphically obtained, much as is now done in plane-tabling; but so far as we know, the first to introduce triangulation from a measured base and angles was Willebrord Snell (or Snellius) of the Netherlands, who lived in the early part of the seventeenth century, and to whom I have already incidentally referred.

The work he undertook was in connection with the measurement of an arc of the meridian. Up to his time the distances between the two ends of the line had been obtained by direct measurement of a doubtful value as regards accuracy.

In order to obtain a better result, Snell decided to measure a short line as a base and obtain the total length by the measurement of angles and computation, which must have been a most laborious undertaking since he had no tables of logarithms to work with. The

instrument used for the measurement of the angles was a graduated semicircle of 3½ ft. diameter. The vernier was not invented till about sixteen years later, so the angle readings

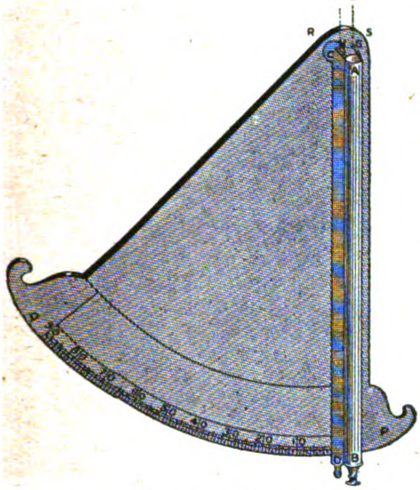

FIG. 5.—NEWTON'S OCTANT.

were necessarily very rough, but it was thought that having such a large circle would add considerably to the accuracy.

The length of the arc was about eighty-five miles, and extended from Alcmaar to Bergen-op-Zoom. A base-line was first measured with a chain 326·4 Rheinish rods in length (a little over three-quarters of a mile), and then, with

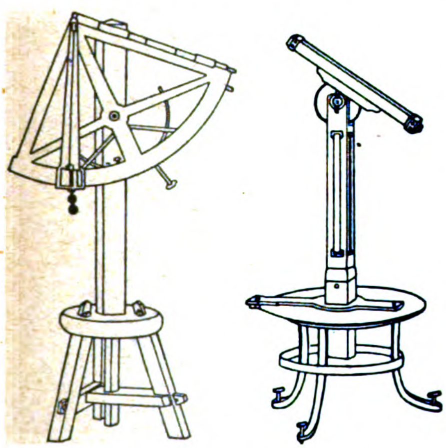

FIG. 6.—INŌ CHŪKEI'S INSTRUMENTS.

this line known and the angles measured, the sides were computed, and upon these sides other triangles built up. Altogether thirty-three triangles were constructed and computed between the terminal points of the chain. This process is practically the same as that now employed in extending a triangulation, and the debt of gratitude due to Willebrord Snell is very great indeed. Like all things of the kind, it seems easy enough, and only natural when once the way is shown, and it is remarkable that it was not thought of before.

The result obtained by Snell was not so accurate as might have been thought likely; but there were many sources of error, some of which he was fully aware of, and so he attempted to repeat the whole of the work, but never lived to finish it. The error in the length of a degree was about 12,789 ft., which is large, since the

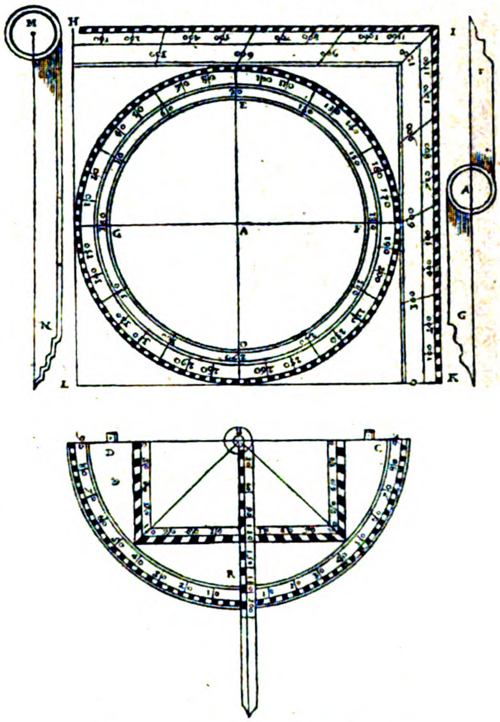

FIG. 7.—DIGGES' THEODOLITE.

method employed was correct, and was doubtless due to a combination of several causes, some instrumental and others in the computation.

Musschenbrock, a descendant of Snell, undertook the revision of the work about one hundred years later, and with a telescope attached to the quadrant used, and new determinations of the latitudes of the terminal points, he obtained a length for the arc very much nearer the truth.

The introduction of triangulation laid the foundation for all accurate surveying since Snell's time. Much has been done by way of improvement, but the great Survey of India, the Ordnance Survey of this country, and the

trigonometrical surveys on the Continent and in America, have all been conducted on the basis of the system which he was the first to introduce.

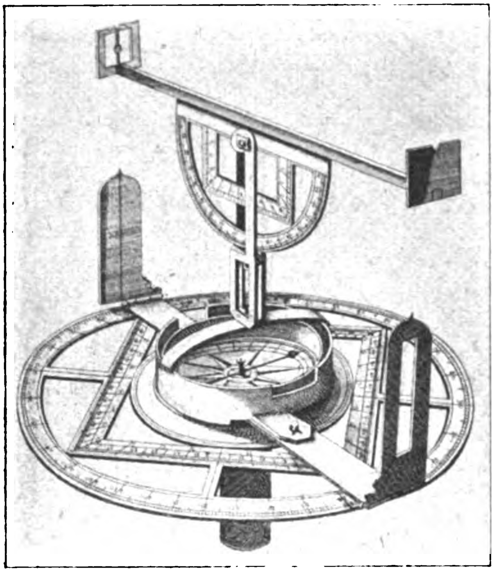

FIG. 8.—OLD THEODOLITE (Bleau's Atlas).

From this time great and rapid advance was made in surveying instruments which tended to increased accuracy, such as the improvement in chronometers, the invention of the reflecting quadrant and sextant, which, though attributed to Hadley, was really first proposed by Sir Isaac Newton. Fig. 5 shows Newton's design for a reflecting octant.

The invention of the nonius by Peter Nunez, in the middle of the sixteenth century, marked a step forward in the means of accurate reading of the circle divisions ; but with the introduction of the vernier in 1630, by Francis Vernier, the nonius rapidly became obsolete, as the simple and extremely ingenious invention of the Frenchman very soon took its place, as indeed it deserved.

We are apt to imagine that it was only Europeans who made any advance in the art of geographical surveying in these early times, but although this may be true to a great extent, there have been one or two brilliant exceptions. A very remarkable one was that of a Japanese named Inō Chūkei, who, with instruments designed and constructed by himself, carried out a survey and mapped the greater part of Japan by his own individual enterprise.

Inō Chūkei was born in 1744, and until 1795 was a brewer of saké, but in his spare time studied astronomy and became quite a good astronomer. When he was fifty-five years of age he petitioned the government to be allowed to make a survey of his country at his own expense. At that time no accurate maps existed, the only ones that were any good at all being those made by the Jesuit missionaries, which were very rough and erroneous.

Fig. 6 is a sketch of Inō Chūkei's instruments. These consisted of a brass quadrant, an azimuth instrument or sort of theodolite for giving vertical angles, and a compass. The quadrant was for observing altitudes, and the arc had a radius of 19 in. It was mounted on a wooden stand, with a telescope fixed to one of the straight sides. By means of a diagonal scale readings to 1′ of arc could be obtained with the plumb-line.

The azimuth instrument had a horizontal circular disc of copper, 19 in. in diameter, graduated to degrees, and by means of a diagonal scale could be read to 10′. Passing through the disc, or horizontal circle, was an upright wooden pillar carrying a telescope, and a flat horizontal arm. The pillar, telescope and arm rotated together, and when the distant point was sighted in the telescope the indicator on the arm gave the horizontal angles.

These instruments, or rather reproductions of them, were on view at the Japan-British Exhibition in London some years ago. The survey made by Inō Chūkei was certainly very good, considering all the circumstances. When compared with the modern correct values, many of the observed latitudes were found to be less

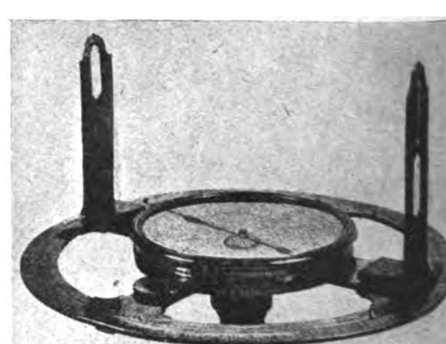

FIG. 9.—THE COMMON THEODOLITE.

than 1′ in error, while the error in the difference of longitude between places seems to range from 0′ to 6′ as compared with recent values.

Altogether Chūkei surveyed about 137,000

square miles, 16,000 square miles more than the area of the British Isles.

When we take everything into consideration, I think we must agree with Mr. E. B. Knobel,

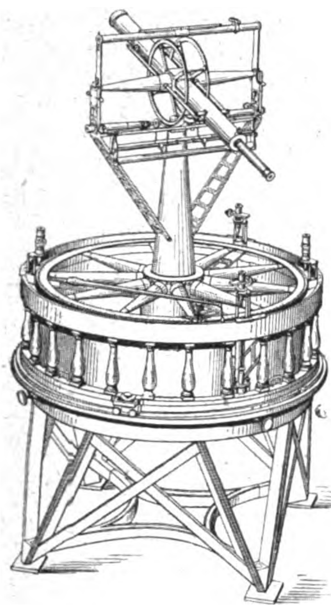

FIG. 10.—RAMSDEN'S THEODOLITE.

who gave an interesting account of Chūkei's surveys in the *Geographical Journal* for September, 1913, that "it is pathetic to read that he met with no reward in his lifetime, for on the termination of his work he was thrown into prison by the Shōguns, where he remained until his death in the year 1821." However, when more enlightened days dawned upon Japan, his works were published, in 1870, and an Imperial Order was conferred on the man long since dead, and a monument erected to his memory in the Shiba temple at Tokyo.

Of all the instruments used by the surveyor there is doubtless none more important than the theodolite, and I propose to close this lecture by giving some idea of the development of this instrument.

Fig. 7 shows the theodolite of Leonard Digges, who seems to have been the real inventor, and whose invention was described by him in his book on surveying, which was completed by his son, and published in 1571. As you see, the vertical and horizontal arcs are here separately shown; but it is clear that the former is intended to be inserted in a vertical position in the centre of the latter.

Fig. 8 shows a theodolite much of the same form, taken from Bleau's famous old seventeenth-century Dutch atlas.

Fig. 9 is a photograph of the "common theodolite," as it was called, since it had no telescope, carried by Messrs. Mason and Dixon to the United States, and used by them during the survey of the boundary between Maryland and Pennsylvania, which was commenced in 1763. It was made by Adams, of London, and was evidently only intended for observing horizontal angles. In many respects it resembles what is generally known as a circumferator rather than a theodolite. The instrument itself is now in the museum of the Royal Geographical Society, and was described in the *Geographical Journal* for January last.

We may, I think, be proud of the fact that the theodolite is really an English instrument, both in its origin and principal improvements.

Fig. 10 shows the famous Ramsden theodolite, which was used on the triangulation of England in 1787, when it was decided to connect the triangulation of France with that of this country. In 1763 Ramsden had invented a graduating machine for dividing the circles, and soon after

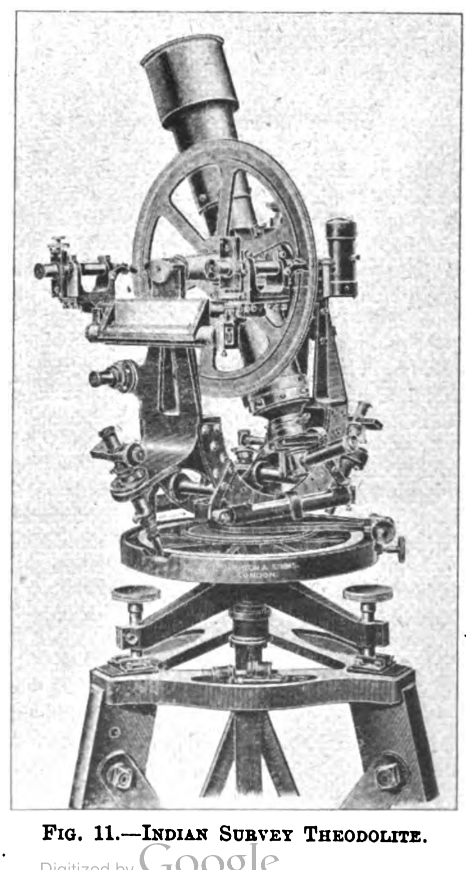

FIG. 11.—INDIAN SURVEY THEODOLITE.

commenced the construction of the excellent instrument. After being used on the triangulation of this country for many years, and having done good service in India, it has found a permanent resting-place at the Ordnance Survey Office. It was constructed with a horizontal circle of 3 ft. diameter, and by means of micrometers could be read to single seconds. By way of completing the series, I show (Fig. 11) finally a micrometer theodolite used by the Survey of India.

ENGINEERING NOTES.

Irrigation, etc., in the Crimea.—The Russian Supplement of the *Times* describes the rich valleys of the Crimea which are receiving great attention from the Russian Government. In 1913 there was established at Simferopol an office for the survey of water sources. Here an able staff of engineers has collected a vast amount of water statistics and other information, erected meteorological stations, measured the flow of all the rivers mentioned, and prepared large irrigation projects. For example, in the Salgir Valley one such has been drafted involving an expenditure of £300,000, which will give Simferopol a new water supply and convert 1,859 square miles into valuable apple or tobacco land. Such irrigated land is valued at from £110 to £150 per acre, and the land alone would be worth some £1,500,000. These engineers are also making great preparations for sanatoria all along the coast from Otusi to Sevastopol and at the Saki mud baths, where artesian wells have been sunk by them. The increase of visitors is so great as to justify this, and it is no exaggeration to say that the Crimea is rapidly becoming a very popular resort. As to the irrigation schemes, it is hoped to increase the area from 50 square versts to 500 square versts, when the Crimea will offer to the fruit planter attractions equal to those of Cripple Creek, California, or the Australasian apple lands, for the Crimea has unlimited markets near at hand for her fruit products, and even now supplies Russia with her choicest apples and pears from the Apple Valleys, with rich wines and grapes from the Vine Valleys, as well as other fruit and nuts, not forgetting tobacco. The Russian Minister concerned with the great work proceeding has just paid a visit of inspection, and is well satisfied with what has been done.

The Reversing Falls, St. John, New Brunswick.—The proposal in the *Electrical Review* to harness the tides of the Bay of Fundy, at Cape Split, Nova Scotia, by means of a current motor, which would pump the water into huge reservoirs on the cliff above, the descending water furnishing the power, has been followed by a suggestion to utilise the Reversing Falls at St. John, New Brunswick, in a like manner. The suggestion has come from the acting Resident Engineer of the Department of Public Works, who says that a stronger current is available at the Falls than at Cape Split, and there would be a longer period between tides for a motor-pump to operate. All attempts to utilise their tremendous energy have, so far, failed, but by the application of a current such as has been suggested at Cape Split, and by the erection of reservoirs on the height above, it is thought that, at last, a way has been found by which the Falls may be harnessed.

The Folla Scheme in Norway.—A scheme has been prepared for the utilisation of 50,000 h.p. through the exploitation of the Folla in Norway. This stream comes from the Troldheimen Mountains, and after a course of about twenty-five miles joins the Surna, which terminates in the Surendal Fjord. The Folla has no natural regulating basin, not passing through any lake of a size to serve as a reservoir, though it has abundance of water, the catchment area being 347 square kilometres. A valley, which is of no special value to anyone, is therefore being flooded to create a lake, having an area of 8 square kilometres, by building a wall 30·5 metres high and 648 metres long. There will be a fall of 300 metres, and at the turbines the power will be 40,000 to 50,000 h.p. In addition there are two other falls in the Folla. below the regulating dam, of respectively 7,200 and 10,000 h.p. The large power-station will be situated at the bottom of the Fol Valley; a tunnel over two miles long and 12 square metres section, will lead from the intake to the distribution basin. The energy will be transmitted over eight miles to Surendalsören, in the vicinity of which the promoter of the scheme controls large lime deposits, which can supply necessary raw material. The manufacture is likely to comprise carbide and cyanamide, an annual production of 25,000 to 30,000 tons being expected. The aggregate cost is calculated at nearly £800,000, of which nearly £350,000 is allocated to the power-station, etc., and nearly £75,000 to the electrical plant. The *Times* is our authority for these details.

The New Welland Ship Canal.—This connects the lakes Erie and Ontario and is the greatest engineering work at present under construction in Canada. When completed the canal will accommodate vessels up to 800 ft. long, and with a draught of 25 ft. It will be twenty-five miles long, and will have seven locks, each with a lift of 46 ft. 6 in. The work on the canal was commenced in 1913, and the complete work will probably take six years, the approximate cost being £10,500,000. The canal will form the third connecting link between these two lakes

PROCEEDINGS OF THE SOCIETY.

FOTHERGILL LECTURES.

SURVEYING, PAST AND PRESENT.

By EDWARD A. REEVES, F.R.A.S., F.R.G.S.,
Map Curator and Instructor in Surveying to the Royal Geographical Society.

Lecture II.—Delivered April 3rd, 1916.

PRESENT POSITION OF SURVEYING AND MAPPING OF THE WORLD.

In my last lecture I described briefly some of the earliest attempts at surveying, and the instruments and methods by which these surveys were carried out; and I will now try to give you an idea of what has so far been accomplished toward the mapping of the earth's features, and the present position of various parts of the world as regards the surveys upon which the maps depend. In doing this I shall also endeavour to describe briefly, and show examples of, the work that has been done during the past fifty or sixty years, as well as give some indication of what remains to be accomplished by future explorers and geographical surveyors.

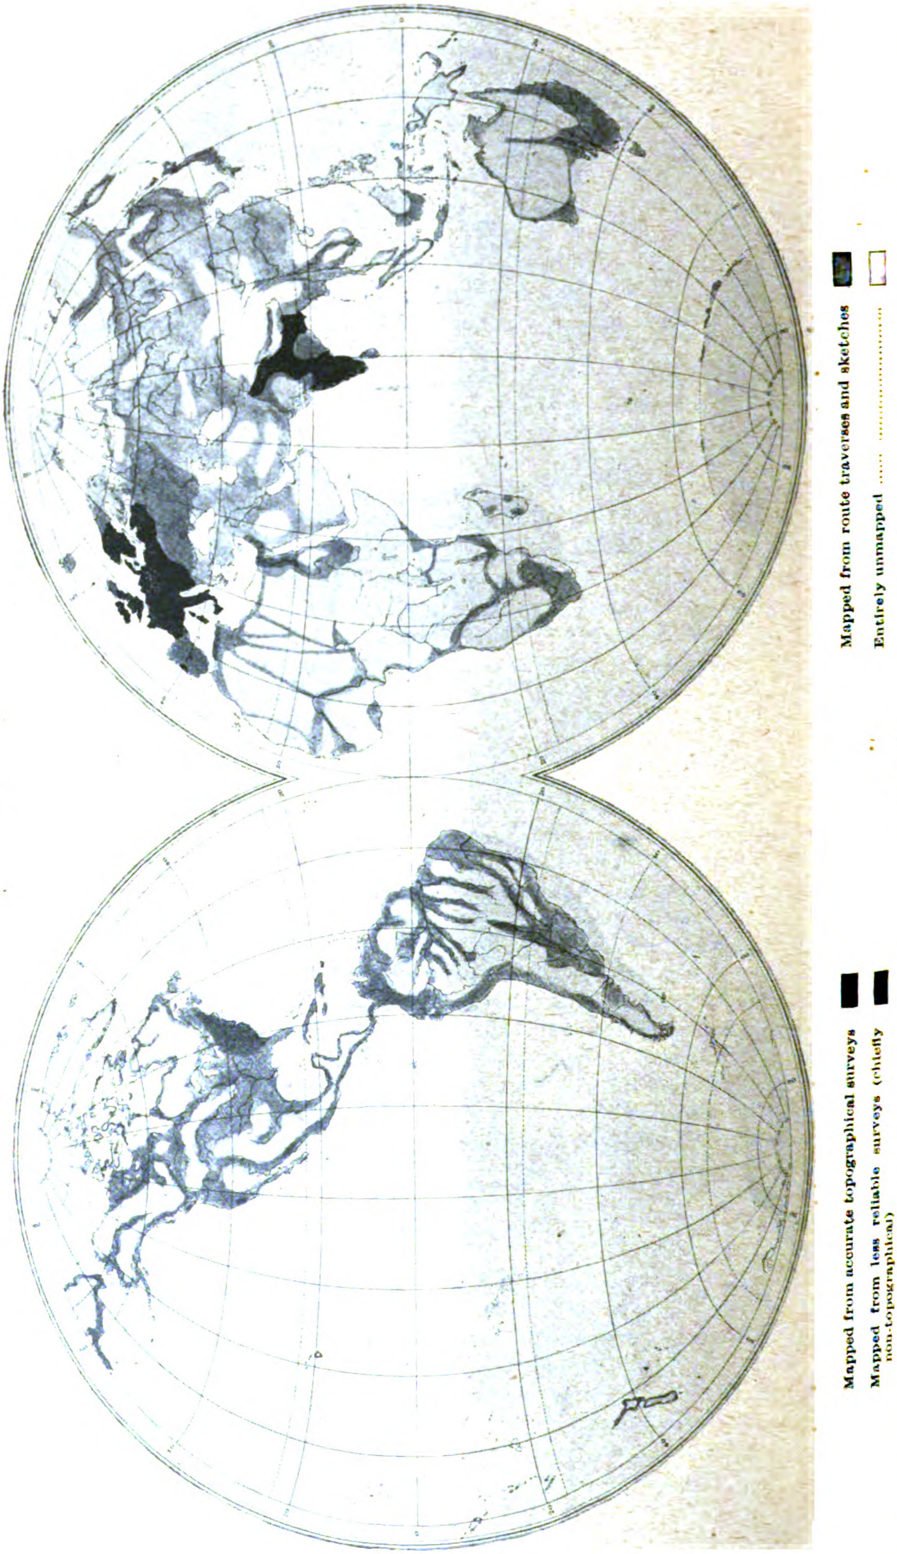
All human progress and endeavour that has achieved any success has been the result of hard struggles and long perseverance against many difficulties, and this is specially the case with regard to the subject with which we are dealing. Little by little civilised man, by his daring, his love of adventure, and the necessities of events and circumstances, has penetrated into the unexplored parts of the earth, and pushed back the clouds and mists that so long shrouded it from his knowledge, until at the present time the regions that are entirely unknown are very few indeed, and do not amount to more than one-seventh part of the whole land surface of the globe, including the unexplored areas of the Polar regions which may be either land or water. Not content with a mere vague acquaintance, he has striven for greater accuracy, and has turned to various branches of science and called them to his aid in order that he may obtain more correct knowledge, and a better comprehension of the earth's features. To enable him to fix with definiteness the position of places, map out the various land forms, and obtain their accurate measurements, he has consulted the astronomer and mathematician.

Commencing with modest instruments and measuring apparatus, these, as greater accuracy was required, have gradually been improved until the present-day appliances and equipment of the surveyor are wonders of refinement and delicacy, in the construction of which the greatest ingenuity of mechanical skill has been called forth. But the work has been gradual; not only the progress of geographical surveying itself, but as regards the appliances for accomplishing it; and the two are so interwoven and connected that it is impossible to describe the one without dealing to some extent with the other, so that it will be necessary for me to combine them in what I shall bring before you.

To begin with, it is important that we should have a general idea of what parts of the world have been surveyed and what have not, as well as ascertain something of the relative value of the survey basis for maps of the various parts of the world at the present time; and so I propose to show a map of the world I have recently drawn. It is merely an outline and diagrammatic in character, but, I trust, will help to make the matter clear. By way of comparison I have drawn another map showing what was surveyed at all accurately, mapped from rough surveys, and entirely unsurveyed and unmapped in 1860—that is, nearly sixty years ago. These maps will, I hope, convey more to you than if I placed before you mere tables of figures and statistics, which, though important in their place, do not give at a glance the facts and proportions that can be furnished by maps and diagrams.

The maps are both drawn on an equal-area projection—that is to say, a certain area on the map, such as a square inch, everywhere represents the same number of square miles on the earth's surface.

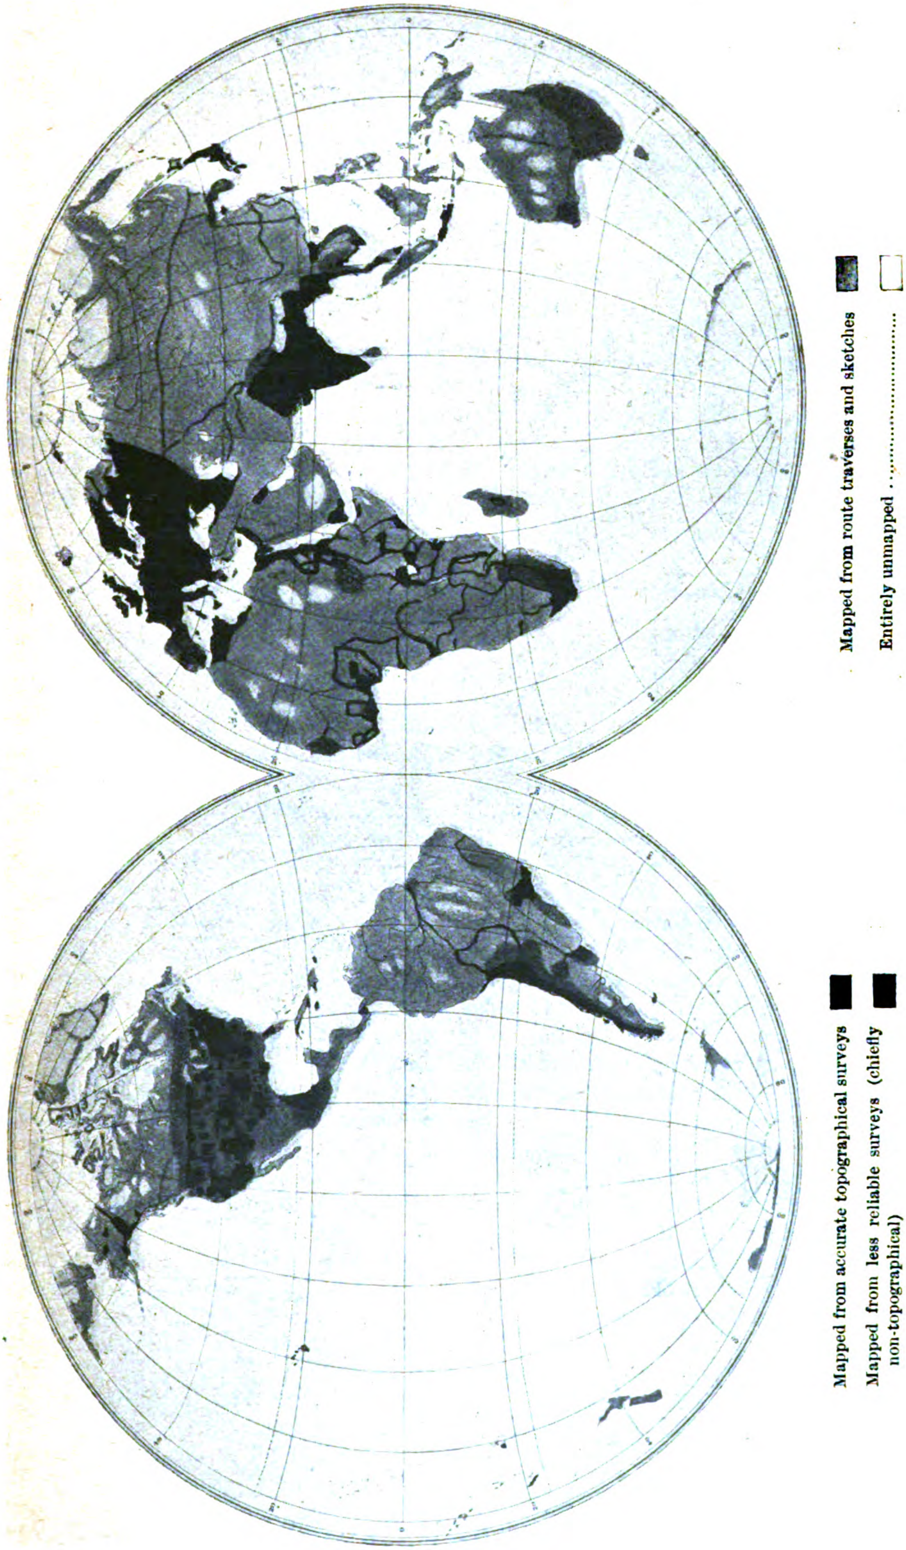
1860.



Mapped from accurate topographical surveys
Mapped from less reliable surveys (chiefly non-topographical)
Mapped from route traverses and sketches
Entirely unmapped

Fig. 12.

1916.



Mapped from accurate topographical surveys
Mapped from less reliable surveys (chiefly non-topographical)
Mapped from route traverses and sketches
Entirely unmapped ....

FIG. 13.

The idea kept in mind in drawing the maps is that the shade deepens as the accuracy of the surveys increases: (1) The parts topographically mapped from triangulation or rigorous traverses are shown by the darkest tint; (2) those less accurately mapped from surveys chiefly non-topographical, and of which in many places the basis consists to a great extent of disconnected land-office and property plans, are shown by the tint next in density; and then the third (3) tint represents the parts of the world only mapped from route surveys or traverses of explorers. Although these traverses vary greatly in degree of accuracy, they cannot be considered so reliable as the surveys shown by either of the other two shades; and in many instances the mapping consists of the roughest sketches; (4) the regions entirely unsurveyed and unmapped are indicated by the lightest tint of all—almost white.

Before dealing with the present-day map, which we shall consider somewhat fully, I desire to call attention to the 1860 map.

The first map (Fig. 12) shows the state of surveys in the Eastern Hemisphere in 1860, and it will be seen at once that outside the continent of Europe, where a considerable extent of accurate surveying had been done, the only country where there was any mapping based upon triangulation was India. These areas are shown in the darkest shading. In Europe the British Isles, France, Germany, Austria, Italy, Russia, Switzerland, Denmark, the Netherlands and Scandinavia had already made a good commencement with their government surveys, but these were in several cases by no means complete; and it is interesting to note that even of Scotland there existed at that time no Ordnance Survey of its northern part. The southern part had been surveyed and mapped on the 1-inch scale long before this date, but the survey was afterwards carried on in England, and on the 6-inch scale in Ireland, so that the northern part of Scotland was not done in 1860.

India has been noted for the excellence of its surveys ever since the days of Major Lambton, who started the work in 1804, and Colonel Everest, who succeeded him as head of the Government surveys after his death in 1823. As will be seen by the map, in 1860 a considerable extent of India had been mapped from trigonometrical surveys. Even before Lambton's time India had been well ahead with its surveys of any other country outside Europe, which was entirely due to the energy and skill of Major James Rennell, who, as Surveyor-General of Bengal, surveyed the Ganges and lower Brahmaputra Rivers, as well as the districts of Bengal and Behar, between 1763 and 1782.

In the parts of the Eastern Hemisphere that were surveyed and mapped in the second degree of accuracy, according to our system—that is, those shown by the next tint—may be included most of the remaining parts of Europe, Egypt, and parts of Algeria near the coast. For the rest, such mapping as was done was based upon rough route sketches, as shown by the third tint. In this must be included practically all other known parts of the African continent, such as those explored by Mungo Park, Beke, Livingstone, Speke and Grant, and others; as must also be the early exploratory surveys in Central Asia and Australia.

The regions that were entirely unsurveyed and unmapped at this time were, as will be seen, enormous in their extent, and included not only those in the neighbourhood of the Poles, but vast areas of Central Asia, Africa and Australia.

Turning to the Western Hemisphere, we find that at this date, 1860, no triangulation of any extent had been carried out. The United States Coast and Geodetic Survey had made a good start, but their work had been confined to the coastline or districts near the coast. There had been La Condamine's attempt at measuring an arc of the meridian near Quito in South America in 1736, the measurement of the Mason and Dixon line, and their survey of the boundary between Pennsylvania and Maryland in the latter part of the same century; but neither of these resulted in any serious topographical mapping. Such surveys as existed of the interior parts of the United States in 1860, although they varied considerably as regards their merits and degree of dependence, could not be considered as anything but approximate.

Some parts of the Eastern States are shaded with a tint of the second density, but apart from this, such mapping as had been done either in North or South America cannot be considered of a higher order than route traversing and rough sketching, and is tinted accordingly.

Vast areas of Central Asia, and a still larger portion of the interior of Africa were entirely unmapped in 1860, as was also the case with South America away from the courses of the great rivers, vast areas of North America, and the Arctic regions.

Attempts had been made to penetrate and traverse the desert-like interior of Australia, but to a great extent this region still remained entirely unmapped.

Several important expeditions had commenced the exploration and mapping of the coastline of the Antarctic continent, such as that of Captain James Clarke Ross, which had penetrated a considerable distance south in the neighbourhood of South Victoria Land, and Captain Wilkes and others who sighted land to the west of this region; but, after all, little had been done in the way of surveying and mapping in the Antarctic regions.

Referring now to the present-day map (Fig. 13) on which the same shades of tinting have the same meaning as on the previous map, you will see at once that the parts that are accurately surveyed from a topographical point of view, based on triangulation or rigorous traverses, have greatly increased in extent, and these now represent, according to a rough estimate I have made, about one-seventh of the total area of the land surface of the earth, instead of only one-thirtieth, as was the case in 1860. Remarkable progress has also been made with regard to both of the less accurate classes of surveying and mapping, while the parts that are entirely unsurveyed and unmapped only amount to about one-seventh instead of a little over half, which was roughly the extent fifty-six years ago.

I have attempted to form an estimate of the condition of the world's surveys as represented by the differently tinted areas on the maps for 1860 and 1916; and, taking the total area of the land surface of the earth, together with the unknown parts of the Arctic and Antarctic regions which may be either land or water, to be 60,000,000 square miles, I have obtained the following results:—

It may be interesting to see these proportions in diagrammatic form (Fig. 14), which gives the general results perhaps more clearly than in any other manner.

From the figures given it is plain that, with the same rate of progress as that of the past fifty-six years, it would take just over 400 years more to complete the accurate surveying and topographical mapping of the earth's land

1860. 1916.

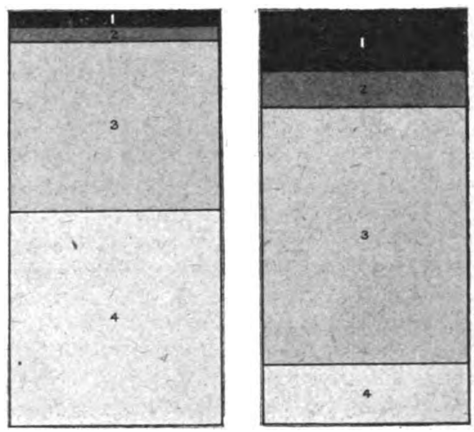


FIG. 14.

surface, including the parts of the Polar regions that may possibly be land, that is the 60,000,000 square miles which we have taken for this total area: but this will certainly not be the case, since the rate at which such surveys have been carried out has been greatly accelerated during recent years, owing to the rapidly increasing demands for accurate maps, improvements in methods ane other causes; so that it will

	1860.		1916.	
	Square Statute Miles.	Proportion to Whole.	Square Statute Miles.	Proportion to Whole.
1. Mapped from accurate topographical surveys, based on triangulation or rigorous traverses.	1,957,755	0·0326 or roughly $\frac{1}{30}$.	8,897,238	0·1482 or roughly $\frac{1}{7}$.
2. Mapped from less reliable surveys, chiefly non-topographical.	2,017,641	0·0336 or roughly $\frac{1}{30}$.	5,178,008	0·0866 or just over $\frac{1}{12}$.
3. Mapped from route traverses and sketches.	25,024,360	0·4170 or roughly $\frac{2}{5}$.	37,550,552	0·6258 or little less than $\frac{2}{3}$.
4. Entirely unsurveyed and unmapped.	30,997,054	0·5166 or just over $\frac{1}{2}$.	8,350,794	0·1391 or little less than $\frac{1}{7}$.

probably not be half this time before all the parts of the earth's surface that are likely to be of any use to man as settlements, or are capable of being developed, are properly surveyed and mapped. There are, of course, regions such as those near the Poles and in arid deserts that are never likely to be accurately triangulated and mapped, and it would be merely a waste of time and money to attempt anything of the kind.

The surveying and mapping of the surface of the earth, so far as it has been accomplished, has called forth all the spirit of adventure in the pioneer, who has penetrated the vast unexplored regions through tropical forests, scorching sands and fields of polar ice and snow, despising all risks, that he may bring back a knowledge of the regions he has visited, and a representation in the form of the best map he was able to make of the geographical features of the country; while for the trained surveyor, who follows the pioneer explorer with his theodolite and other instruments of precision, it has meant long journeys and sojourns, often under enormous difficulties, in all sorts of climates and adverse conditions.

As might be expected, the parts of the earth's land surface that are accurately surveyed, about one-seventh of the whole, are those inhabited by the most civilised nations and their dominions. The areas so mapped include the European countries, with the exception of some parts of the Balkan States, India, Japan, Algeria, Tunis, Egypt, and other parts of Africa under the domination of European nations or inhabited by Europeans, the United States, parts of Canada and Mexico, the international boundaries between some of the Asiatic, African and South American countries, and very restricted areas of Australasia. These are all shown by the darkest tint on the map.

The parts that are still unsurveyed in any sense are, as has been seen, certain remote unexplored regions near the Poles, a few patches in Central Asia, much of the interior of Arabia, parts of the Sahara and some other areas in Central Africa, parts of the interior of South America, specially those between the great rivers, and certain areas of the interior of Australia. These are shown by the lightest shade on the map, and at the present day represent slightly less than the area that is accurately mapped. Between these two extremes the surveying and mapping varies in merit and degree of reliability from that of a fairly accurate nature (such as land-office plans, which make little pretence at showing topographical features), which may be taken as covering about one-twelfth of the earth's land area, and that enormously extensive area only roughly mapped from route traverses of explorers and others, which now constitutes about two-thirds of the whole of the earth's land surface.

These different kinds of surveys, and the methods by which they have been carried out, will be dealt with specially in the next lecture, although that with which I am mostly concerned is perhaps the last, since it is one of my duties at the Royal Geographical Society to instruct travellers in geographical surveying.

Ordinary land surveying, such as undertaken by civil engineers, does not immediately concern us at the Geographical Society, since its function is for the most part to produce large-scale plans for engineering and other special purposes, usually of very small areas, and it does not yield much topographical or geographical result.

Trigonometrical surveying forms the basis of all accurate mapping, so this comes within our province, in so far as it constitutes the framework and points of control for topographical mapping.

Many and varied have been the influences that have led to the surveys that have already been carried out, and it would be interesting if we could analyse them; but there is only time now to refer briefly to some of the more important.

Among the preliminary reconnaisance surveys it would, I think, be found that military operations hold an important place. Many an unexplored region has been mapped for the first time as the result of frontier expeditions, such as those on the transfrontier regions of India, like the expedition to Tibet of 1904, during which most important mapping work was done from Sikkim to Lhasa, and west along the Brahmaputra valley. Under Captain Ryder and Captain Rawlings an excellent route traverse was carried out, and parts only very imperfectly known before were mapped.

The Afghan War of 1879–80 is another example, and the dispute concerning the Russo-Afghan boundary, which nearly led to serious complications with Russia, resulted in the excellent survey by Sir Thomas Holdich, of the line of the northern boundary of Afghanistan, in 1884.

The wars in South Africa and numerous other examples could be quoted to show that much of the early surveying has been the outcome of military expeditions.

As many of you are aware, there had long

remained a small section of the Brahmaputra that was unknown, that part of the course of the river where the great bend occurs just before the river reaches the plains of India. Quite recently this has been mapped—with the exception of a few miles—by Captain Bailey, again as the outcome of military expeditions sent to teach the turbulent tribes that they cannot murder British officials with impunity.

Yet it is remarkable that although warlike operations have so often led to the surveying of hitherto unmapped regions, the risk of war or of complications that might lead to it have not infrequently been a hindrance to surveying, and many parts adjacent to our frontiers could have been surveyed long ago had there been no fear of political difficulties arising.

Just to the north of India is the most interesting country of Nepal, containing the highest mountain on the earth, and yet there is no part more imperfectly mapped. Many an adventurous explorer has cast wistful eyes in that direction, but so far none have been permitted to cross the border for surveying, with perhaps one or two exceptions to do a piece of special work and quickly return.

Among other expeditions that have resulted in surveying, or at least rough map sketching, might be mentioned those for the delimitation of boundaries, commercial or industrial undertakings such as gold-mining and land development, and projects for new railway lines, all of which have occasionally been fruitful in good cartographical results. Nor must we forget Christian missions. The better-trained missionary has always recognised the importance of some sort of survey of the remote field of his operations and the route to it, if for no other reason than to assist his fellow-workers and those who come after him; and in the earlier days specially a great deal of route surveying and mapping was done by the self-sacrificing labours of the missionary. We have only to think of the work of the early Jesuit missionaries in China and Japan, and of that of such men as Moffat, Livingstone, Rebmann, Grenfell, Arnot and others in more recent times, to be reminded of how much geographers owe to the missionary.

Most of the expeditions referred to so far have not had surveying as their primary object, and such as has been done has been incidental on the necessity for prosecuting the main purpose in view; but the properly-equipped surveying expeditions that have been despatched from this and other countries have, during recent times, added enormously to our knowledge, whether the more exact Government trigonometrical surveys undertaken for geodetic purposes, or those whose only object it has been to produce a good topographical map.

In times gone by geographical and topographical surveying has been too much carried out by numerous independent agencies of different nationalities, acting pretty much in a limited sphere, and without any mutual coordination. What has been lacking is the treating of the subject as one connected whole, and dealing with the survey question not from a national but an international point of view. There have been many opportunities lost of extending a triangulation or carrying on topographical surveying, just because it would mean passing over a boundary line, or crossing into the territory of another nation.

In the short time given to this lecture I cannot attempt to describe, however briefly, the various Government trigonometrical surveys of European and other countries to which reference has already been made; but I should like to say a few words here about the triangulation of our own Ordnance Survey.

The first base-line for the survey, in England, was measured by General Roy on Hounslow Heath in 1783 with wooden rods tipped with bell metal. The rods were supported at the ends by stands, and each measured 20 ft. 3 in. Later on Colonel Calderwood substituted glass rods for the wooden ones, but the distance obtained by both the wooden rods and glass ones agreed very well, and was taken as 27,404·0137 ft. at a temperature of 64° F.

In 1827-28 a base-line was measured near Lough Foyle in Ireland with a new apparatus known as Colby's Compensation Apparatus, and with the same apparatus the Salisbury Plain base in England was measured in 1848.

It is interesting to note that the difference between the measured length of the Salisbury Plain base and its length as computed by the triangulation from the Lough Foyle base only amounted to 4·6 in., although the distance between the two is something like 345 miles.

A few years ago some attention was turned to the Ordnance Survey in connection with certain loose and vague statements that were current as to its not being accurate enough for the modern requirements of geodesy. People who knew little of the subject began to run away with the idea that the Ordnance maps were not so accurate as they were supposed to be after all, which was, of course, absurd, and entirely

due to a misunderstanding of the facts. Apart from furnishing the basis of our maps the triangulation is of the greatest importance from a purely geodetic point of view, since it forms the northern portion of the western arc of the meridian of Europe and Africa, and the western portion of the great European arc running from east to west along the 52° parallel of latitude.

Many improvements have been introduced in instruments and methods since this triangulation was done, nearly 100 years ago, and the question was raised by geodesists as to whether the work, although of course sufficiently reliable for mapping purposes on any scale however large, was quite up to the modern standard, so that it could be safely used in the discussion of the lengths of arcs for obtaining the true figure of the earth. The matter having been raised at two meetings of the British Association, in 1909 it was decided to test the accuracy by measuring an entirely new base far away from the original Salisbury Plain and Lough Foyle bases, extend a triangulation from this new base to certain stations of the old triangulation, and see how the sides computed from this new base agree with the original values. The position of the new base, measured with invar tapes, was Lossiemouth, on the shores of Moray Firth, on the east coast of Scotland, and the work was carried out with every refinement by Major W. L. Johnstone and Captain H. St. J. L. Winterbotham, of the Royal Engineers, under the direction of Colonel C. F. Close, C.M.G., R.E., Director-General of the Ordnance Survey.

Detailed reports have been published by the Ordnance Survey Office, and Colonel Close, in his "Notes on the Geodesy of the British Isles" which appeared in 1914, sums up the matter as follows:—

"We may, I think, safely say that the published length of any side of the principal triangulation is not likely to be in error by a

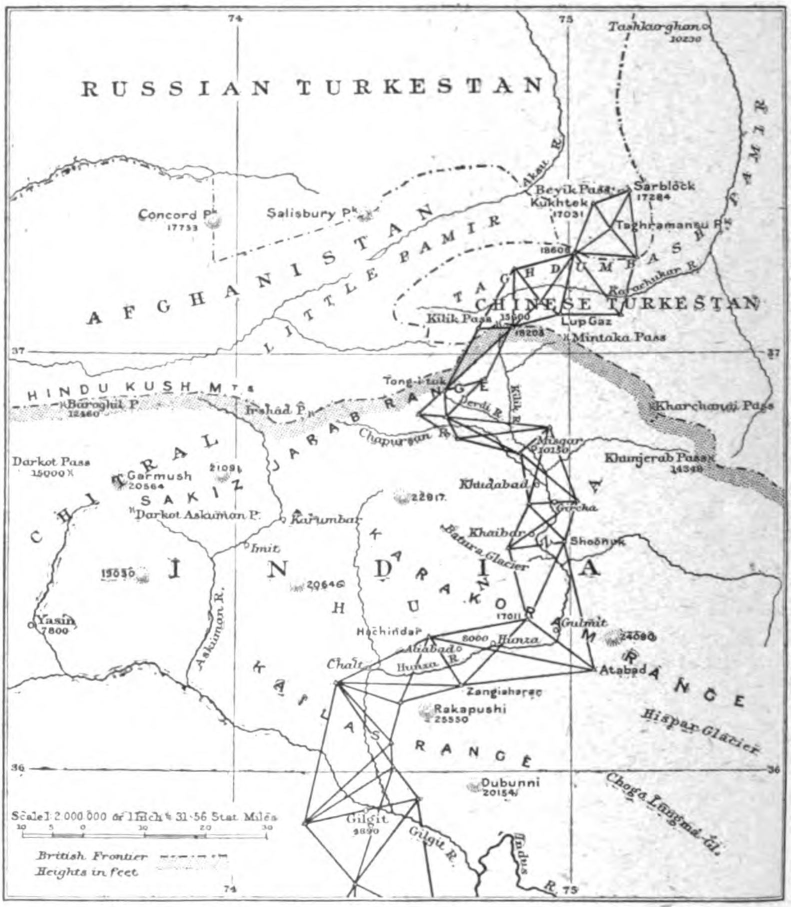

FIG. 15.—THE INDO-RUSSIAN TRIANGULATION CONNECTION.

quantity much greater than 1 inch in a mile. It may be noted that American geodetic regulations allow a maximum discrepancy of 2½ inches in a mile. The probable error of an observed angle is 1″·23, or about three times as large as would be expected in modern work, but the strength of the network largely compensates for this. Not very much would be gained by re-observing the angles of the triangulation along the line of the two arcs, and the expense would be considerable, not less, I suppose than £20,000."

A large amount of triangulation work has been done in recent years in hitherto imperfectly mapped parts of the earth, and although a line of triangles run across a country does not in itself constitute a topographical map any more than the skeleton-like framework of a new building to be erected constitutes the building, yet it answers much the same purpose, and enables the topographer to adjust his map accurately to definitely fixed points of the chain of triangles, and binds the whole together.

Many such chains have been run recently, and I should like to call attention to one or two of these, which must have a very important influence on future mapping.

The accurately determined points of the great trigonometrical survey of India, in the Himalayas and the frontier regions, have for a long time past been used for the extension of surveys into the little known countries beyond the borders of India; but until just recently there has been a gap between this remarkable triangulation and that of the Russian Government far to the north. During the International Geodetic Conference of 1909, which met in London, the question of connecting these two triangulations was discussed, and its importance from a geodetic point of view pointed out. The Survey of India undertook the work, and Lieuts. Bell and Mason, with other survey officers, commenced operations in 1911, and carried a chain of triangles by way of Gilgit, Hunza, over the Karakoram range to the Kilik Pass, the Pamirs, and thence into Turkestan. Fig. 15 shows this important piece of triangulation, but it gives no idea of the difficulties under which the work was accomplished. What with the continual climbing of almost inaccessible ranges and peaks, the severity of the climatic conditions and difficulty of transit, the work was indeed most arduous, and poor Lieut. Bell lost his

Fig. 16.—Geodetic Arcs.

life in carrying it out, doubtless through the strain and exposure. Still it is done, and will in the future be of the greatest value, not only from a purely geodetic point of view, with which it was primarily undertaken, but as furnishing definitely fixed points for future surveyors in this region. (See *Geographical Journal*, June 1914.)

Fig. 16 shows the principal chains of triangles on the earth which have been run chiefly for geodetic purposes, although they also serve to form the basis of mapping.

In Africa, valuable work of this kind has been carried out in recent years, and the line of triangles which you see running right across the continent from the Cape to Egypt is likely to hold a most important place in the future mapping of Africa, as well as constituting a most valuable transcontinental arc which will be of the greatest importance to geodesy. The work, so far as it has been completed, was carried out in South Africa under the superintendence of the late Sir David Gill. Starting from the triangulation of the Cape, it passes through the Orange Free State, Transvaal and Rhodesia, right up to the southern shores of Lake Tanganyika. Then there comes a break. It was hoped that the Germans would see their way to carry it through their territory, but as things are now, we may have the pleasure of doing this piece of the line as well, not through German but British territory. To the north of Tanganyika the triangulation has been further completed in the neighbourhood of Mount Ruwenzori, and some day it is sincerely desired that it may continue down the valley of the Nile to Egypt and the Mediterranean. The Egyptian triangulation is in an advanced state, and when money is forthcoming let us hope that this most important piece of work will be finished.

If in years to come this triangulation can be connected with the European arc, extending to the Arctic Ocean, it will add enormously to the accuracy of the geodetic measurement for obtaining the figure of the earth.

As a basis for survey work in Africa, the line has already proved valuable, and will be more so as time goes on, since it gives the most needed points to which secondary triangulation and topography can be adjusted. The official reports of the geodetic triangulation are published, and provide excellent examples for those who may have to undertake anything of the kind at a future time.

In Africa, as you have seen, much of the mapping depends on the roughest kinds of surveying; but during the last twenty years the accurate demarcation of international boundaries has been in steady progress, and the stations of the triangulation constitute the points to which the topographical surveys of the interior regions can be adjusted.

The international triangulation between British and German East Africa has proved of the greatest value in this respect, and since its extension round the northern shores of Victoria Nyanza to Lake Albert and Mount Ruwenzori, it has been possible to produce excellent topographical maps of the adjacent regions. The triangulation of the western part of Uganda (Buganda as it is called) was based upon this, and the topographical map of this province is one of the best of its kind in existence.

Although in the south the surveys of our East African Protectorate have advanced considerably, there are parts in the north and centre of the country that are hardly explored, much less surveyed, and such work as has been done is of an isolated and disconnected character.

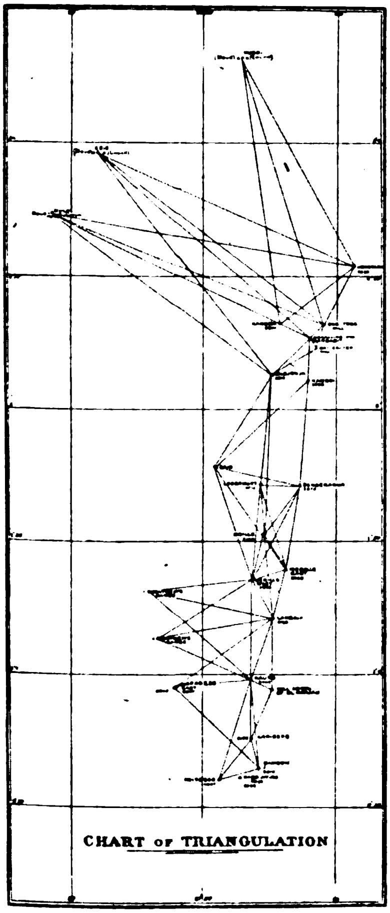
A most important piece of surveying was carried out in 1909–12 by Mr. G. F. Archer, which was the connecting of the triangulation of the south, near the waters of the Uaso Nyiro, with certain points fixed by Captain Maud and Major Gwynn on the Abyssinian frontier; and although this chain of triangles was rapidly run, and not of the highest order as regards accuracy, it is quite good enough for mapping purposes, and will furnish the most needed points from which the future surveys of the country can be carried to the unsurveyed parts to the east of the line. Fig. 17 is taken from a map showing Mr. Archer's work, which was published in the *Geographical Journal* for November, 1913.

Other examples of recent triangulation that have had, and will have in the future, an important bearing on topographical mapping, could be mentioned, such as that of the Chile-Argentine Boundary Commission, and the still more recent piece of work along the boundary between Peru and Bolivia, of which Sir Thomas Holdich gave an account a short time ago in the *Geographical Journal* (February, 1916), and which was, to a great extent, carried out by my old pupil and friend Captain Toppin—who, like so many other excellent men, was killed soon after the outbreak of the war. I have only mentioned a few examples, but shall be pleased to furnish particulars of any others if those interested will apply to me at the Royal Geographical Society.

I propose now to deal with some examples of route surveying and mapping, taking them from the work of early travellers as well as from those of a later date.

As you have already seen, about two-thirds of the earth's surface is at present mapped only in this approximate manner.

Beginning with the route traverses and maps of early travellers, the first (Fig. 18) I shall show you is the map made by Dr. D. Livingstone of his famous journey from Bechuanaland to Angola. You will remember that he left the mission station of Kuruman in June, 1852, where Dr. Moffat, his father-in-law, laboured so long, travelled through the then unknown region to the north, by way of the Upper Zambezi, and finally came out at St. Paul da Loanda, on the west coast. It was during this journey that he first heard of the Victoria Falls, and although he did not actually visit them till later, he placed them on his map from native information.



Dr. Livingstone was a good observer with a sextant, and determined astronomically the position of numerous places on the route, while the actual mapping was done by compass traversing.

After a short stay at Loanda a start was again made with the object of travelling right across the continent from west to east. During this journey he struck the Zambezi again, and followed the river right down to its mouth, discovering the Victoria Falls on the way. The original of the map made on this journey and the one just shown are in the collection of the Royal Geographical Society, as are also the sextant and boat's compass used by the famous missionary-explorer in navigating his boat down the Zambezi.

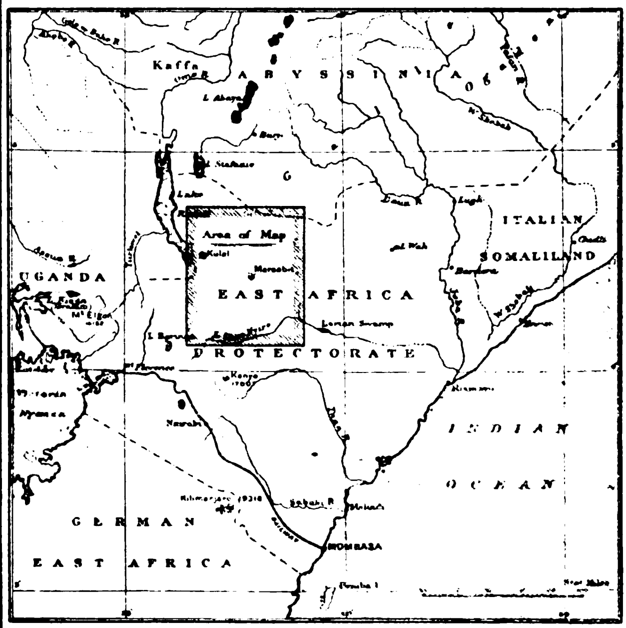


FIG. 17.—ARCHER'S TRIANGULATION IN EAST AFRICA PROTECTORATE.

When compared with recent maps Dr. Livingstone's first route maps are remarkably good, taking all things into consideration—far more accurate in many respects than some later route traverses in the same part of Africa.

Captain Speke's manuscript map of the journey he made with Captain J. Grant from Zanzibar to Lake Tanganyika in 1858 is also an interesting example of pioneering work and another of the Royal Geographical Society's treasures. This was the first time the country had been

traversed by Europeans, and the map is therefore important.

Considerable improvement has been made in recent years in the instruments used in route traversing and surveying, and in the methods employed; but in these early days the usual equipment was a sextant and artificial horizon, a chronometer or watch, prismatic compass, boiling-point thermometers and aneroid; and it was with these that most of the work shown by the third degree of shading on the map, *i.e.* those regions mapped from route traverses and sketches, was, until quite recently, carried out. With the sextant and artificial horizon the astronomical observations for latitude and longitude were taken, as well as those for finding the

FIG. 18.—DR. LIVINGSTONE'S MAP.

error of the compass. The route was plotted from the compass bearings, and adjusted to the astronomically determined positions. The latitudes were usually from meridian altitudes of the sun or stars, and the longitude from altitudes taken east or west of the meridian, or if the man knew his work properly, and could manage it, by both. The local time thus found was compared with the times shown by the chronometer, which was supposed to give the Greenwich Mean Time, and the difference was taken to be the longitude of the place.

The sextant, if in good adjustment, in the hands of a man accustomed to it, is capable of giving results in latitude that should not be more than 10″ or 20″ in error, and the local time should not be far wrong, although the accuracy cannot be expected to be anything like equal to that obtainable with a theodolite; but for azimuth or finding the true bearing of a point it is not very suitable, since the angle observed between the sun and the distant point selected is not the horizontal angle, and has to be reduced to this by a somewhat lengthy computation.

An ordinary observer has no means of testing accurately the centering or graduation errors of a sextant, and a great drawback to its use for survey work is that it is impossible with it to measure accurate horizontal angles, since unless the points are all exactly at one altitude the angles will be too large. The sextant is essentially a navigator's instrument, and nowadays it has been almost entirely superseded by the theodolite in land surveying.

As regards the longitude, the difficulty was to obtain a steady rate for the chronometers, owing principally to the unavoidable oscillations and concussions they met with in transit. Sometimes lunar distances were observed for obtaining the Greenwich time instead of trusting to the chronometer; but these, even with the utmost care, are very unsatisfactory, and the results obtained unreliable. I have had to compute hundreds of lunars, and my experience goes to prove that they are far too uncertain to be of any service in present-day geographical surveying. I well remember, on one occasion, having to work out some of these observations for a noted traveller in Africa, whose name you would all know, and they placed him anywhere between the Indian Ocean and the Great Lakes.

In more recent years the occultation of a star method of finding the longitude has almost entirely superseded lunar distances, as this gives more dependable results; but all of these so-called "absolute methods" of finding longitude are now fast being superseded by the introduction of triangulation and either ordinary or wireless telegraphy.

Heights of the land were usually obtained by the boiling-point thermometer or aneroid, since the mercurial barometer is not convenient to carry, and very liable to be broken.

Such, then, was the general equipment of the pioneer explorer and geographical surveyor in the early days of, say, from twenty to sixty years ago; and in many respects, for rapid pioneering journeys, it is much the same to-day, except that a small theodolite usually takes the place of the sextant and artificial horizon, and the

plane-table has come into general use. For more important geographical survey work the outfit is now more elaborate, and this will be dealt with in my next lecture. With such an outfit as that just mentioned, the greater part of the first mapping of Africa, and other unexplored regions of the earth, was carried out, with results that were more or less reliable according to the skill of the explorer and the time and opportunities at his disposal.

When I first became connected with the Royal Geographical Society, one of the things I remember doing was to place the instruments to be taken by Keith Johnston on a table for his inspection, just before he started on his journey from Zanzibar inland towards the Great Lakes. This was in 1878.

You may remember that this young pioneer-explorer's life came to an early termination before he had been long on this expedition, and the work was completed by the geologist, Joseph Thomson, who afterwards so successfully carried out the mission entrusted to him by our Society of exploring the region, then almost entirely unknown, between Mombasa and Victoria Nyanza. The route survey he made was of considerable importance, and was really the first piece of surveying done in the region, except just near the coast.

It is not only Africa, but Central Asia, South America, Australia, and the Polar regions have all to a great extent been mapped from route surveys made in much the same manner in times past, and many examples could be referred to; but those given may suffice to show the kind of work done by the earlier explorers of the last century.

I will now refer briefly to a few of the more recent examples of geographical surveying and mapping.

As already mentioned, the plane-table has recently come into more general use, and where the country is suitable and the topographical details can be adjusted to triangulation points, excellent results can be obtained. As an example of this sort of surveying, the map of the Siachen Glacier in the Karakorum region is worthy of attention. This map is from the surveys of my pupil, Mr. Grant Peterkin, who accompanied the Workman Expedition of 1912, and was published in the *Geographical Journal* for February, 1914. All the available points fixed by the triangulation of the Survey of India were first carefully laid down, and these were supplemented by others determined by a 5-in. theodolite by Mr. Peterkin himself as the work progressed. The triangulated points served as a basis for the plane-tabling, and the glaciers, ridges, peaks, and other topographical details were carefully adjusted to these triangulation points. Heights were principally obtained from theodolite or clinometer vertical angles, and were dependent upon the known heights of the triangulation, supplemented by hypsometrical observations.

The survey work in Central Asia varies a great deal in its reliability. For instance, while most of Tibet is mapped from the roughest sketching, there are certain sections of it that are from surveys of a higher standard. The survey of the British Expedition to Lhasa of 1904 is an example of this latter, for during the journey west of that place a traverse was carried along the valley of the Brahmaputra by Major Ryder and Captain Rawling, and the latter officer afterwards did some excellent mapping in Western Tibet and Kashmir. These surveys were published by the Survey of India, and reductions of them appeared in the *Geographical Journal.*

Some of the more important expeditions have been accompanied by officers of the Survey of India, even when the expedition has been a private enterprise; and the results as regards mapping have naturally benefited considerably by this arrangement.

Such was the case with regard to the Workman Expedition just referred to, to which was attached a native Indian plane-tabler, and with the journeys of Sir Aurel Stein, who has done really excellent survey work in Chinese Turkestan and in the mountainous region between there and India. Mention may be made of the recent remarkable expedition of the Italian explorer, Dr. de Filippi, who in 1913–14 conducted a thoroughly well-equipped scientific expedition from India to the Karakorum region, and thence to Yarkand and Kashgar. The final plotting of the results of the journey is now being done in Italy, and this should be most valuable.

The expedition was accompanied by the well-known Indian Survey officer, Major Wood, R.E., and two native Indian surveyors, besides several Italian surveyors, and the work consisted of theodolite triangulation and plane-tabling, supplemented by photographic surveying. An interesting feature was the determining of the differences of longitude by wireless telegraphy, which was most successful. Time signals were sent from the wireless station at Lahore and received simultaneously at the headquarters of the Trigonometrical Survey of India at Dehra

Dun, and, with the greatest clearness, by the surveyors at their various stations right over the Himalayas.

From what has already been said, it will be certain that the old rough-and-ready methods of route surveying are fast being superseded by more exact methods. The recent improvement in the micrometer theodolite, and the manufacture of light and portable forms, specially the 4-inch tangent micrometer theodolite, has made it possible for a traveller to carry with him a really good and useful instrument capable of considerable accuracy, with which he can not only take rounds of horizontal angles, but astronomical observations for latitude, longitude and azimuth of a higher degree of accuracy than was possible by his predecessors with a sextant and artificial horizon.

A useful piece of route surveying of this kind is that of Mr. C. Clementi, who in 1907–8 travelled from Kashgar through Chinese Turkestan and Western China to Canton, a journey of altogether about 4,000 miles, during which he fixed 141 places in latitude by north and south stars, and 139 places in longitude by a careful series of chronometric differences, by means of half-chronometer watches, with east and west stars for local mean time. To these astronomically-determined positions the route traverse has been adjusted, and the whole is a most creditable and useful piece of work. A list of the positions determined and a map showing the places appeared in the *Geographical Journal* for December, 1912.

I have specially referred to this here in connection with route surveys, as it is a good example of what can be accomplished by individual enterprise in mapping a route with small instruments.

If the longitudes could have been determined by wireless telegraphy they would doubtless have been more reliable still, but at that time this was impossible.

A similar piece of route surveying was carried out in South America, with the same kind of instruments, by Dr. Hamilton Rice in 1912–13, who travelled from Bogota, in Colombia, to the Rio Negro and Amazon, through an entirely unexplored region; and a map, with description of the journey and surveys, was published in the *Geographical Journal* for May, 1914.

The determination of longitude by wireless telegraphy has been undertaken with great success in recent years in connection with the Bolivia-Brazil boundary survey. Much of the country through which the boundary line passes is thick tropical forest, dense undergrowth, and along the courses of the Upper Amazon tributaries, so that a regular triangulation was quite out of the question; and all that could be done was to carry a careful traverse through this difficult jungle region. The work was first undertaken by Major P. H. Fawcett, R.A., and completed by Commander H. A. Edwards, R.N.R. During the latter part of the survey Captain Edwards determined the longitudes by wireless telegraphy, and an interesting description of the methods and results was given in the *Geographical Journal* for May last. It may be noted in passing that it was previously supposed to be almost impossible to send wireless signals for any great distance in the tropical forests of South America, but Captain Edwards's results were most satisfactory, and prove that, when properly carried out, there is little difficulty either in sending or receiving.

In connection with the present state of the mapping of the earth, I have dealt at considerable length with the subject of route traversing. I have done this first of all because at the present time by far the greater part of the earth's surface is still only mapped in this way, and in many regions it will doubtless be impossible to do anything more accurate for years to come, and it will be long before the darkest shade on our map is likely to extend to the remoter regions of the globe.

Before leaving this part of our subject, I want to say a little about the kind of surveying that is usually carried out by explorers in the Polar regions, and from which most of the mapping there has been done. As was apparent from the maps showing the state of surveys, it is in the Arctic and Antarctic regions that a large amount of the area of the earth still unmapped exists, which is what might be expected, considering the serious climatic and physical difficulties met with in penetrating into these regions. Such surveying as has been attempted has been carried out at the risk and sacrifice of many noble lives, and considering the circumstances it is not to be wondered that it is not as a rule of the highest order of accuracy.

Apart from climatic difficulties, there are others that render surveying in the Polar regions by no means an easy matter. Near the Poles the magnetic compass is most unreliable, partly because the "dip" is so great that there is very little directive horizontal force, and partly because the "variation" is changing so rapidly that in many places an alteration in position of

a few miles makes a considerable difference in its value. Then again, it is only possible to travel in daylight, so stars can but very rarely be used except at, or near, winter quarters; and, consequently, all astronomical observations must be made by the sun, which is generally so low that the refraction becomes uncertain. Still, latitude can be observed fairly well as a rule, since all that is required is to be sure that one has obtained the highest altitude; but longitude is another matter, as the change in altitude of the sun is so small for a considerable interval of time that it is almost impossible to get the local time with sufficient accuracy with such instruments as are usually carried, certainly remarkable, under the circumstances, that the position of the Pole as fixed by Amundsen about a month before, with a sextant, differed only from Scott's determination by about half a mile.

At the North Pole, Peary used a sextant and artificial horizon, and so have many others on Polar expeditions. After Peary's return, I took sextant and theodolite observations at low angles for the sake of comparison. These were made as a result of Peary's observations, since some persons at the time seemed to think that it was impossible to take observations with a sextant and artificial horizon at such low angles as 7°. The comparison shows that even

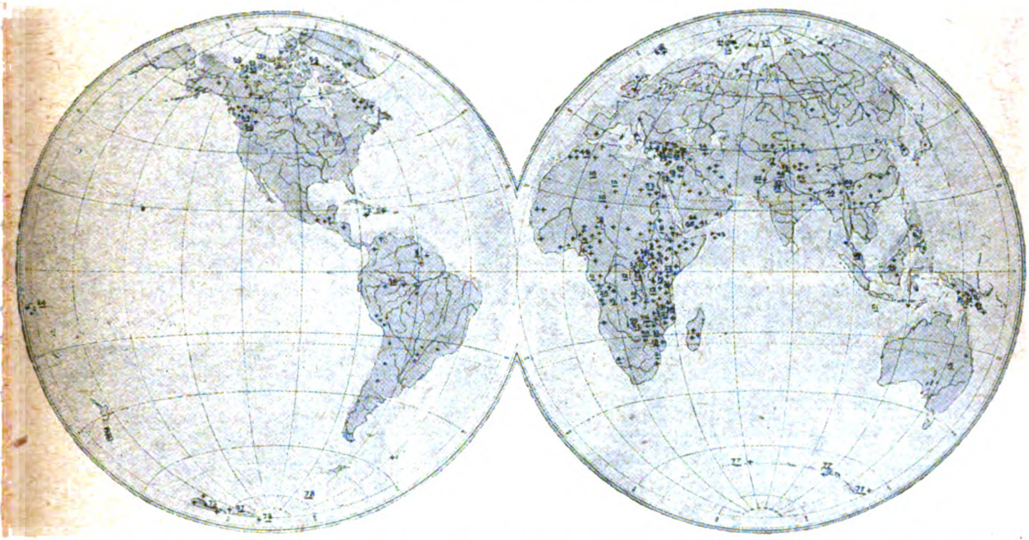

FIG. 19.—EXPEDITIONS TO WHICH THE ROYAL GEOGRAPHICAL SOCIETY HAS GRANTED MONEY AND LOANS OF INSTRUMENTS.

and under the trying circumstances in which the explorer finds himself.

It has become the custom now to take a small 3-inch or 4-inch theodolite on the journey to the Poles, and on Shackleton's remarkable expedition of 1907–9 the latitudes were observed with one of these. Distances were measured with a sledgeometer, and rounds of angles were obtained at every convenient halt to the different peaks and points along the coast. Compass bearings were read, and the variation found, by equal altitudes of the sun before and after the meridian passage. Heights were obtained from boiling-point readings and vertical angles. Subsequent expeditions have proved that, on the whole, this was a remarkably good piece of work.

Captain Scott on his last journey to the South Pole also took a small theodolite, and it is at 3° the sextant and artificial horizon observations differ only by about 1′ from those taken with a theodolite.

From its very foundation the Royal Geographical Society has had a remarkable influence on the surveying and mapping of the earth's surface, and specially those parts of it which have been previously but little known or entirely unexplored. I think it must be admitted that its influence has increased as years have passed, and it is no exaggeration to say that it has done more in this respect than any other body. It is therefore, perhaps, fitting that I should close this lecture with some account of what the Society has accomplished, specially as it has a direct bearing on the subject before us.

It is not only by the awarding of annual medals to explorers and surveyors, whose journeys have

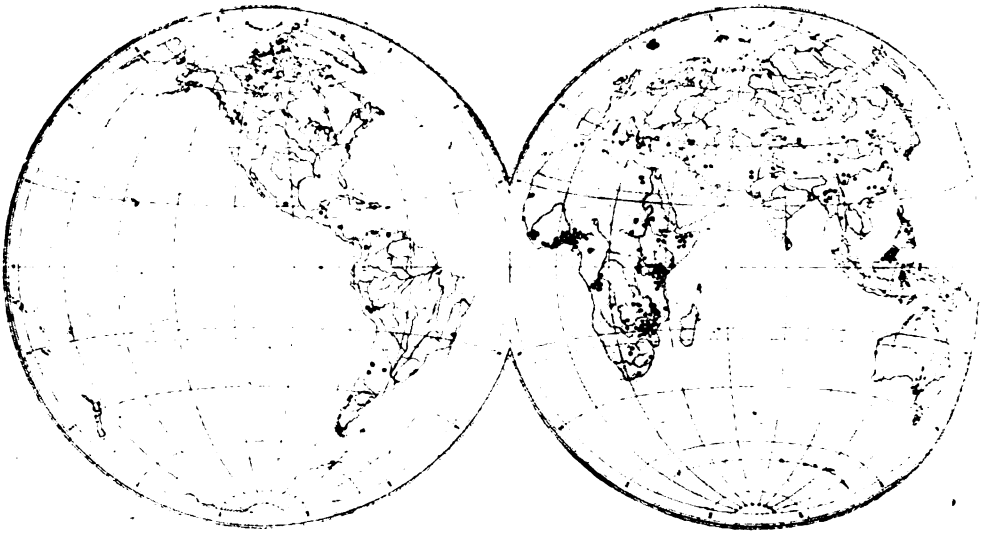

FIG. 20.—ROYAL GEOGRAPHICAL SOCIETY SURVEY PUPILS, 1879-1897.

resulted in the more accurate surveying and mapping of the world, that the Society has stimulated and encouraged geographical research, but it has also assisted financially a large number of expeditions, and the money thus granted has enabled many a man to carry his explorations to a successful issue which he otherwise could not have done for the want of funds. Still more frequently has it been the case that travellers going into little known parts of the world have been granted loans of surveying instruments, which they could not have purchased themselves; and, thus encouraged, they have brought back excellent cartographical results.

Altogether 331 expeditions have been lent instruments, and about £38,500 have been devoted to grants of money to further geographical exploration and surveying by the Society.

I have tried to represent something of the work the Royal Geographical Society has done in these two ways graphically on a map, which I will now give. In Fig. 19 the crosses show the regions which have been mapped, at any rate partially, by expeditions to which instruments have been lent, while the figures represent those expeditions and the field of their operations towards the expenses of which money grants have been made.

There is still another way, by no means the

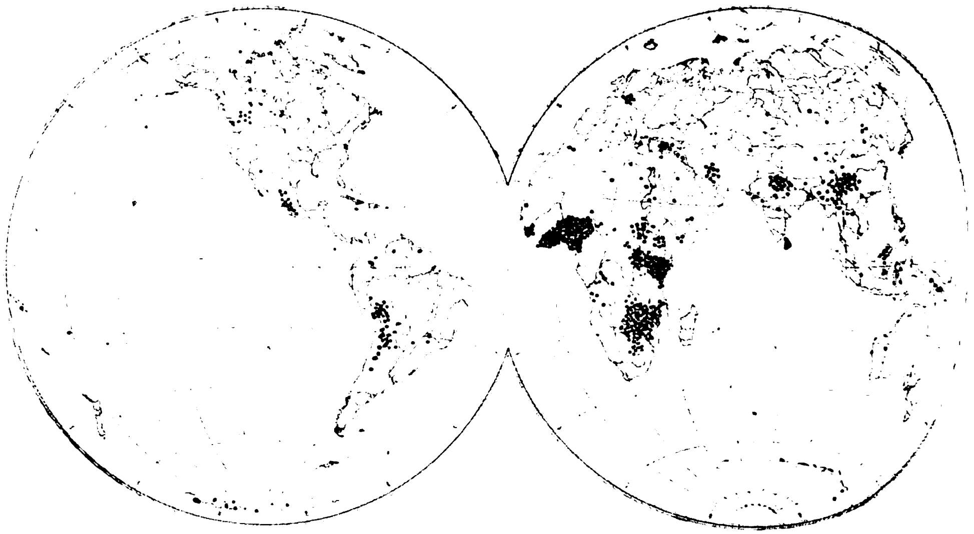

FIG. 21.—ROYAL GEOGRAPHICAL SOCIETY SURVEY PUPILS, 1897-1916.

least important, in which the Royal Geographical Society has done much to promote geographical surveying, and that is by providing suitable instruction in the work of surveying for travellers. It is all very well to grant money and lend instruments, but the important thing is that a man should know how to make use of the money and the instruments lent so as to take proper advantage of opportunities afforded, and to make the best possible surveys and maps of the regions visited.

In the early days of the Society a traveller had to pick up this requisite knowledge as best he could, but in 1879 a scheme of proper instruction was started at the suggestion of the late Sir Clements Markham, who was then one of our honorary secretaries. This had small beginnings, but in recent years has made rapid strides, until at present it forms one of the most important branches of the Society's work. This course of instruction in geographical surveying, which has now been in existence for about thirty-eight years, was first conducted by my predecessor, Mr. John Coles, and since 1900 has been under my charge.

Altogether 730 surveyors and explorers have received instruction without reckoning special large classes of forty or fifty men each, from various parts of British Africa and elsewhere, who have during the past few years, before the war, been sent to us by the Colonial Office to learn the more elementary parts of compass traversing and mapping.

In order that you may obtain some idea of what has been done in this respect, and the progress the course of instruction has made, I have divided the thirty-eight years since its commencement into two parts of nineteen years, for each of which I have drawn a map which I now place before you (Figs. 20, 21). The first map deals with the period from 1879 to 1897, and the second from 1897 to 1916. The students are represented by dots, and these are in each case placed approximately in the region forming the field of operations. Where the expedition extended over a considerable distance I have tried to place the dot in the locality which formed the most important part visited by the surveyor.

By comparing these two maps a general idea can, I hope, be formed of the vast field covered by the Society's pupils, and the great increase in the number of students as seen by the far greater number of dots in the second map. In the first half of the period, that is from 1879 to 1897, there were 195 students, and in the second half, from 1897 to 1916, the number equalled 535, giving a total of 730 for the whole period of the course.

Some of these men have only obtained a few lessons and so gained a little knowledge, but others have been able to go pretty fully into the subject.

Men who have time to pass through the complete course of instruction can place themselves before a committee of the Society for examination, and if they pass obtain its Survey Diploma. Only comparatively few have had time to do this, the number being 75, or just over 10 per cent. of the total number of students.

Now as to the work remaining to be done. It is clear from the maps and figures I placed before you at the commencement of this lecture that this is considerable, as, notwithstanding the great progress that has been made, there is still only about one-seventh of the earth's land surface that can be considered to be accurately surveyed, and about the same amount not surveyed at all.

The need for men who can do really good work is increasing every year, and after the war is over it will be much greater. There will be new boundaries to survey and delimit, and many parts of which we have had to be content with incomplete and approximate maps will come into prominence and require to be properly surveyed; so the field will be greatly widened.

LONDON EVENING CLASSES.

The London County Council polytechnics, technical institutes, and evening institutes will reopen for educational work next Monday. It is especially hoped to secure the attendance of youths under eighteen years of age and of girls and women. Owing to the war youths below eighteen have largely taken up work of a less educative kind than formerly, and are now engaged in repetition processes which will cease to employ them when peace returns.

The facilities for evening education have been greatly improved, especially in the case of modern languages, for proficiency in which large prizes have been offered by the Chambers of Commerce and employers. After the war a knowledge of the languages of our Allies and of other nations will be of the greatest service, and a special feature is being made of classes in French, Russian, Italian, Spanish, and Portuguese, as well as in German.

The County Council is appealing to both parents and employers to encourage young people to join the classes as early as possible after leaving the day schools. Many employers already let their young employees leave business

early in order to attend the classes, and a general adoption of this plan would greatly help the junior institutes. Particulars can be obtained from the Education Officer, L.C.C. Education Offices, Victoria Embankment.

COMPRESSION TEST FOR KEEL BLOCK.

An important test was conducted recently by the United States Bureau of Standards to determine the ultimate strength of a cast-iron keel block. As designed, the block was expected to withstand a load greater than could be exerted by any testing machine in existence. It did withstand the full capacity of the Bureau's testing-machine (10,000,000 lb.) when the load was applied over the entire bearing surface of the block, but when the load was applied over part of its bearing surface it failed at 9,600,000 lb.

The test of the block itself was preceded by several preliminary tests to determine the strength of oak timbers, which are usually placed between keel blocks and the keel of the ship. At loads from 300,000 lb. to 800,000 lb. the timbers were completely shattered, the variation in the load depending entirely upon the variation in the area over which the load was applied.

After these preliminary tests the keel block was subjected to a load equal to the capacity of the machine. At about 6,500,000 lb. several sharp reports were heard, but after the full load was applied there was no apparent damage to the exterior of the block. On dismantling it, however, it was noticed that several of the webs of the various sections were cracked. It was then reassembled, and the load applied over a smaller area, when it failed at 9,600,000 lb. with a very loud report and almost complete shattering of the various sections, throwing parts of them to a distance of 12 ft.

OBITUARY.

Sir Cavendish Boyle, K.C.M.G. — Sir Cavendish Boyle died in London on the 17th inst., after an operation. He was born in 1849, a younger son of Captain Spencer Cavendish Boyle. His first official appointment was that of magistrate in the Leeward Islands, 1879. From 1882 to 1888 he served as Colonial Secretary in Bermuda, and after this he filled numerous Colonial offices, the latest being the Governorship of Newfoundland, 1901-1904, and that of Mauritius, 1904-1911. On leaving Mauritius he retired on a pension. In the year 1899 he took part in the discussion on Mr. H. A. Acworth's paper on "Leprosy in India," and soon after he became a member of the Society with which his elder brother, Sir Courtenay Boyle, had been connected since 1891. He also took part in the discussion on Sir Nevile Lubbock's paper on the West Indies in 1901.

GENERAL NOTES.

The Institute of Metals.—It will be remembered that when the Peter Le Neve Foster Prize was awarded to Mr. J. C. Moulden, A.R.S.M., M.Inst.M.M., for his essay on "Zinc, its Production and Industrial Applications" (which was published in the *Journals* of May 26th and June 2nd last), a very favourable opinion was expressed by the judges of the paper entitled "The Development of the Spelter Industry," by Mr. Ernest A. Smith, Deputy Assay Master of the Sheffield Assay Office, which was placed second in the competition. The latter paper was read before the Institute of Metals at their meeting on the 20th inst.

Indian Woods for Bobbins and Pencils.—In consequence of the war the supply of wooden bobbins from Europe required for Indian jute and other mills failed, and measures had to be taken to get them from elsewhere. According to a report of Mr. Cox, Imperial Forest Economist, a demand for suitable indigenous timber for bobbins arose in 1914-15. Thirty different kinds of wood were sent to a Calcutta firm from various parts of India, and these were duly seasoned before being tested as to suitability. The result has not yet been made known, says the *Pioneer Mail*; but it should be possible to find some Indian timber at least that will answer the purpose. Meanwhile, a cheap grade of bobbin has been imported from Japan, which, as usual, is on the alert for a fresh line of business. The lead-pencil industry, which has been stimulated by the war, is also in need of suitable wood. According to Mr. Cox, the *Juniperus macropoda*, from Baluchistan, upon which reliance has hitherto been placed, is becoming increasingly difficult to obtain, and the Calcutta pencil-makers have felt acutely the shortage of wood. Specimens of other timber from Madras, Sikkim, and Assam were experimented with, but no good substitute was apparently found for the juniper from Quetta. Further experiments are being tried, and it is to be hoped that they will be successful, as the lead-pencil industry, though of minor importance, is one that should have a future before it in India.

Sisal in the Philippines.—According to the United States correspondent at Manila, a determined effort is being made to develop the growing of sisal in the Philippines. Exporters of fibre are interested in the project. It has been found that the plant does exceedingly well in the islands, and that the fibre produced from it there is of excellent quality. The officials of the Bureau of Agriculture of the Philippine Islands are also lending their support to the propaganda for the cultivation of sisal. Already considerable plantings have been made, especially on the island of Masbate, and it is expected that within a few years the United States will become more independent of tropical America in obtaining a sisal-fibre supply.

NOTICE.

FOTHERGILL LECTURES.

The Fothergill Lectures on "Historic Buildings in the Western War Zone: their Beauty and their Ruin," by the Rev. G. Herbert West, D.D., A.R.I.B.A., have been reprinted from the *Journal*, and the pamphlet (price one shilling) can be obtained on application to the Secretary, Royal Society of Arts, John Street, Adelphi, London, W.C.

A full list of the Cantor and Howard Lectures which have been published separately, and are still on sale, can also be obtained.

PROCEEDINGS OF THE SOCIETY.

FOTHERGILL LECTURES.

SURVEYING, PAST AND PRESENT.

By Edward A. Reeves, F.R.A.S., F.R.G.S.,
Map Curator and Instructor in Surveying to the Royal Geographical Society.

Lecture III.—Delivered April 10th, 1916.

MODERN INSTRUMENTS AND METHODS OF GEOGRAPHICAL SURVEYING.

Last week I attempted to give a general idea of the present standpoint of geographical surveying, and to show by means of maps and diagrams what has been done during the past fifty or sixty years towards the surveying of the earth's surface, and what now forms the basis of our maps of various parts of the world. This afternoon I desire to say something about the more important instruments and methods employed by geographical surveyors at the present day.

As stated in a previous lecture, I propose to confine myself almost entirely to geographical surveying, or that branch of the subject which deals with the surveying of a considerable extent of the earth's surface on a scale sufficiently large and with the accuracy necessary for exhibiting all the main geographical features and topographical characteristics—in fact, to produce a good map of a country for general purposes. The points on such a map, on the scales of 1 : 125,000 or 1 : 250,000, should be accurate within the breadth of a pencil line, and if the work is properly carried out there is no reason why this should not be the case.

The principle underlying all surveying is much the same, and the whole subject really amounts to the best and most accurate methods of measurement with a view to representing on a plane, on a greatly reduced scale, the leading features of a certain area on the earth's surface in their relatively correct positions. Thus it resolves itself into a geometrical problem of similar angles and proportional distances.

This being the case it is clear that it becomes a question of correct angular and linear measurements and the computation of results; and all the improvements in survey methods have had for their object the increase of accuracy and facility in accomplishing these.

What we do now is exactly what was attempted by the early Greek geographers and others in ancient times, only we use far more accurate instruments and improved methods. If, for instance, we compare our modern micrometer theodolite with the old scaph of the Greeks, which was perhaps the first idea of an angular measuring instrument, or even with an early pattern theodolite, the contrast is striking. Many of these old instruments were extremely rough, and the angles could only be read with approximation, and to a great extent by estimation; and it could only be by chance, or by taking readings many times repeated, that any useful results were obtained. With the introduction of telescopic power and fine cross-wires in the seventeenth century, the vernier, and later the micrometer, it became possible to construct surveying instruments of great precision and accuracy. The theodolite, which is now frequently used in geographical surveying, has a circle of only 5 in. in diameter, yet with the micrometer it is quite easily read to 2″ of arc, or even as close as one second by estimation. When one comes to think of it, this is a marvel

of refinement, since it really means that we can measure to about $\frac{1}{50000}$ part of an inch, which is the space occupied by 1″ on the arc of a circle of 5 in. diameter. At least, this is the theoretical accuracy, but in actual practice there are, of course, errors in sighting, setting the micrometer wires, and those arising from other sources that have to be taken into consideration.

The continual striving after greater accuracy of measurement applies not only to angular measurement instruments, but to linear distance measurement as well; and the improvements in apparatus for this purpose, could we follow them in detail, would be most interesting.

From the rough methods that would naturally suggest themselves to early intelligent men, and some of which I referred to in a previous lecture, to the modern base-line apparatus, micrometer theodolite, and accurately computed sides of a geodetic triangulation is a far cry, and the advance in these matters is certainly remarkable. What would the ancient geographers have said if they could have been told of the accuracy of a modern triangulation, such as our own Ordnance Survey or of the Survey of India?

Still, absolute accuracy of measurement of any kind seems to be an impossibility, and the best we can do after all is to approach it as near as we can, and to arrange matters so that the errors will tend to balance one another.

Nature herself appears to object to perfection in measurement, even if other difficulties could be overcome. For instance, when we attempt to measure a distance, and have taken all precautions we can, change of temperature alters the length of our measuring tape, making it longer or shorter according to whether it becomes warmer or colder; and in spite of all that has been done by manufacturing tapes of alloys of different metals, in order to counteract this effect, change and uncertainty must exist to some extent. Then, as regards our angular measuring instruments, not only must there always be some imperfection in the graduation and centering, but the change of temperature affects the metal and again attempts to defeat our object of obtaining perfection. If we desire to measure the true vertical angle, there is always the troublesome and uncertain effect of the refraction of the atmosphere, which makes the mountain-top appear higher or in a different place to what it really is, according to the heat, moisture in the air, and all sorts of other unknown causes, which, in spite of all the corrections we may apply, occasion at least some uncertainty in our result; whilst in the case of the sun or star it is considerably worse. So great is this refraction, that when the sun appears to be just above the horizon as you see it over the sea, it is not there at all, and has actually gone down below the horizon. Of course, tables have been constructed for correcting all this, but no one can say that they are really accurate as the values depend so much upon special conditions, so that, in any case, they are only devices for making the best of a bad job.

There is another way in which Nature seems to do her best to show that she disapproves of our attempts at accurate measurement, and one which is most serious at times in its results, since it is often quite unsuspected—and that is the manner in which she pulls the spirit-level of our theodolites out of its proper central position. This is usually called the "deflection of the plumb-line," and it really means that the earth's crust is made up of irregular masses of matter so that the effect of gravity on the spirit-level or plumb-line is irregular; and as no one can tell exactly how much or in what direction this deflection is going to be, there is always an uncertainty of a second or two, and indeed sometimes much more, introduced in a latitude or other observation, however carefully they may have been taken. In quite a number of regions of the world, such as various parts of India, the British Isles, and the United States, experiments have been made to try and find out what the effect of this is, but there are far more places where nothing of the kind has been done, so that the geographical surveyor has always this sort of nightmare to haunt him, that his latitude and other observations, in spite of all his care, may not be so correct as they appear after all.

Again, as regards levelling, who can tell exactly what the mean level of the sea is upon which the difference of level depends? The best that can be done is to take a series of tidal observations at certain points over a lengthy period and accept the mean value; but the result would probably be different if taken at other times and in different places round the same coast.

Many other instances of the kind could be mentioned, and it is clear that in surveying, as indeed is the case with all other human effort, we are not likely to reach absolute perfection, however much we may strive after it and notwithstanding the astonishing degree of accuracy that has been attained. This being the case,

it is most important that whenever possible observations should be taken so that the errors have opposite effects and tend to balance one another.

The methods to be adopted in carrying out a survey must depend to a great extent, not only on the purpose of the survey, but upon many other circumstances, such as the time that can be given to the work, the funds available, and upon the character of the country to be surveyed. The latter is a most important matter, since it frequently happens that all else is controlled by it, specially as to the methods of determining the points to which the survey can be adjusted. For instance, there are parts of the world, such as the thick tropical forest region of the Amazon basin, the Gold Coast and parts of the Congo basin, where it is out of the question to carry out a regular triangulation, since it is not possible to obtain any extensive view, and so angles to distant points cannot be observed, and the surveyor is restricted to running traverse lines, which are checked and adjusted by the best means available. Again, in perfectly flat country with no prominent features, it frequently becomes necessary to adopt special methods. The question of transport and carriers also plays an important part. For instance, however desirable it might be to take large and accurate instruments and carry out triangulation in the Polar regions, except near the base stations and certain small areas more readily accessible, this has always been considered out of the question, chiefly from the difficulty of transport, climatic conditions, and the impossibility of devoting the necessary time to the operations without seriously delaying the expedition.

It is therefore clear that there are many things to take into consideration before undertaking a survey, and it is frequently impossible to follow the most approved methods, however much we may desire to do so. It really comes to it, as in many other things in life, that we have to do the best we can under the circumstances.

Still, whatever decision may be arrived at, there are fixed principles that should be always kept in mind, and a certain order in which the various operations should be performed—of which I hope to say something later on. First of all, we will deal with instruments, and although I cannot attempt a lengthy description of those now generally used, I desire to refer to some of the latest pattern, and call attention to a few of the important points in the construction of the instruments which are frequently overlooked by makers. Some of these are simple, although the accuracy of the work done may depend upon them.

Without doubt, the most important instrument for the geographical surveyor is the theodolite, and too much care cannot be taken in its selection, since a great deal of the whole work will depend upon this instrument. It is with the theodolite that the triangulation is performed which is to constitute the framework of the survey, and the fixing of points to which the topographical mapping is afterwards to be controlled and adjusted.

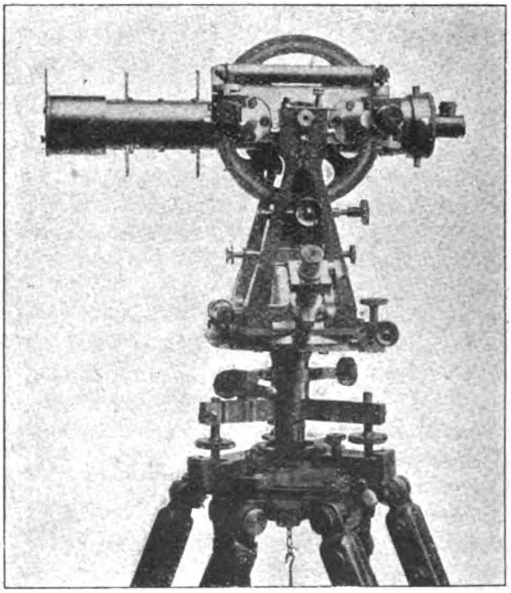

FIG. 22.—5-IN. MICROMETER THEODOLITE.

With this instrument are also taken such astronomical observations as are necessary for latitude, time and difference of longitude, and azimuth or true bearing, so altogether it is well to obtain a really good instrument.

The theodolite shown in Fig. 22 is a 5-in. transit, with micrometers divided to 10″ for reading the circles, such as is now generally used in the sort of surveying we are dealing with. You will remember that in the first lecture we traced rapidly the development of the theodolite from its early forms to the latest type of the instrument. For ordinary survey work it is not necessary to have such a heavy or elaborate instrument as this latter, and the one now shown has proved from experience extending over a number of years to meet

general requirements. It has been used extensively in the surveys of British possessions in Africa, on recent boundary surveys in South America and elsewhere, and has given satisfactory results. Although the micrometer "drums" are only divided to 10″, it is quite easy to read to 2″ or even 1″ with care, by estimation.

Whatever theodolite it is decided to take, there are certain features that should be carefully considered. For instance, the vertical and horizontal circles should be complete circles and not merely sections of circles or arcs, and the upright supports of the telescope should be long enough to admit of the reversing of the telescope with any eyepiece set to focus. In order to eliminate instrumental errors, all observations must be taken "face left" and "face right"—that is, with the face of the vertical circle first to the left and then to the right, as one looks through the telescope, except in the case of those astronomical observations in which the errors are eliminated by taking stars on opposite sides of the zenith.

Another important point is that the principal level should be on the vernier or micrometer arm, and not on the telescope as used generally to be the case with ordinary theodolites. This is most important for all accurate vertical angle observations, whether for astronomical work or otherwise, since it is necessary to note the reading of the level when each altitude is taken as well as the circle reading itself, and apply a correction. It will be clear that if the level is on the telescope it will revolve with it, and will be out of sight when the reading on one of the faces is taken; it would for other reasons be useless for the purpose in view.

It is true that when the theodolite is likely to be much used for running lines of levels as well as taking altitudes, it is convenient to have a level on the telescope; but it is better in that case to have an additional level.

There is quite a lot to learn about a theodolite in order to use it properly, and even the levelling of the instrument is not a thing that can be easily done, at any rate, with an instrument of this pattern, unless you know exactly how to do it.

If I were giving you a lesson in the use of the theodolite, there are many points beside those referred to with which we should have to deal; but you will find most of them explained in any good book on the subject.

Although the theodolite has many advantages over the sextant for geographical surveying, it is strange that it is only in recent years that it has been at all generally used, except on large elaborately equipped expeditions. One reason for this is that it has been considered too bulky and heavy for carrying on small expeditions. However true this may have been in the past, it does not hold good at the present time, as there are now several light forms with which it is possible to do quite useful work.

I was so constantly hearing of the difficulty of taking a theodolite on small expeditions where transport is a serious consideration, that some years ago I tried to remedy the matter by designing an instrument that should be portable and yet have all the latest improvements. The circles are read by means of special micrometers, which are, in fact, combinations of the tangent-screw and micrometer, so arranged that they greatly reduce the size and weight of the theodolite. The circles are 4 in. in diameter, and by means of the micrometer can be read to two seconds of arc. This instrument has, during the past six or seven years, been used on many expeditions with satisfactory results.

Even the extremely small 3-in. theodolite is quite a useful little instrument in proper hands, and has been taken on expeditions when no larger theodolite could be carried. As mentioned before, it was one of these that Shackleton and Scott took on their journeys towards the South Pole, and it has been used on other Polar expeditions. One of the latest instances of its use was on a journey through the centre of Arabia. Latitudes were obtained with it during this expedition three years ago, which, when compared with observations taken previously by other travellers at fairly well-known places, agree within 1′ of arc; and altogether I think we may consider that the observations are quite near the truth.

I have dealt somewhat at length with the theodolite; but there are many other instruments I might refer to. However, I shall only be able to say a little about a few of the principal of these in the time at my disposal.

While the theodolite gives the angular measurements, it is necessary that there should be some accurate means of obtaining linear measures or distances. For instance, while a triangulation would be relatively and proportionately correct, provided the angles were accurately measured, the actual lengths of the computed sides depend upon the accurate measurement of a base-line, and if this is in error the whole of the distances on the map must be wrong; therefore it is absolutely

essential that there should be some apparatus for measuring distances accurately. For rough route traversing, pacing or measurement by time, an estimated rate of travel is frequently all that can be managed, but in more exact surveying some better method has to be adopted.

To measure a base-line accurately is not such an easy operation as it may be at first supposed, and many things have to be taken into consideration, and to obtain a really good value needs the greatest possible care. Not only must the alignment be true, corrections be made for slope, and sag when the tapes are suspended on tripods, and the base reduced to the horizontal distance at sea-level, but corrections have to be made for the effect of expansion and contraction due to change of temperature.

for a change of 1° cent. instead of about $\frac{1}{204000}$, as is the case with steel, so that for all purposes of ordinary geographical surveying it may be considered invariable. The invar tapes have to be carefully handled, and must be wound on drums or reels of fairly large diameter.

Fig. 23 shows this base-line apparatus as it is when in use. The photograph was taken during Major Jack's survey for the continuation of the geodetic arc in Western Uganda, to which I referred in a previous lecture.

The tape itself commences at the connection near the inner tripod. Here a cord is fastened to the tape, and passes over a grooved pulley-wheel with ball-bearings, so as to reduce the friction as much as possible. Over the top

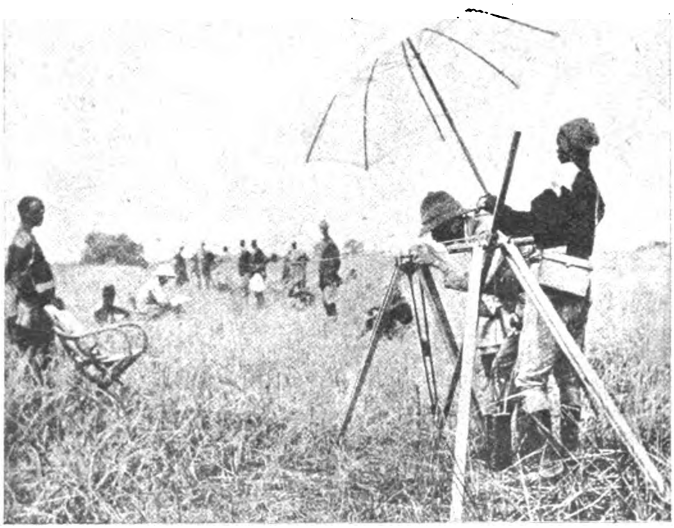

FIG. 23.—INVAR TAPE BASE-LINE APPARATUS.

The base-line apparatus of early days was bulky and generally heavy and difficult to carry about; but considerable skill and ingenuity has in recent years been exercised in the construction of light and portable apparatus, so that it could be carried on geographical surveying expeditions in rough countries; and the results have been most successful.

The difficulty of combining accuracy with portability has, I am glad to say, been practically overcome by the introduction of tapes made of an alloy of steel and nickel (containing 36 per cent. of nickel) called "invar," on account of its being almost invariable whatever the temperature may be. The expansion or contraction is only about $\frac{1}{1000000}$ of the length of the inner tripod is a very finely-divided scale for reading the lengths.

The tapes are of various lengths from 100 ft. to 400 ft., and 25 or 100 metres, and when in use are suspended between tripods at one tension by weights.

Having measured a base-line, or a section of it, it is necessary to mark its terminal points accurately on the ground, and there are various ways of doing this. In ordinary work it is sufficient to use a plumb-line, but when great accuracy is required this is not good enough, and all sorts of other methods have been attempted. The one that seems most satisfactory is the theodolite method. Two theodolites are placed roughly at right angles to one another. Each is carefully

levelled, and sighted on to the terminal point on the tape; each telescope is then lowered until the ground is sighted, and the mark placed

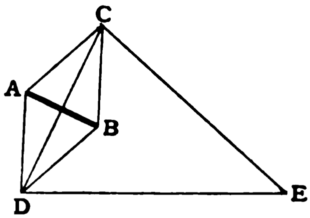

FIG. 24.—EXTENSION BASE.

where it can be seen exactly at the intersection of the central cross wires of the two telescopes.

One essential condition for all good triangulation is that the angles of the triangles should not be too acute or too obtuse, and this means that it frequently happens that a base-line sufficiently long or in a suitable position to give good intersections cannot be measured directly, in which case an extension base is resorted to. Here is an example of an extension base on the screen.

If AB (Fig. 24) is a measured base it will be seen at once that this is not long enough, nor in a suitable position for obtaining the lengths of the sides of the triangle CDE, so it is extended by triangulation to CD by measuring all the angles in the quadrilateral ABCD, and then from the base AB and the measured angles computing the sides AC and AD and BC and BD, and thence the side CD. CD can be computed two different ways, *i.e.* from the triangle ACD, and then from the triangle BCD, thus furnishing a good check on the work.

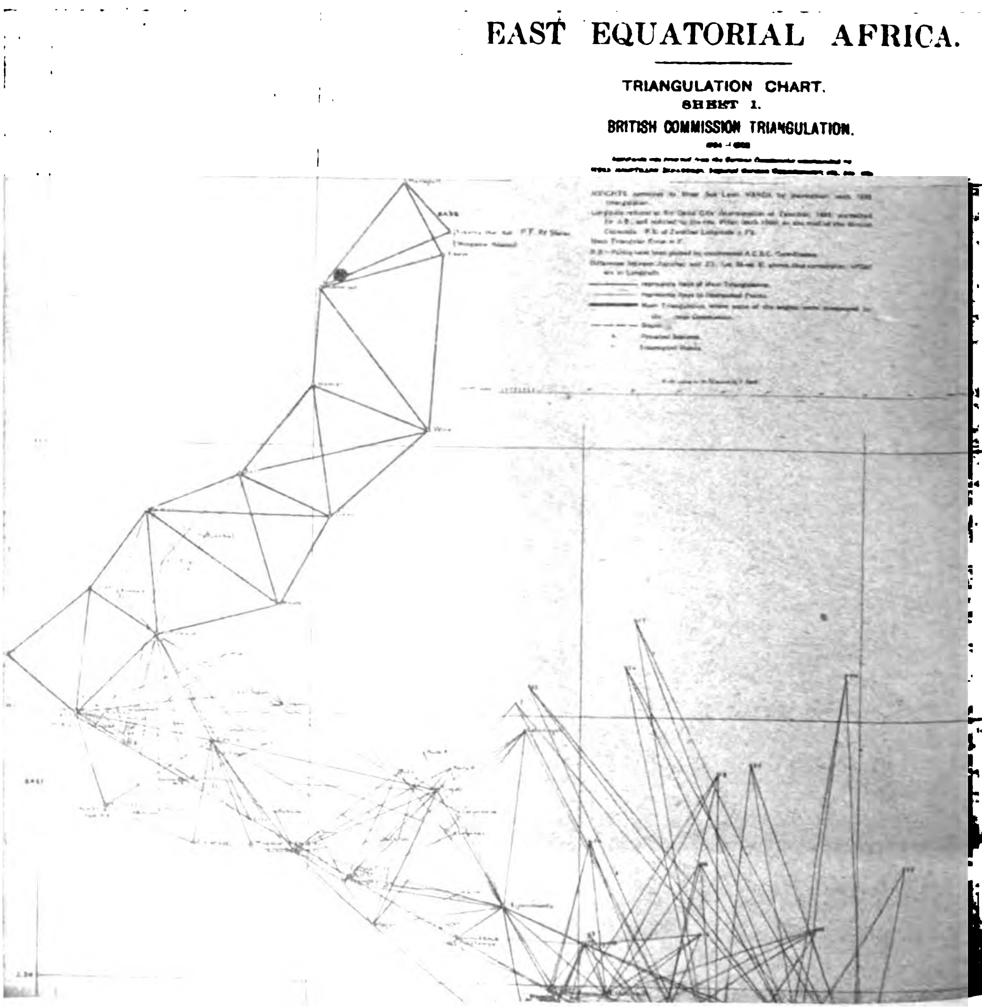

FIG. 25.—PART OF BRITISH EAST AFRICA TRIANGULATION.

I will now show two examples of triangulation taken from work done in recent years in connection with geographical surveying.

Fig. 25 is a specimen of the British East Africa triangulation, referred to in a previous lecture.

Fig. 26 is a part of the triangulation carried round the north end of Victoria Nyanza to the Belgian and German frontiers by Colonel Delmé-Radcliffe in 1902–4.

At the time of the so-called partition of Africa, it was decided that the boundary between the British sphere of influence west of Uganda and the Congo Free State should follow the line of the 30° meridian of east longitude, which was then supposed to run through the middle of Lake Edward, then but recently discovered by Stanley's expedition for the relief of Emin Pasha. However, Colonel Delmé-Radcliffe's triangulation placed the lake to the west of that meridian, which led to serious diplomatic discussion with the Belgian Government, and with Germany also, since it affected the German boundary to the south as well.

It should be a lesson for the future, as it shows the importance of having a good survey made before deciding upon boundary lines.

As already mentioned, owing to the features of the country, it is frequently quite impossible to carry out a regular triangulation; at least, it could not be done without enormous labour and expense. For instance, in the tropical forest region of parts of West Africa, such as the Gold Coast, it would be out of the question without first clearing away the trees, or erecting numerous high towers so as to get a distant view. The same is true of the recent South American Boundary Surveys of which we have read a good deal lately.

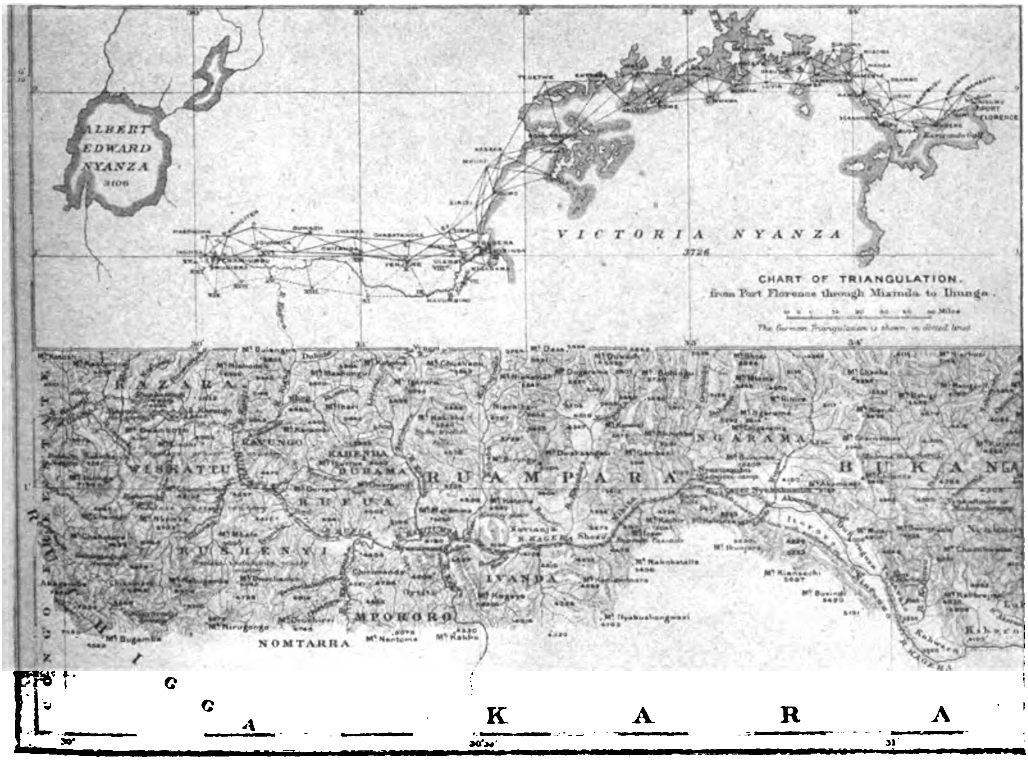

Fig. 26.—Colonel Delmé-Radcliffe's Triangulation.

When on the high mountain region of the Andes a triangulation could be run, but when this was left for the low forest region of the Upper Amazon basin to the east, triangulation became quite impossible as no distant points could be seen.

In these cases, when no triangulation can be carried out, other means of fixing definite points to which the survey can be adjusted have to be resorted to. The only way then is to run a traverse, as it is called, of some kind—that

is, to measure the distances between the points along the route and the inclination of the various lines, or "legs," of the traverse with one another. Thus, suppose a man travels from A to B (Fig. 27),

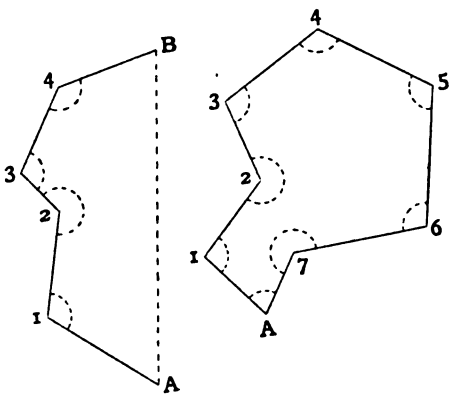

FIG. 27.—THEODOLITE TRAVERSE.

he would measure the distances A–1, 1–2, 2–3, 3–4, 4–B with a chain or tape, and the angles that one leg makes with another with a theodolite, from which the rectangular co-ordinates of all the stations can be computed, and the traverse corrected and closed, as it is called, if the points A and B are known. This is what actually takes places in the case of a theodolite traverse; and although the result is not likely to be so accurate as triangulation, with care a good theodolite traverse can be carried over a considerable number of miles without any serious error.

In work of this kind several things must be borne in mind, of which one of importance is that, unless the ground is perfectly level, the measured distances will be too great and must be reduced to their horizontal values. Then the traverse should be checked wherever possible, and closed on to fixed points, in which case the angles and computed co-ordinates have to be corrected in order to make the closure. The diagram to the right (Fig. 27) shows a traverse that closes on its starting-point A.

Running a theodolite traverse through thick tropical forest is no light undertaking, and entails a vast amount of labour, as it frequently happens that a line has to be cleared through the forest for many miles.

Sometimes the country through which a traverse is run is not only thickly wooded but marshy and full of swamps, and not long ago a surveyor in West Africa told me that he had had to work for six weeks at a time in such a region, with water up to his knees, nearly pitch dark, and water continually dropping on him from the trees above. Add to this the pest of millions of mosquitoes and other insects, and numerous snakes, and you have a condition of things about as unpleasant as can be imagined.

In accurate traversing, distances are measured with a steel tape or chain; but, as you may suppose, this is often a difficult and lengthy business, and it frequently happens that some more rapid method has to be adopted.

For this purpose the tacheometer is of the greatest service. The ordinary tacheometer, in which two fixed wires, or points, are placed in the diaphragm of a telescope, for measuring distances directly by reading the number of feet and parts of a foot subtended between the two wires is well known; its principle is shown by Fig. 28.

There are many different kinds of tacheometers, but they all depend upon the same principle —that is, the obtaining of the distance by the measurement of the small angle subtended by a certain known space on a rod, such as 1 ft., 1 metre, etc. From the diagram it is clear that, taking AB as the rod and BC the known distance, AB : BC :: ab : bc, and the angle subtended by the rod AB will depend entirely upon the distance the rod is away.

A tacheometer of the ordinary kind is limited to comparatively short distances, such as 500 ft. or 600 ft. if any accuracy is required, since for long distances the figures and divisions become too indistinct; so for geographical surveying another form is generally used, called a subtense instrument, in which the wires, instead of being fixed, can be moved across the diaphragm, and made to cover the two target-like discs at the ends of a long rod, say 10 ft. in length, placed horizontal at right angles to the instrument.

The further the rod is away, the smaller will be the angle subtended by it. The angle is measured on the drums of the micrometer, and the distance corresponding to this found by referring to a table, or by simple computation.

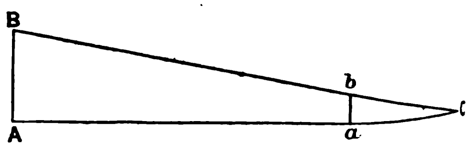

FIG. 28.—PRINCIPLE OF TACHEOMETER INSTRUMENT.

Fig. 29 is a view of the Indian Survey pattern subtense instrument.

Any good theodolite can be fitted with "stadia" wires, as they are called, in the diaphragm, for giving distances in the proportion

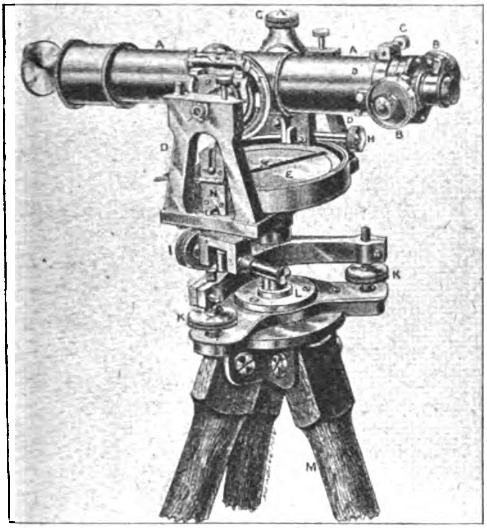

FIG. 29.—INDIAN SURVEY SUBTENSE INSTRUMENT.

of 1 in 100, or the small angle the rod subtends can be measured on the circles of the theodolite, if care is taken to provide checks and obtain means.

With tacheometers or subtense instruments of either of these patterns it is, of course, necessary for a man to go to the distant station and place a rod there, and when the stations are on the line of the traverse followed there is little difficulty about this, but there are many cases when it is most desirable that the distance of points to the left or right of the route, or any other inaccessible points should be fixed. For instance, in mountainous country intersected by deep gorges and passes, an instrument that really gives reliable distances to inaccessible visible points would be of the greatest assistance. A really good range-finder would answer the purpose, but the difficulty as a rule is that they are too approximate in their results. Occasionally a range-finder of the Barr and Stroud pattern has been carried, and found useful. There is also the distance-finder which I designed some years ago, a modification of which has been arranged for use in combination with a plane-table alidade.

The principle will be clear without much explanation. A rod $2\frac{1}{2}$ ft. to 3 ft. in length has at each end a telescope placed at right angles to the rod. Each telescope has a fixed horizontal and vertical wire in the diaphragm, and one of them has, in addition, another vertical wire that moves across the diaphragm by means of a micrometer screw, the divisions of which are marked on the micrometer drum. The rod is placed on the plane-table and levelled, and the left-hand telescope with the simple cross-wires accurately sighted on to the object of which the distance is required. On looking through the other telescope the same object will be seen to be slightly to the side of the centre, and this small amount is the angle subtended by the rod at the distance of the object. Errors are eliminated by taking the readings with the rod and telescope reversed, and accepting the mean as the true reading.

In open country, when there is not time to carry out a regular triangulation, it frequently happens that all a surveyor can do is to run a traverse and fix points by what is known as the latitude and azimuth method, and when the route follows a suitable direction, and other circumstances are favourable, this can be made to yield quite good results, although, of course, not so accurate as triangulation.

The principle of this method will perhaps be clear by referring to the diagram (Fig. 30). Let A and B be two stations on a route of which the latitudes have been obtained by astronomical observation, and let the azimuth or true bearing of B from A (= angle PAB) also be found from an observation. Then in the spherical triangle APB we have the co-latitudes AP and BP with the angle PAB given, to find the angle APB, the difference of longitude, and the length of the side AB, the distance between A and B.

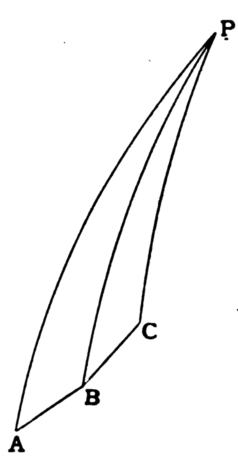

FIG. 30.—PRINCIPLE OF LATITUDE AND AZIMUTH TRAVERSE.

Having fixed B, the traverse can be continued to the next station, and so on, whilst theodolite horizontal angles can be obtained to side points along the route to fix their positions.

When the observations are carefully taken

and due allowance is made for the figure of the earth in the computation, the results are quite satisfactory for a first preliminary survey across a little-known region, and indeed much work has been done in Africa and elsewhere by this method.

So far the greater part of what has been said has had reference to the fixing of points, either by triangulation or on a traverse line; but it is clear that this alone does not make a map; and what a geographical surveyor has to do is to produce the best possible cartographical representation of the country, for which the definitely-fixed stations of a triangulation or traverse are but the points of control to which the topographical mapping may be adjusted. This is a matter of some importance, and one which should be borne in mind.

I could mention several instances in which surveyors have been supposed to carry out a geographical and topographical survey of a new region, but have spent nearly the whole of their time and money in attempting to fix points, forgetting altogether that the main object of their expedition was to produce a map showing the topography of the country.

It is in this representation of the leading topographical features that so many surveyors in the field come short. In fact, it is no easy matter to produce a proper generalisation of the leading characteristic features of a region, and not to give undue prominence to details because they appear large and important owing to the fact that they are close at hand. As is the case with many other things of the kind, to be a really good topographer a man has to be born with it in him, and if he has no natural aptitude for the work no amount of training will really make up for the deficiency, although he may be fairly good at other branches of the work.

There are several different ways of filling in topographical features in a survey, but whenever it can be used there is no doubt that there is nothing to equal the plane-table for rapid work on a geographical survey.

Although for many years past this instrument has been used in India and America, yet it was a long while before its merits were at all generally appreciated by the British surveyor.

I well remember the time, twenty-eight years ago now, when a young American engineer came to the Geographical Society in the days of my predecessor, full of the praises of the plane-table, and of the work that was being done with it in the United States. His astonishment at the little the possibilities of the instrument were appreciated in this country was great, and it was chiefly through the encouragement given by Sir Thomas Holdich and a few others interested, that he read a paper on the instrument before the Institute of Civil Engineers.

I have always looked upon this as marking an important epoch in the history of the use of the plane-table by British surveyors.

We are all doubtless familiar with the appearance and use of the plane-table in a general way, but there are some special features and improvements recently introduced that I should like to call attention to, as some of them are not so well known as they might be.

By way of refreshing your memories, I will make a few general remarks on the subject.

Plane-tabling is a graphic method of surveying by which, instead of measuring lengths and angles, and recording them in a book to be plotted afterwards, the map is produced on the spot, and grows gradually under the eye of the surveyor as his survey proceeds.

The plane-table consists, in its simplest form, of a board on a tripod stand, and a ruler, called an alidade, for sighting on to distant points. Now, suppose we wish to make a map of the district shown in the diagram (Fig. 31). To begin with, a base-line is measured and the plane-table set up at A, one end of this base-line. Then the alidade is sighted on to B, the other

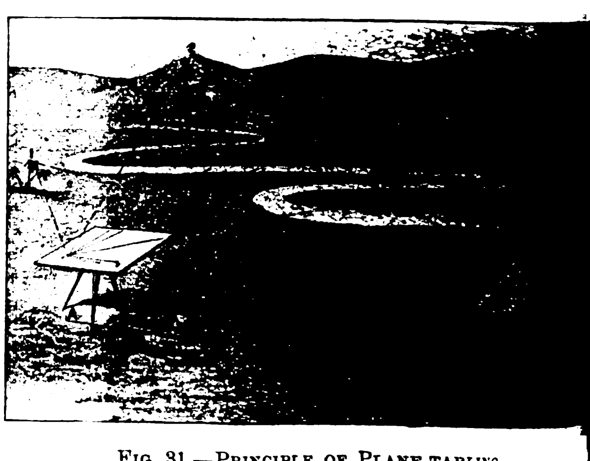

FIG. 31.—PRINCIPLE OF PLANE-TABLING.

end of the base, and a line drawn on the paper (mounted on the plane-table board) to represent the base-line to any suitable scale. With the alidade on the point A, all definite points in the country are sighted, and lines drawn towards them. Next the plane-table is moved to B, the other end of the base-line. The alidade is placed along the base-line and the plane-table and alidade together turned on to A. The board will now be oriented, as it is called—that is, placed with its sides in the same direction of the compass as they were at A. This orientation can also be made with the magnetic compass, if means are taken to test it. Now, having oriented the board, fresh rays are drawn to the same points to which rays were drawn at A, and you will see at once that the points of intersection of the lines drawn from B with those previously drawn from A will fix the points on the plane-table.

It is clear then that the plane-table can be used for making an independent survey; but with no means of checking the work and no points of control, serious error will be likely to creep in as the survey proceeds.

Where the plane-table is invaluable is in filling in the topographical features between points that have been previously fixed by triangulation. These points are first placed accurately on the plane-table, and then are used for the adjusting and filling in of the features of the ground, by methods known as resection and intersection. Practice is necessary, not only to learn what to show, but what to leave out; in fact, the surveyor has to grasp the whole, show the salient features, and not give undue prominence to mere minor details. Here a knowledge of geomorphology, as it is called, comes in—that is of the physical structure of the region to be surveyed—as this would teach a man what to expect, and keep him from making an impossible map.

The ordinary plane-table is a very simple affair, and any carpenter could construct one that would do quite well in an emergency, provided he could manage to make a board that would not alter its shape with damp and change of temperature. This is a serious difficulty in damp tropical climates, but has been got over by permanently mounting the paper on a sheet of aluminium, which is clamped on to the board when the survey is in progress, but taken off and placed in a suitable case when it is finished. This excellent arrangement was devised by the Ordnance Survey some years ago, and has been found most useful.

Instead of an ordinary alidade, or sighting ruler, it is a decided advantage to have one with a telescope, specially when long-distance points are concerned, and many such have been designed. These are, however, often much too heavy and bulky for general use, besides being awkward to pack in a case.

To obviate these difficulties, some years ago I designed the folding telescopic alidade. The pedestal of the telescope is hinged to the ruler, and the whole thing can be quickly folded up and placed in a small case when not in use. There is a vertical arc for giving angles of elevation and depression from which the difference of height between points can be computed, and to render this operation simpler the tangents of the angles are engraved on the arcs as well as the degrees and minutes. This folding telescopic alidade has been found of considerable service, and an elaboration of it is now generally used in the colonial surveys in Africa.

In all surveying the question of the height above sea-level, or the relative heights of points, is most important; for a place is not fixed by knowing only its horizontal position. It is necessary to bear in mind, too, that heights in lowlands and valleys are as important as those of peaks or high points of land, in order to give a representation of the relief of a country. This fact is frequently overlooked by inexperienced surveyors.

The most accurate method of determining the differences of height is by levelling either with a dumpy level, or, better still, by one of the improved levels that have been introduced in recent years, such as the Zeiss or the United States Coast Survey "Precise" level, in which it is possible to see the bubble at the same time as the wires, object, and staff reading.

The accuracy of modern levelling is certainly remarkable, and Colonel Close states in his "Notes on the Geodesy of the British Isles," that in the recent lines of levels run by the Ordnance Survey the probable error in 100 miles was found to be only a quarter of an inch.

It frequently happens that levelling is out of the question, since time does not admit of such a lengthy process, and all that can be done under the circumstances is to obtain heights by theodolite vertical angles. This method, when the distances are accurate and the necessary corrections are made for curvature and refraction, gives very fair results, and if reciprocal angles are observed, relative heights between two places will come out to within 3 ft. or 4 ft. of the

truth, and closer still sometimes, if the points are clearly visible.

When no more accurate method is possible for absolute height above sea-level the geographical surveyor has to depend upon barometric and hypsometric readings, which are far less reliable and may be as much as 50 or 150 feet in error, according to circumstances, and the accuracy with which the reference station reading is known.

The most reliable of the instruments for obtaining heights by methods depending upon the change in atmospheric pressure is the mercurial barometer, which may give results much nearer than those stated, perhaps not more than 10 ft. in error; but this is difficult to carry on an expedition through rough country as it is very liable to be broken, so an aneroid usually has to take its place, which is the least reliable of all. From experience I have found

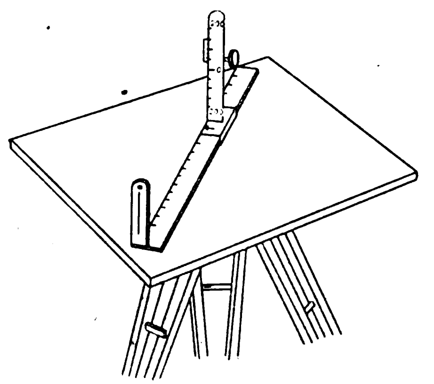

FIG. 32.—NEW PLANE-TABLE CLINOMETER.

that the aneroid, unless checked by some means, is almost useless for great differences of height, and seems to have no constant error.

The boiling-point thermometer may be as much as 100 ft. to 150 ft. out; but this, as a rule, remains fairly constant, even at great altitudes.

The Indian Survey clinometer is a good and serviceable little instrument for use with a plane-table. In appearance it is much like a short plane-table alidade. The eye is placed at a small hole in the sight near the eye, and at the point where the distant hill-top, or whatever the object may be, comes in line with the scale on the further vertical sight, will be found the tangent of the elevation or depression angle. The distance taken from the scale of the map multiplied by this tangent is the difference of height between the surveyor's position and the distant point.

The computation is simple, and does not take very long; yet if there are many points it would be a considerable advantage and a decided saving in time, to have some kind of clinometer that gives heights in feet or metres right off at a glance without any computation whatever. I have lately designed such a clinometer which is shown in Fig. 32. It can be made to suit any scale, or interchangeable scales can be fitted to the same instrument. In general appearance this instrument represents the ordinary plane-table alidade; but it differs in this respect, that the further vertical sight is made to slide along the alidade and so can be set on to the position indicating the point of which the height is required on the map; while the near sight is placed on the surveyor's station. When this is done, the instrument truly levelled, and the movable wire made to intersect the object, the difference of height above or below the observer's station is read directly off the scale without any computation.

In geographical surveying, as in many other things in this world, a man has to do the best he can under the circumstances in which he is placed, and there is nothing that tests one's resources more than this work, nor is there anything that requires more experience to do well.

In unexplored regions, or those that are only partially mapped, it still more frequently than not happens that all that can be done is to make a rapid route traverse with a prismatic compass or sketching-board, and adjust it where possible by astronomical observations for latitude and differences of longitude. Distances are usually obtained by time and estimated rate; and with practice better results can be gained by this method than might be expected.

So much depends upon the character of the country and the man himself, that it is difficult to say what error may be expected; but I have frequently been surprised at the degree of accuracy it is possible to obtain even by this rough method. In a fairly level country it is not unusual to find that the error does not exceed 4 or 5 per cent. of the whole route, while in rugged mountainous country it is likely to be much more, probably 8 per cent. Over long distances, plus and minus errors have a remarkable tendency to balance one another.

I have not, so far, referred to photographic surveying, and I propose now to say a few words on the subject, without attempting to go at all into detail.

For years past the subject has received considerable attention, and recently a great deal

has been written about it. There can be no doubt that under special conditions the method is of considerable service in geographical surveying; but its use is limited, and it has not proved of such general value as was once supposed that it would. It will never supersede the ordinary exact methods, and the most that can be said of it for geographical surveying, at any rate, is that it at times constitutes an important and rapid means of filling in topographical features. In rugged mountainous regions, difficult of access, the method has proved itself decidedly useful, and much of the Rocky Mountain districts of Canada has been mapped by it, as also have certain districts of Central Asia, the Himalayas and other mountainous regions. It is of little service in a country without well-defined features; and since the ground is not, as a rule, visited, the mapping is necessarily incomplete.

Ordinary photographic surveying consists of taking photographs at the two ends of a measured base-line, or at several known stations, and then, with these photographs properly oriented, fixing upon the map the positions of the unknown points shown on the photographs by intersection. This really amounts to plane-tabling from photographs in a room instead of from the points themselves in the country; and it will be understood at once that the chances of error are far greater, although with care quite good results have been obtained.

Many photo-theodolites, as they are called, have been devised for taking the views. The Bridges-Lee photo-theodolite* is certainly one of the best, and a photograph taken with it shows the horizontal and central vertical lines, as well as the scale of degrees of horizontal angles and the compass-bearing on the top.

Photographic surveying has been improved by the introduction of what is known as the stereo-photo method, which was described by Lieut. F. V. Thompson, R.E., in the *Geographical Journal* for May, 1908, and further by myself in the same journal for April, 1913.

Briefly this consists of taking photographs in the same vertical plane, at a measured distance apart, and viewing the negatives or positives taken from them in a special form of stereoscope. The eye-pieces of the stereoscope are provided with exactly similar indices, which can be made to combine stereoscopically with any given point on the view by increasing or decreasing the distance between the slides holding the photographs. The amount of separation required for the stereoscopic combination gives the distance of the point from the plane in which the plates are exposed, and the angular measurement round the horizon of any point, as well as its vertical elevation, can also be obtained from the scales, so that the point is definitely fixed.

The astronomical observations usually taken by a geographical surveyor consist of meridian and circummeridian altitudes of north and south stars, or of the sun, for latitude, and sets of east and west stars, or the sun, for time, rating the chronometer, differences of longitude and observations for azimuth. Occasionally other observations are taken, such as equal altitudes, double altitudes, and occultations of stars by the moon. These are all explained in Colonel Close's "Text Book of Topographical and Geographical Surveying," the Royal Geographical Society's "Hints to Travellers," and other works.

The method of fixing a position and finding time and azimuth by three or more equal altitudes is now being used a good deal with excellent results, and the French have brought out a special instrument, called the "Astrolabe à Prisme" for observing the altitudes; but these can, of course, be taken with a transit theodolite set at a fixed altitude angle, with which several surveyors have obtained results that compare very favourably with those taken with this special instrument. However, the Astrolabe à Prisme is an interesting instrument, and is stated by those who have used it to be superior to the theodolite for the purpose. Those who are interested will find a description of it in my paper in the *Geographical Journal* for March, 1913, and a more detailed account in the paper by Colonel Woodroffe in the number for May, 1916.

The instrument consists, in the main, of a telescope in front of which is fixed a prism, with the faces cut at an angle of 60°, and a flat circular dish of mercury placed below the prism, so that rays of light passing from a star are reflected from the mercury on the lower face of the prism, and thence down the telescope to the eye, while other rays from the same star fall directly on to the upper surface of the prism, and, like the former, pass down the telescope to the eye. Thus, when the star attains an altitude of exactly 60° its two images are seen to coincide, and when this takes place the time is noted. Equal altitude observations of a number of stars, at least three, on different sides of the horizon, are taken, and from these the latitude, local time, and azimuth can be computed.

* The apparatus was described by Mr. Bridges-Lee in a paper read before the Royal Society of Arts in 1902 (*Journal*, Vol. L. pp. 493-508).

With a 5-in. micrometer-theodolite it is quite possible to obtain latitudes to within 2" or 3" of the truth, by north and south stars, and if a mean of several pairs is taken the result may be nearer still; but it should be remembered that there is always an uncertainty of a few seconds in any astronomically-determined latitude, due to the uncertain effect of gravity and deflection of the plumb-line or local attraction, as it is called.

It is easy enough to find latitude and azimuth within the limits of accuracy required for geographical surveying. Local mean time also presents very little difficulty, but longitude is quite another matter, for although this is also quite easy in theory the practical difficulties are considerable. There is no difficulty about taking the observations for finding the time at the place where the surveyor is, but longitude is the difference of time between two places, that of surveyor and of some initial meridian, and it is in obtaining the latter that the difficulty comes in. At sea it is simple enough, for the navigator takes five or more carefully-rated chronometers, which give him his Greenwich mean time, but on land during rough travelling it is quite another matter. Occultations, lunar distances, and all other methods that depend upon the moon's motion are far too approximate for modern requirements—at least, all except the occultation method, which is still occasionally resorted to. What it has really come to in recent years in route traversing is that no attempt is made to carry Greenwich mean time, but differences of longitude are obtained by theodolite observations for local mean time at the different places and rate of the watch. But then the difficulty again arises of obtaining a reliable and steady rate for the watch, which is not at all easy in travelling over rough country.

In recent years wireless telegraphy has come to our aid in this matter, and, as I have stated elsewhere, has given excellent results. Wireless signals are sent from some distant transmitting station, and the surveyor carries a portable receiving apparatus about with him—which weighs only a few pounds, and is comparatively inexpensive. With this he receives the signals, and the difference between the local mean time he finds from his theodolite observations, and the time of the place from which the wireless signals are sent, obtained by his receiving apparatus, is the difference of longitude between the two places.

One of the most recent examples of the use of wireless in obtaining longitude is that of Captain Edwards, R.N.R., of the Bolivia-Peru Boundary Survey, and another is that of the Italian expedition of Dr. de Filippi in the Himalayas, 1913-14, both of which have been described in the *Geographical Journal*.

In conclusion, I desire to express my thanks to the Royal Geographical Society for the use of many of the blocks which illustrate these lectures.

OBITUARY.

COLONEL JOHN ORD HASTED.—Colonel John Ord Hasted, late of the Royal (Madras) Engineers, formerly chief engineer of the Public Works Department, Madras, and Deputy Chief Engineering Inspector of the Local Government Board, Whitehall, has died at his residence, Brook House, Rickinghall, Suffolk, at the age of eighty-one years. The son of the Rev. H. J. Hasted, of Sproughton, Suffolk, he obtained a commission in the Madras Engineers in 1853. He served in the Public Works Department, Madras, from 1856 successively as assistant, executive, and superintending engineer, and in 1884 was appointed chief engineer for irrigation and joint secretary to the Government, and in 1886 secretary in the general and buildings and roads branches. Colonel Hasted retired in 1890, and was elected a Fellow of Madras University in 1883. He was elected a member of the Royal Society of Arts in 1891, and in the same year he read a paper before the Indian Section on "The Periar Irrigation Project, Madras Presidency."

GENERAL NOTE.

TESTING AND USE OF MAGNETIC MATERIALS.—The United States Bureau of Standards has published a circular on "Magnetic Testing" for the benefit of engineers and others who are interested in the testing and use of magnetic materials. The circular gives definitions of the fundamental magnetic quantities ordinarily employed in technical work, outlines the scope and describes the magnetic methods employed at the Bureau of Standards, and discusses the type of data required in engineering work. Typical data and curves are given which may be considered characteristic of the common magnetic materials, and a table of magnetic susceptibility is given for the elements. The circular also considers the more important empirical formulae which may be used to represent the behaviour of magnetic materials under different conditions. A list is given of the publications of the Bureau on magnetic subjects. Copies of the circular (No. 17) may be obtained by interested persons from the Bureau of Standards, Washington, D.C.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

VIBRATIONS, WAVES AND RESONANCE.

By J. Erskine-Murray, D.Sc., F.R.S.E., M.I.E.E.

Lecture I.—Delivered May 1*st*, 1916.

Vibrations.

The extent of the field covered by the subject of these lectures is so vast that it would be quite impossible for me to describe in detail even one of the many types of periodic motions which exist. I shall not attempt to do so, but shall try to explain to you the general principles underlying all wave motions, and describe only such particular cases as appear to illustrate these principles most simply and directly. You will understand, therefore, that when I have demonstrated any property of vibrations or wave motions by experiment or otherwise, the property is in general a quality of all such motions whether material or electrical, and, if the nature of the vibrator or of the medium in which the wave motion takes place be specified, the results obtained in the demonstration are applicable, *mutatis mutandis*, in all cases. I shall, in fact, treat the subject from the point of view of natural philosophy, which deals with the laws of the natural world, rather than that of physics, which is mainly concerned with the description of phenomena.

A vibration is a to-and-fro motion. It is called periodic if it is repeated in equal successive periods of time, and this even if the repetitions are only similar in character though not in magnitude. The *period* of a vibration is, therefore, the time of one complete vibration—there and back again—and its *frequency* is the number of complete vibrations in one unit of time.

The frequencies of the vibrations which concern humanity range from about thirty million-million-million per second in the case of the gamma rays given out by a radio-active substance, to one in twenty-six thousand years, which is the frequency of the motion known as the precession of the equinoxes. Briefly, the result of this latter is that thirteen thousand years hence midwinter will be in June and midsummer in December in the northern hemisphere. And here it suggests itself that if we can "save" an hour of daylight by "merely turning on the clock," might we not "save" a summer by merely altering the calendar?

Between these limits of frequency, the greater of which is twenty-five million-million-million-million-million times the less, lie the frequencies of motions with which we have to deal. These run through X-rays; ultra violet and visible light; heat waves; waves which are recognisable by what are known as electrical actions and are therefore called electric waves, whether fast or slow, conducted or free; the vibrations of sound; of the heart and respiration; of machinery and structures; of ocean waves and tides, and of the earth itself—a wonderful list, almost every item of which is present with us at all times.

It is hardly astonishing that rhythmic motions should be of so much interest to humanity, for the life of each of us is wholly dependent on two vibrations. If the heart or lungs cease their regular periodic motions we cease to live, and even small changes of frequency or amplitude may be of serious moment. Music, dancing, the beat of the drum and the regular tramp of marching troops are all pleasant, for our hearts respond to the rhythmic stimulus, and even "carriage exercise," with its comparatively gentle vibrations, is often of value to health.

Although the variety is apparently so great, there are in reality only two kinds of physical vibration—one in which the thing moved is electric, and the other in which it is ordinary, or

ponderable, matter. In both cases the energy associated with the material moved is converted from energy of stress into energy of motion, and back again to energy of stress twice in each period of the vibration. In this pendulum, for instance, the energy of the gravitational stress between the bob and the world is converted into kinetic energy as the bob swings down towards the world, and is reconverted into energy of stress as it rises again on the other side. On the return journey, completing the period, the same conversion and reversion takes place. In these other oscillators which I show you the stress is that of a strained elastic solid or fluid, but the cycle of energy and motional changes is still the same.

In all cases the primary condition for the possibility of a vibration is that the body or system, to use a more general term, must have a position of stable equilibrium—that is to say, one from which to move it in any direction requires that the work done on it should be converted into energy of stress. The pendulum, for instance, is stable in its lowest position, and an electric vibrator when it has uniform potential throughout. There is a secondary condition which must be fulfilled if the vibration is to be periodic, and this is that the energy of motion must not all be converted into molecular motions, by friction or otherwise, by the time the system first reaches its position of equilibrium. If, for instance, the pendulum be moving in a sticky fluid such as treacle, it may come quite to rest on its first arrival at the lowest point of its course, or rather it may take an infinite time to get there, all its energy of motion being used up in molecular friction in the liquid and so converted into heat.

I have another vibrator here in which gravity plays no part, since its motion is entirely in a horizontal plane, neither rising nor falling. It consists of a cast-iron wheel threaded firmly on to a vertical strip of clock spring, the latter being fixed, at its upper and lower ends, to a rigid frame. If I turn the wheel and let go, it swings round to its position of equilibrium, passes it, stops and reverses its motion, and continues to rotate to and fro with slowly decreasing motions. Here the potential energy of the elastic stress in the steel strip, which is twisted when the wheel is turned, is converted into kinetic energy of the rotating wheel in the first quarter period, reconverted into potential in the second quarter, and so on.

All the while, however, some small proportion of the energy is being lost in friction, or rather is being converted into the energy of molecular vibrations in heating the steel strip and the surrounding air. This is so entirely general a condition of all physical motions that one may state it as a principle, thus: In every physical motion of greater than molecular dimensions, whether of ponderable matter or of electricity, there is a continuous conversion of energy into the energy of molecular vibrations. Thus all friction produces heat, and no motion of real matter is perfectly frictionless nor is any electric circuit entirely without resistance. If no other proof existed of the molecular nature of matter we should still have one here which would be almost incontrovertible, for the vibrators which produce short waves must themselves be small.

Returning to the torsional vibrator, you can see that its rate of vibration depends mainly on its inertia and on the restoring force of the spring, for by placing an additional mass on the wheel the rate of vibration becomes visibly slower, while the same result is observed if a weaker spring is used. Frictional resistance also slows the motion, but, unlike added inertia, it produces the further effect of rapidly damping it out altogether.

Three factors such as these determine the nature of all free vibrations whether mechanical or electrical. Thus, in an electrical vibrator, having no mechanical motion, the electric stress in the dielectric produces a current in the conductor, which in turn generates magnetic force around it, thus delaying the growth of the current, but temporarily maintaining it when grown, just as inertia does in the torsional vibrator. Electrical resistance, like friction, retards the motion throughout, and finally converts into heat all the energy that has not been radiated as electric waves.

We may make some sort of mental picture of what goes on in an electric oscillator during its action by translating into terms of ordinary materials the electrical quantities concerned. A non-conductor or dielectric, for instance, is equivalent to an elastic but incompressible jelly or mass of indiarubber, while a conductor is a cavity in the jelly filled with an incompressible liquid. The conducting plates of a condenser may thus be represented by two cavities filled with water in a great mass of jelly and separated from one another only by a thin wall. I say a great mass because the air surrounding them is like the glass between the plates, a non-conductor. The plates are, therefore, two isolated cavities filled with water in a mass of jelly. Suppose now that I drive a small tunnel, also

filled with water, from one cavity to the other, and in this tunnel place a pump or piston by means of which I can take water from the one and drive it into the other. As I do so, taking water from the left-hand cavity and driving it into the right-hand one, I cause the latter to swell and the former to contract, and since the thin wall of jelly between the cavities has little rigidity, it is here that the greatest swelling and contraction take place. The wall bulges towards the left-hand cavity, and of course the jelly forming it is strained. Now the wall represents the dielectric of the condenser, the increase of volume of the right-hand cavity is the positive charge, and the equal decrease of volume of the left hand is the negative charge on the other plate of the condenser. This picture is correct in two important respects at least; firstly, it shows that the amount of charge which a condenser will hold is not, like the capacity of a pint pot, simply defined by its dimensions, but is also dependent on the pressure or voltage between its plates and on the stiffness of the dielectric; the electrical capacity has, therefore, to be defined as the charge at unit electrical pressure; secondly, it shows the potential energy stored, not in the charges themselves, but in the elastic stress in the dielectric. (See Fig. 1.)

If now the piston in the tunnel connecting the cavities be suddenly annihilated, the tension in the bulging wall will tend to drive the excess liquid in the right-hand cavity back through the tunnel towards the left hand, and this pressure will continue to act until the elastic strain is entirely relaxed and the cavities return to their original sizes. At this moment, however, the water will be flowing rapidly through the tunnel from right to left, and, although there is no longer a pressure driving it, it will continue to do so on account of its inertia even after the position of equilibrium has been passed. Thus the left-hand cavity will be charged to a high or positive pressure and a negative charge will be produced in the right-hand one. When all the energy of motion of the water has been converted into potential energy in the elastic wall, now bulging towards the right, the motion will cease, the flow will reverse, and the operation will recommence in the opposite direction. These reversals of flow will continue, though becoming gradually less and less, until all the energy originally stored in the stretched wall has been converted into heat through friction or radiated throughout the mass of jelly as elastic waves.

This picture apparently fails in one respect only to represent an electric oscillation, and that is in the representation of the inductance of the circuit by the inertia of the water. In the electric case the kinetic energy of the current is not in the conductor itself, but is located as magnetic stress in the medium surrounding it, while inertia we usually think of as a property located entirely in the mass itself. Who knows, however, that this is so? We cannot appreciate inertia in a single body by itself. Even if we consider a solitary body in rotation we have to imagine it to be divided into two parts between which there is a stress before we recognise its inertia. Thus there must always be two bodies between which the force can act by which we know of the existence of mass, and if there must

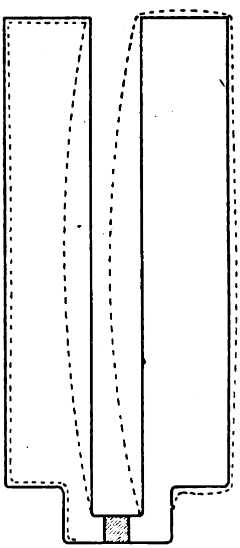

Fig. 1.—Model Condenser Circuit.

be two bodies we at once realise that the property which we supposed was wholly located in the body may in reality be just as likely a property of the medium surrounding them such that their relative motion through it causes a storage of energy in it and not solely in the bodies themselves. If so, our picture may be more complete than it at first appears; but in any case it is a good and serviceable representation, equally true to nature whatever theory of the ultimate constitution of electricity may be adopted.

The vibrations which I have so far shown you have been simple and more or less exactly of the type known as "simple harmonic." Such vibrations, however, are not as common in nature as the more complex kinds; but,

luckily for us, Fourier discovered that every complex vibration could be analysed into a group of simple harmonic ones, and on the other hand, that by superposing properly chosen simple vibrations on one another any desired complex vibration could be built up. The simple harmonic or sine wave type of vibration is, therefore, not only simple, but is also fundamental. The vibrator which I now show you in motion consists of two elements, each being formed by a helical spring with a weight attached to it (Fig. 2). If the two are hung up in series from a firm support, that is to say, in the order counting downwards, of support, spring, weight,

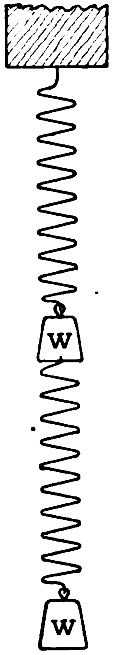

FIG. 2.—COMPLEX VIBRATOR.

spring, weight, you see that by giving impulses in opposite directions to the upper and lower weights we obtain a curiously jerky, complex motion of the lower weight as it rises and falls. The fact is that we have superposed the vibrations of the parts on the slower vibration of the system as a whole, and the movement of the lower weight, though still periodic, is no longer a simple harmonic vibration.

Complex vibrations of this type are most directly interesting to every human being, though he or she may not be aware of it, since it is through their character, and in no other way, that speech is articulate and that one speech sound is distinguishable from another. The sound "oo," for instance, is merely a smooth vibration, while "o" is a compound of the same sound with a vibration twice as fast, i.e. the octave above. "Ah" contains also the third harmonic, or fifth above the octave, and "ee" is a still more jerky vibration. All other articulate sounds are defined in the same way, each by its component simple vibrations, and each can be represented by a single wavy line having a definite character of its own. If the pitch on which the sound is spoken is higher or lower, the rate of vibration becomes greater or less, but its character is unchanged.

I move my hand smoothly to and fro. If I could do so at something over thirty times per second you would hear the sound "oo": I move it again to and fro, but this time in a series of small jerks. If it were fast enough you would hear the sound "ee." Every sound in every language could be produced in this way, if one could only move one's hand sufficiently rapidly and give its motion exactly the proper form.

About fourteen years ago, when lecturing on physics in University College, Nottingham, I constructed a little instrument which will show you the actual forms of the vibrations of various sounds. A piece of thin sheet indiarubber is stretched over the end of a short hollow cylinder about 2 in. in diameter. On the centre of the indiarubber a small circle of paper is stuck in order to give a little greater stiffness, and to the paper is attached, by a small indiarubber hinge, a rod of wood about 5 mm. long and 1 mm. or less in diameter. The top of the rod is hinged to one edge of a little mirror, which lies parallel to the membrane and is mounted on a fine needle pivoted at both ends and borne by supports attached to the cylinder or mouthpiece. Holding this little instrument, which I have named the phonoscope, in my hand, I direct it so that a spot of light is reflected from its mirror on to the screen. If I speak to the membrane it vibrates and the spot of light becomes a short vertical line, and if at the same time I turn the phonoscope to and fro this line is stretched out into a beautiful wavy curve, which changes its form with every inflection of the voice. You can see the different characters of the vowel sounds—the large explosive wave of the letter "p," and the curious beating trill of the letter "r." You can also see that the number of vibrations per second is greater in a high than in a low note, but that mere change of pitch does not alter the character. If I were to play different musical instruments to the phonoscope you would learn

to recognise that the timbre of each is in reality defined only by the character of its vibration curve; that the flute gives a smooth wave, while that of the violin is complex and full of higher harmonics. Even the combined sounds of a whole orchestra make up but one wave curve—a very complex one, but still quite definite and capable of analysis.

Fascinating as is the study of the forms of musical and articulate sounds, we cannot at present spend more time on it, but must get on to other types of vibration. The earth itself, for instance, is in a constant state of tremor, sometimes more and sometimes less, but never quite at rest. Its vibrations are usually too slow to be audible, but occasionally there are rumbling sounds and dull thuds such as I heard during a small earthquake in the Midlands some years ago. It was like the passage of several heavy traction engines over a causewayed street close by. Quite thirty years ago I was taken to see an earthquake recorder in the little town of Comrie in Perthshire. It was a very simple affair, just a thin lath of wood held in a horizontal position by a fixture at one end, and placed so that the maximum movement of the free end was recorded by the displacement of a straw pointer on a dial. If the earth rose suddenly, the fixed end of the lath and the dial both rose with it, but the free end lagged behind and pushed the straw round to a new position, where it stayed and thus gave a record of the magnitude of the shock. The instrument was, I think, devised by the local baker. Present-day seismographs depend on the same or similar principles, but have been made to give continuous records, instead of merely an indication of the maximum vibration. A large mass is fixed to the end of a spring or forms the bob of a nearly unstable pendulum. As the earth shakes, the bob, owing to its great inertia, remains almost unmoved and the relative motion of earth and bob is recorded photographically, or if the ground is tilted up the pendulum comes over and shows the slope.

I have here a rough model built on the same principle, which will show you the action. A strip of metal is fixed horizontally at one end, and from its other end two short parallel threads run to adjacent fixed points on the table. A small mirror is stuck on to the threads and reflects a beam of light on to the ceiling. If I jump on the floor some yards away, you notice that the spot of light vibrates, showing the transmission of the vibration through floor and lecture table to the seismometer.

The reason why the early seismometer was found at Comrie is that a great geological fault, which stretches from the Firth of Clyde to near Aberdeen, runs through the town. On the south-eastern side of the fault lie the comparatively modern carboniferous strata, while to the north-west of it the ancient Silurian rocks are thrust up thousands of feet; the fault is in fact a great crack or discontinuity in the earth's crust. Now, as the earth contracts its crust becomes strained, and from time to time the stress causes a sudden, though small, slip at the fault itself, one side rising and the other falling to accommodate themselves to the growing pressure. This is an earthquake, and the vibrations caused by the sudden motion spread out through the neighbouring rocks.

To show you how frequently these tremblings occur, I may tell you a story told me by the late Professor Milne some years ago. It was at the time when the Psychical Research Society was investigating household ghosts, and, as you know, there are many of these in old Scottish houses. Often nothing is seen, but curious noises are heard, locked doors open, and the dwellers in the houses are aware that something uncanny is happening. The Society asked Professor Milne to take one of his seismographs to various houses, and, as a result, it was proved that in several cases the ghost was in fact a seismic tremor, too slight to be recognised as an earthquake, but quite sufficient to do the work of the ghost.

Volcanic explosions sometimes produce extraordinarily powerful vibrations. When the mountain of Krakatoa, in the East Indies, was rent to pieces by the steam pressure in the cavities below its crater, the pressure wave produced in the air was so great that it was heard as a loud sound at a distance of more than fifteen hundred miles, and travelled eight times round the earth before it became too weak to affect a registering barometer. The energy and suddenness of the explosion must have been very great, for although the firing of great guns has been heard in the present war up to distances of more than three hundred miles, it is equally true that thunder rarely carries as much as twenty.

Instruments have now been constructed which register the vibrations of all kinds of structures, and many interesting results have been obtained by using them in buildings and on ships and railway trains. It has been shown, for instance, that short and sharp vibrations of ten or more to the second are much more exhausting to the

human frame than those of longer and smoother period. The natural vibration of a torpedo-boat destroyer is about three per second, while an old third-class carriage makes twenty or thirty very irregular jerks in the same time.

All the vibrations which we have considered so far have had what is called a "static" restoring force; in some cases this has been gravitational, and in others elastic or electric. Now, however, I shall show you two cases in which this restoring force is actually and obviously due to motion. Here is a small gyrostat—just a heavy wheel pivoted inside a ring-shaped frame. I cause it to spin rapidly and set it on the table. You notice that it stands up, supporting itself on the edge of the ring, apparently in defiance of gravity. It appears to be held up, as if in virtue of its motion] it had a grip on something that we cannot see. I strike it, and it vibrates as if supported by some intangible elastic solid. Here the restoring force is not static, but is due to the motion of the mass constituting the wheel. May it be that, as I suggested when describing the oscillations of the liquid in a model electric condenser, the rotation of the wheel does actually give it a grip on some all-pervading medium? If so, we should expect that two rotating bodies would react upon one another across space in virtue of their rotations—a notion which may be proved or disproved by experiment, or perhaps by deductions from planetary astronomy.

One most interesting way of looking at gyrostatic phenomena is to consider them in relation to gravitational force. Thus, for instance, a spinning-top when at rest lies with its centre of gravity as low as possible, but when spinning it rises till its centre of gravity is as high as it can get. If I strike the top lightly when spinning it nods, but rises again to its steady position; its rotation has thus changed a position of unstable equilibrium into one of stable equilibrium about which it can vibrate. The spinning-top has thus the curious property that in a field of gravitational force it places itself so that the gravitational potential energy is a maximum, the line from its point of support through its centre of gravity being parallel to the gravitational force and directed away from the earth. It would be very interesting to know whether similar effects are obtainable in uniform fields of force other than gravitational — whether, for instance, an electric or magnetic gyrostat could be constructed which would tend to get into a position of *maximum* potential energy when rotating in an electric or magnetic field.

Now I shall show you a vibrator which really is very strange, for it consists merely of air in air, and yet is a distinct entity, a body capable of vibration, and can travel through the atmosphere of which it forms, and yet does not form a part. Here is a large box full of air, which has in front an elliptical opening and at the back a hinged flap like a bellows. Mixed with the air, to make its motion visible, there is some smoke, or the cloud of fine crystals obtained by mixing gaseous hydrochloric acid and ammonia. I slap the back of the box, and a puff comes out at the front which quickly takes shape as a definite and cleanly formed ring, not circular, but changing rapidly from an ellipse with its greatest length vertical to one which has its greatest length in a horizontal direction, and vice versa. Out of air I have in fact created a vibrator having apparently all the properties of an elastic solid. If I could make it vibrate fast enough you would hear a musical tone—a sound produced by an unenclosed mass of air vibrating in air.

It has occurred to me since first I saw these rings produced in Lord Kelvin's class-room that this experiment may not unlikely have been the origin of his vortex theory of matter. A vortex ring when circular is beautiful, but an elliptical one is so obviously a material thing with elastic properties of its own that, after seeing it, the temptation to make use of it as a possible ultimate basis for a theory of matter must have been irresistible to a mind like Kelvin's.

CHINESE METHODS OF SALT PRODUCTION.

In the course of a report the United States Consul-General at Hankow says that the production of salt is controlled in all parts of China by the Government, although actually in the hands of private producers. There is only one producing centre of salt of great importance in the Hankow consular district. That is Ying Cheng Hsien in Hupeh, producing an estimated quantity of 15,000 tons per annum. Ying Cheng lies north of the Siang River, bordering on a number of shallow lakes and waterways which provide transportation to the Siang River. It is about 25 miles west of the Pekin-Hankow railway station of Siaokan. The district is 13 by 6 miles, and has produced gypsum (selenite) for some 200 years. The producing strata lie from 400 to 900 ft. below the surface, and are reached by shafts sunk vertically. There are 190 pits, of which only twelve are worked for brine in the manufacture of salt. The plan is to quarry the gypsum and to work each pit for this

article for a period of two or three years, and then close for a year.

Brine is produced by natural leakage or by pouring water into the galleries which probably follow the inclined gypsum strata. Salt (sodium chloride), being a common accompaniment of gypsum deposits, appears to be either in solution as brine in the pores of soft rock which lie in layers on either side of the strata or as natural salt. The saline substance is dissolved from the rock laid bare by the quarrying, and after the pit has been closed for a year a sufficient quantity of brine is obtained for working from one to five months, when the gypsum is again worked and the former process repeated.

The brine is brought to the surface by a windlass and rope, in wooden buckets, and is poured at the pit mouth into large wooden reservoirs sunk into the ground. From the reservoirs it is emptied by buckets into mat-covered wooden troughs led across country a few hundred yards to the furnaces, where the brine is boiled in pans. The boiling pans are arranged in batteries of three to five furnaces, and are set up under sheds having tiled roofs and open at the sides. Boiler-plate caldrons of foreign manufacture, 3 ft. in diameter and 1½ ft. deep, are arranged in sets of nine over each brick furnace.

These furnaces are sunk in the ground so that the level of each caldron is just above the surface. Underneath is a fire box, passing below each of the nine iron caldrons in succession to two brick chimneys at the end of the furnace. The fuel used is slack coal procured in the vicinity of Hankow.

DISTRIBUTION TO CONSUMERS BY SMALL DEALERS.

The brine, stored in large wooden reservoirs, is ladled by coolies into the caldrons, which boil so incessantly that the water is rapidly evaporated. The salt gradually precipitates as the density of the liquid becomes greater and is dipped into split-bamboo baskets. The distribution of the salt thus produced is made to the consuming areas by small dealers from two baskets carrying about 50 lb. slung at either end of the pole. The salt produced is snow white, very fine, crystallised, and of good flavour, though described as having a bitter taste, due probably to excessive magnesium.

The 190 active gypsum pits are scattered over an area of 80 square miles. Each furnace in the manufacture of salt is limited to nine iron caldrons, and each of these furnaces has a capacity of production of 32,000 lb. in 24 hours.

A classification of the sources of production in other parts of China may be made as follows:—

LOCATED ALL ALONG CHINA'S SEA COAST.

The Huaipei saltworks are typical of those located all along China's sea coast. They produced more than 500,000 yin of 440 catties each (catty = 1·4 lb.) per annum. Away from the sea coast there are many factories for the manufacture of salt from brine drawn from wells. The product is of good colour and edible, resulting from the condensation by solar heat of this subterranean brine.

The Tientsin (Changlu) arrangements for the production of salt are as follows: There are three large groups of saltworks, one on each bank of the Peiho River and one on the Peitang River. These localities are large mud flats commanded by the tides, and are very favourable for salt manufacture. The levels permit brine to be brought from the sea to the works by flow at spring tides, in canals or channels dug for the purpose. When the brine canals are full, temporary dams prevent any over supply, either of brine from the sea or fresh water from the rivers, and keep the brine in the canals at the required level. The brine is raised from the brine canals into the reservoirs and evaporation pans by an ingenious system of lifts operated by wind sails.

SEVERAL PROVINCES PRODUCE LARGE QUANTITIES.

Shantung produces about 2,125,325 piculs (of 140 lb. each) per annum from sea water. The Provinces of Chehkiang, Fuhkien, and Kwangtung all produce large quantities of sea salt.

Undoubtedly the Province of Szechuan, some 1,200 miles up the Yangtsze River from the sea, offers the greatest opportunities for the development of the sale of salt-manufacturing appliances. Salt in that province is the product exclusively of brine drawn from wells. The total quantity produced during one year is estimated at 5,500,000 piculs. In most parts the wells are few and far between; at Tzu Liu Ching a great number is found within a small area. Szechuan not only supplies its own millions of inhabitants with salt, but some 1,171,000 piculs to Hupeh Province annually; also to Yunnan and Kweichow, two neighbouring provinces. Many millions are invested in the industry.

The points at which rock salt and lake salt are produced are remote places, where it is doubtful if modern methods could be introduced at present.

OPPORTUNITIES FOR SALE OF PANS.

There is no question that the Szechuan district furnishes great opportunities for the sale of pans for salt manufacture, but freight rates through the gorges and rapids are so high that it would be difficult to deliver machinery into that district at a reasonable price. It is understood that a British company has maintained a special representative at Pekin, with a view to inducing the Government to instal modern salt-manufacturing appliances. It is not known how successful it was, but it is thought that certain improvements at the great Tientsin saltern are now under way, and probably some foreign machinery is being installed. Inasmuch as salt production is everywhere controlled by the Chinese Government, an attempt to introduce modern equipments should be made through the Government at Pekin, as it is not likely that private concerns, although they are the actual producers, would undertake any radical changes without the approval of the Government.

THE ARAROBA, OR GOA, POWDER OF BRAZIL.

The supply of araroba, or goa, powder is said to come entirely from the State of Bahia. It contains the substance known as chrysarobin, widely used in medicine in the treatment especially of parasitic skin diseases.

The product is found in the form of a pulp or small solid masses in crevices of the heart wood of the tree known locally as "amargoso do matto" (*Andira araroba*, of the natural order of the Leguminosæ), and is said to be a morbid growth. The trees are not cultivated, but are found in considerable abundance in the forests in various parts of the State of Bahia. They are of large size, from 80 ft. to 100 ft. high, and often attain a diameter of more than 3 ft. They have imparipinnate leaves, the leaflets of which are oblong, about 1½ in. long and ¾ in. broad, and somewhat truncate at the apex.

To extract the powder, the trees, which must have attained full growth and development, are felled and split open in order to reach the deposits of araroba at their centre. There is always present a very caustic liquid, of which no use is made and which is drained off. The damp pulp and lumps of araroba are then removed, dried, and finally powdered. The product is a bright yellow colour when extracted, but becomes a yellowish brown, varying considerably in tint when dried.

It yields about 50 per cent. of the substance known technically as chrysarobin, which is of therapeutic value. It occurs in a micro-crystalline, odourless, tasteless powder, very slightly soluble in either water or alcohol. Chrysarobin gradually oxidises to chrysophanic acid and glucose, and it is in the form of this acid that the drug is generally used. It is administered in the treatment of eczema, psoriasis, and in ringworm and other similar maladies.

The yield per tree may be as high as 60 lb. or 65 lb., although it occasionally happens that trees which are sufficiently large and old enough to give a good yield are found to contain no araroba whatever.

From a report by the United States Consul at Bahia, from which the above particulars are taken, it appears that the powder is an exceedingly dangerous article to handle, for if it enters the eyes it causes blindness, and burns from the caustic liquid referred to produce sores that may incapacitate the person afflicted for a long period. Those engaged in the work for any length of time, although protected by gloves and masks with glass eye-pieces, invariably lose their hair, eyebrows, and eyelashes, and sometimes even become blind. In a case known to the United States Consul a cat lost its fur after sleeping on a bag of the powder. It must be packed for shipment in hermetically sealed tins in wooden cases or it will not be accepted by shipping companies.

Immediately before the outbreak of the war some large shipments (amounting in all to 8,000 lb. or 10,000 lb.) were made to Europe and fully supplied the foreign demand for the time being, so that inquiries for it are only now beginning to be made again. It is said that abundant quantities are available, and that with sufficient inducement in the matter of price as much as five or six tons per month could readily be obtained throughout the year.

Unfortunately araroba lends itself to adulteration by the admixture of powdered wood from the tree with the pure powder, which is practically impossible to detect without analysis. The powder marketed is supposed to show a minimum of 50 per cent. of the pure drug upon analysis.

A NEW FIBRE PLANT IN CUBA.

Some further details are available regarding the "malva blanca" plant grown in Cuba, to which attention was drawn in the *Journal* of August 18th.

It appears that there are eleven known varieties of the so-called "malva" in Cuba, but that locally designated as "malva blanca" (*Urena lobata*) has been determined to be a very promising source of fibre, from which may eventually be woven the supply of sugar sacks for the Cuban market, while the finer varieties can undoubtedly be used in the manufacture of new fabrics for wearing apparel.

For several years experiments have been conducted in Cuba with the idea of utilising the malva fibres; but only in the last two years have the processes of extraction been elaborated on a basis that makes the extraction a commercial possibility. Malva fibre is now being manufactured and sold on the market at Habana, principally to the makers of alpargatas, or cloth shoes, worn by the labouring classes. The fibre is mixed with jute and used for soles. About 20 tons have been sold in the past year at 3*d*. per pound, and the supply is not nearly equal to the demand. The persons producing it claim that they can profitably produce and ship it for less than 1½*d*. a pound with the present crude methods, and that the cost would be considerably reduced with proper labour-saving machinery and equipment.

It is, however, as the fibre from which to make the 20,000,000 sugar sacks needed in Cuba annually that the owners of the process have the greatest hope for it. They assert that sacks of malva of 2½ lb. each can be placed on the market at 3½*d*. to 5*d*. each and still leave a profit. Normally, the Calcutta or Dundee sacks sell, delivered in Habana, at 8*d*. to 9*d*. each, and in war times have been selling at 1*s*. to 1*s*. 3*d*.

The malva fibre is claimed to have about the same textile strength as Dacca jute, and its fineness is between jute and flax. It is believed that by seed selection and cultivation the fibre can be improved in both strength and quality. According to a Report by the United States Special Agent in Cuba, sufficient results have already been achieved to demonstrate that the cultivated plant responds to good treatment, and comparisons with the wild plant show a better fibre from cultivated plants only one year removed from the wild seed. Seed is now being obtained from selected plants with a view to further tests.

"Malva blanca" is generally regarded as a troublesome weed by the tobacco planters of Pinar del Rio, where it grows best. In its wild state it attains a height of 20 ft. under favourable conditions, but usually averages between 6 ft. and 10 ft. on ordinary soil. During the growing season, it is claimed, it will make two crops of 6 ft. to 10 ft. where it is cultivated, and, according to the method of planting it, will produce a stalk ½ in. to 1½ in. in diameter. From the bark on this stalk the fibre is obtained. The plant requires a good soil. It grows wild under ordinary conditions, and the more rain and moisture it gets the better the growth. Windstorms do not injure it, and it is thoroughly hardy in the Cuban climate.

When the plants have reached a height of from 6 ft. to 8 ft. cutting is commenced, this being the best age at which to harvest. It is claimed that two cuttings may be made in a year without the necessity of replanting, new sprouts being thrown up from the stumps left in the ground. The present method of cutting is by hand, the men using machetes or cane knives, and striking a downward blow at the root. This frequently cuts below the buds and destroys the ability of the plant to throw out other stalks, thus curtailing the second crop.

Plants cut after a three or three and one-half months' growth show only one layer of fibre. Old plants that are allowed to go to seed without having been cut, it is claimed, show as many as eight layers of varying degrees of fineness, thickness, and strength; but it is difficult to extract them separately. For commercial purposes the three or three and one-half months' growth has been found best as a result of continued experiments.

At the experimental grounds several miles from the town of Vinalee, in the Province of Pinar del Rio, two methods of handling malva have been evolved. Both require the use of water. The cost of cutting under the present hand methods is about 12*s.* per 10,000 green stalks, or the labour of three men at 4*s.* each per day. They work with machetes or cane knives. The stalks are loaded upon waggons and taken to the retting tank or steeping pond. A waggon can carry only 100 arrobas (of 25 lb. each) at a load, and 4*s.* for each load is charged. It is purposed to use a movable bark-stripping machine, worked by gasoline power, which will handle the crop as it is cut and piled by the harvester. The 2,500 lb. of stalk would yield 20 arrobas (500 lb.) of bark; of this bark 5 arrobas (125 lb.) would be fibre. As much as 200 arrobas of bark could be piled on a waggon at one load, so that the initial cost of transportation from fields to processing vats could be reduced to about one-tenth of what it now is. Moreover, fewer men would be required than where the brush only is handled. The experimenters claim to have devised and patented an economical bark stripper.

The stalks or the bark are placed in the rectangular retting pond, which is about 25 ft. by 60 ft. and 4 ft. deep. The crude product is then weighted down in a solution of weak sulphur water, to which a small quantity of potash has been added. The potash hastens the elimination of mucilaginous matter in the stalks, adds whiteness to the fibre, and does not injure either strength or texture, so it is claimed. The bark or stalks remain in the solution from six to forty days, depending upon the temperature. The higher the temperature the more rapidly the process is completed. Steam pipes in the tank, it is asserted, would hasten the chemical action, make the results certain, and enable the workers to be independent of climatic conditions.

The other method is simply to place the stalks or bark in one of the running sulphur streams in the Vinales district. The fibre from the stream is much whiter than that from the pond or tank. Possibly the sulphur water has a bleaching effect; and, on the other hand, it is very likely the fact of being in clear running water, instead of the stagnant and none too clean water in the "retting pond," has something to do with this feature.

On taking the bark or stalks from the stream or retting pond, when examination has disclosed that it is ready to be worked, the process is slightly different for each method of treatment. The bark from the retting pond is then hung in the air and sun, and atmospheric action loosens the remaining particles of mucilage and bark, which are largely removed by vigorous shaking. On the other hand, the stalks removed from the sulphur streams have to be dried out. Women, who are paid 2*s.* a day, strip off the loosened fibre and tie it in "hands" or small bundles. This costs about £1 per 1,000 lb. The fibre, having been put into "hands," is ready for shipment, and is packed in open rope-bound bales of about 400 lb. each.

It is suggested by the experimenters that a dry kiln would hasten the process of drying materially, and if a carding machine and drawing frames were installed, these would produce a cleaner fibre, and moreover deliver it in "slivers," which could be done directly

into the press, and considerable economies in handling thus effected, besides giving a better quality of fibre. The combings from the cards could be worked over and sold for 1¼d. per lb., to be used for mattress filling, horse collars, upholstering material, and the like.

It is further suggested that in making the sugar bags machinery could be installed whereby the slivers from the carding machines would be carried on mechanically and worked into yarn to be used on the looms.

The present equipment at the experimental grounds referred to is crude, and is given as costing about £500. This includes the wooden "retting tank" alluded to, an 8 h.p. gasoline engine, a home-made "barking machine," which is patented and which is sometimes used for cleaning fibre badly dried as well as working the green stalks, a bale press, pump, and several hand machines for breaking up the stalks and taking the bark off.

POWER FROM TIDAL CURRENTS IN BAY OF FUNDY.

Efforts are now being made to utilise the swift tidal currents in the Bay of Fundy in the production of power. This bay extends from the Island of Grand Manan, off the mouth of the St. Croix River, in a north-easterly direction for about 150 miles. It separates the provinces of New Brunswick and Nova Scotia, and for two-thirds of its length from Grand Manan is a straight solid body of water some forty miles in width, then is split by a narrow neck of land into two almost equal legs, the left leg known as Chignecto Bay and the right leg as Minas Basin. In this great body of water the tides of the ocean rise to a greater height than anywhere else in the world.

At the head of the bay in the two legs mentioned the tides reach the height of 50 ft.; even at the city of St. John, on the main body of the bay, they rise 28 ft. to 30 ft. In some places there are very swift currents, exceeding, in fact, the flow of the swiftest rivers, and it is the utilisation of these currents for power that is now greatly interesting the maritime provinces of Canada.

The general flow in the middle of the bay is from one to two knots per hour, and the maximum rate at Digby Gut, on the Nova Scotia coast, is four knots, but in the right leg of the bay, known as Minas Channel, the rate is from eight to ten knots.

This rapid current, says the United States Consul at St. John, in an interesting report on the subject, is doubtless due to the peculiar shape and formation of a neck of land known as Cape Split, which extends up into Minas Basin in the shape of a hook narrowing the waters of Minas Basin at the extreme end of the cape to a very few miles. It is at this point that the waters of the bay offer the greatest advantages for water power, because, first, there will be no obstruction to navigation; second, it is an ideal situation for a power house; third, the swiftest current is here; fourth, here are the highest cliffs; and, fifth, it is the central position in relation to the needs of the provinces. Within a radius of 100 miles an urban population exceeding that of any city in Canada, except Montreal, can be reached.

Up to this time the use of tidal power has been almost entirely by means of large reservoirs, one of which is kept at high-tide level and empties through power gates to the other kept at low-tide level. Those who are promoting this power scheme at Cape Split because of the great current at this point expect to use just the tidal current rather than the head system. Storage will have to be provided for to meet the periods in every twenty-four hours when the tidal flow stops, and a specially designed motor will have to be made. These features are now taxing the skill of engineers and others who are endeavouring to harness the tides of the Bay of Fundy.

TESTING OF OIL-BEARING NUTS IN THE PHILIPPINES.

Investigations have been made by the Philippines Bureau of Science concerning the qualities of the calumpang nut, which has been found to be edible, though slightly purgative when eaten in quantities. The composition of the nuts, as analysed by the Bureau of Science, is: Fat (by extraction of dry seeds), 51·78 per cent.; protein, 21·61 per cent.; starch, 12·10 per cent.; sugars, 5 per cent.; cellulose, etc. (by difference), 5·51 per cent.; ash, 3·90 per cent.

The oil expressed from the calumpang is sweet, with a comparatively high melting-point. Its colour is a light yellow. One chemist reports that it appears to resemble olive oil very much in its physiological action. It is nontoxic, and has no irritating action. It can be used in the same manner as olive oil, and should be especially useful for culinary purposes.

Additional facts, writes the correspondent at Manila of the United States Department of Commerce, have also been ascertained concerning the oil-bearing nut, *Chisochiton cumingianus* (Harms), in recent investigations by local scientists. The plant belongs to the natural family in which the Philippine santol occurs. The nut is known in many parts of the islands from northern Luzon to southern Mindanao. The name applied to it in Camarines and Laguna, "balucanag," is taken to indicate that the natives recognise the nuts as oil-bearing, for the same name is applied to another and well-known

oil-bearing nut, although the two are not alike in any other particular.

The *Chisochiton cumingianus* (Harms) is described as half ellipsoidal in shape, when fresh, and as averaging 3 centimetres (1·18 in.) in length, and 2·5 centimetres in width at the widest portion. The shell is rather hard, constituting about 60 per cent. of the total weight, and it is difficult to separate it from the meat. In a quantity of shelled nuts tested by the Bureau of Science, which used petroleum ether for the purpose, about 31 per cent. of the whole nut was a reddish brown oil. The composition of the dry kernels was found to be as follows: Fat (by extraction), 44·12 per cent.; protein, 9 per cent.; ash, 3·19 per cent.

The dry kernel yielded 35·56 per cent. of oil on expression. The oil had a rancid odour, and was non-drying. On experiment it was found to have purgative properties. This oil, however, was found to have a weaker laxative effect than castor oil, five parts of it being approximately equivalent to one part of castor oil. This oil, more commonly called cato, was found by the Bureau of Science to be valuable for soap-making. One local firm now employs the oil in that industry.

OPENING OF THE FIRST RAILWAY IN PERSIA.

The following account of the opening of the first railway in Persia is from a report on the subject written by the United States Commercial Attaché at Petrograd (Mr. H. D. Baker), who had the opportunity of witnessing this extremely important event in the history of Persia. Mr. Baker reached Tabriz about the beginning of March last, travelling part of the way from the Russian frontier by the new railway, which was almost completed, and part of the way by carriage. Several days after, the railway was completed, and the first train arrived in Tabriz gaily decorated with the flags of Russia and of Persia. Thousands of people, including all the foreign Consuls and other officials in the city, came to witness the entrance of the first train, and there was immense excitement as the blowing of whistles announced its approach. In front of the locomotive was a huge emblem showing the Persian lion with the sword, with the sun in the background. The train consisted only of goods waggons, the railway being at present intended, not for carrying passengers, but for military purposes.

The great crowds waited to see the train start on its return journey. Through the courtesy of the Russian military authorities, the Commercial Attaché was permitted to be the first passenger on this first train on its return to the international boundary, one of the waggons being specially furnished for his accommodation. The train left Tabriz about 5 p.m., and the distance of ninety-three miles to Jhulfa, on the Aras River, separating Russian Transcaucasia from Persia, was covered by 5 a.m. the following morning. The journey would have taken three days travelling by carriage.

After the train left Tabriz it was interesting to watch the excitement occasioned among the rural population. In the different villages the people climbed up on the roofs of their mud houses to see this great spectacle; it was probaby the first time that most of them had ever seen a railway train. The sheep and cattle and teams of horses along the route were greatly terrified.

When the train crossed the bridge over the Aras River, its trip on the Persian side was ended. As there is railway connection here for Tiflis, and thence for all parts of Russia, there is no reason, says the Commercial Attaché, why it might not be possible for trains to run from any part of Russia to Tabriz, the chief commercial city of Persia. The gauge of the new line is the same as that of the Russian railway system, and the railway is under Russian control and management. Possibly the railway may be extended to Teheran, and thence south-east to Ispahan, in Central Persia, and into Baluchistan, where it could connect up at Nushki with the railway system of British India.

The railway now follows between Jhulfa and Tabriz the line of the Indo-European telegraph system of India. From the town of Sophian, about twenty-five miles from Tabriz, a branch of the railway has already been completed to Lake Urumiah, which is a great body of intensely salt water extending about 100 miles from north to south in north-western Persia. Around this lake is one of the richest districts of Persia, producing large quantities of raisins and other dried fruit, as well as considerable wine and wool. The completion of the railway to Lake Urumiah has made it possible to bring big motor-boats to take the place of the old primitive sailing-boats.

The railway to Tabriz, with its branch line from Sophian to Lake Urumiah, will doubtless cause an enormous development through all this part of Persia. Much new land will be opened up to agriculture, and various mines, chiefly copper and wolfram, will be worked, which have not been developed because of transportation difficulties. Although the railway is to be used at present only for military purposes, it is the intention later to devote it to the interests of trade between Russia and Persia. The railway will doubtless cause a diversion of traffic to a large extent from the caravan route from Trebizond in Turkey to the railway route *via* Tiflis and other cities of the Caucasus. Before the war the greater part of the trade of north-western Russia went through the port of Trebizond and through Persian and Russian ports on the Caspian Sea. The Caspian Sea

ports will still be used for business originating in and around Teheran, the capital of Persia, but it will be unnecessary hereafter for any of the business of Tabriz, the largest commercial city of Persia, to be conducted through Caspian Sea ports or through Trebizond on the Black Sea. The commercial importance of Tabriz, now the leading carpet market of the world, should be greatly increased. It is understood to have at present a population of about 200,000. Its bazaars cover many miles of arcaded streets, and its carpet bazaars are specially noted. Besides the enormous trade in carpets, there is an important trade in cotton, dried fruits, tragacanth, etc.

THE DEVELOPMENT OF THE TEXTILE INDUSTRIES.

Mutual Accommodations.—The common problem is that of satisfying the demand for goods with a constantly dwindling number of men, and its solution is necessarily one of increasing difficulty. Hitherto the task has consistently turned out a little easier than could be expected. Circumstances adapt themselves in a mysterious way to the troubled manufacturer. Demand grows up for the sorts of goods which can be produced rather than for those which cannot, and by grace of small accommodations industry is enabled to proceed to good purpose. Cash turnovers receive the assistance of higher prices, and the amount of skilled work to be done in maintaining them is reduced by the avoidance of changes in the kind of work in hand. Carried beyond a certain point the reduction of man-power inevitably implies reduction of productive capacity, but it has been shown that upon an emergency unanticipated results are possible. There are mills and works producing goods of more total value than ever with the staff of skilled men cut down by one-half or two-thirds. As a fact of this kind is liable to misconstruction, it is necessary to emphasise the distinction between value and volume.

Restrictive Influences.—Manufacturers of goods indispensable for war occupy the privileges of their situation. They have first call upon the supplies of fuel, and are permitted to extend buildings while others are not; they have less difficulty in retaining the services of men of military years, and their applications for new machinery receive priority at the machine works. They alone are allowed to receive raw materials of particular sorts, but the privileges are bought at a certain price. Contracts are issued on terms which severely limit the charges which may be made, and convert the contractor virtually into an agent of the War Department. Increasingly the war becomes the first business of the industry, and the opportunities of attending to any other market diminish. Export cloths and home trade goods continue to be made upon one scale or another, but manufacturers have nothing like a free hand at present, and are perhaps destined to have less before regaining their liberty to go as they will. Doubtless it is widely recognised abroad that the situation of our textile manufacturers is singularly cramped, but without a strong effort of the imagination their exact position can scarcely be realised. The pre-occupation with war contracts removes the participants from their old trades, and precludes them from embarking upon the new ones that will have to be sought later.

Work after the War.—The resolute opposition to the proposal to apply the unemployment provisions of the National Insurance Act to workers in wool affords a test of opinion as to the effect of the ending of the war. Were it held seriously likely that large numbers of workers would be brought to destitution, a small weekly payment insuring a modest relief in case of need need hardly be grudged in present conditions. Virtually all the employers and all the employed concerned vigorously resisted the application of the Act, and were not dismayed to learn that no other financial assistance need be expected from the State. The industry accepted full responsibility for its own hardships gaily. The disbanding of the forces will bring the woollen industry contracts for the civilian suits, overcoats and cardigan jackets for which the King's Regulations provide, and were the war to end to-morrow it would catch the woollen warehousemen and clothiers almost without a piece in stock. While the war lasts the need for army clothing must be continuous and heavy, and when peace comes the call for goods will almost certainly be great.

Discarded Uniforms.—Arrangements have been made for firms of dry-cleaners in this country to receive soiled service uniforms, and to clean and repair them and send them out in a condition not very different from new. The bargain promises economies, and contracts have been made for the renovation of tens of thousands of uniforms weekly. Uniforms beyond repair are being collected for dispatch to the rag-wool district, where they are being bought at about £80 a ton for conversion into new cloth. Ordinary rag-picking is one of the industries that has been seriously disorganised by the war, and military rags, by virtue of the size and systematisation of the supply, are becoming the chief staple of the market. Except in a limited way, second-hand official khaki cannot be used to make standard khaki again. although it may serve for inferior qualities. Blended with rags of other colours, its fibres

may be looked for in fancy woollen cloths for the civil market. It is the exception to re-dye coloured rags even in times when dyestuffs are plentiful, and an observant eye will probably be able to trace some of these old uniforms to their new destinations.

Dyeware Syndicates.—The syndication of the French colour manufacturing firms following upon the amalgamation of the two great groups of dyeware companies in Germany, supplies an additional argument for combining together the principal British producers. Negotiations to that end have been in progress for some time, fostered by large consumers of dyes who have realised the dangers of isolation and of unco-ordinated effort. It is unmistakably true that dyers' colours can be more economically produced upon a large than a small scale, and a system allowing of the full specialisation of individual works is aimed at. So far as they are known, the schemes of the larger consumers provide for the amalgamation of the four principal colour manufacturing concerns in this country, with opportunities of including other factories later. The combined works would receive Government support in return for a participation by the State in the profits. For the encouragement of colour producers at large, a substantial duty would be placed upon imported coal-tar colours. The conditions cannot be said to have been fully agreed upon by the authorities whose assent is indispensable, but a strengthening of the British position more or less upon these lines may be expected. It is certain, in any event, that the arrangements made last year for the promotion of colour manufacture in this country are to be revised. In putting the eggs all into one basket great responsibility is thrust upon the central control, and it may be said that great importance is attached to the selection of some one business man with the gift for eliciting the best from chemists, engineers, managers and subordinates, and with power to put each in his proper place.

Puttees.—The prototype of the modern puttee is possibly the hay-band, as worn by the rustic who has to cross snow-filled fields. It may be observed that as far back as Anglo-Saxon times, bands known as *scanc-beorg* were worn around the leg. Puttees can be said to have been worn before stockings, and to have been wound round the leg both in the simple spirals and in the cross-gartered fashions that are affected to-day. To trust illuminated records, kings wore puttees of gold, and as the laity in France wore them of woollen, the monks of St. Gall were commanded to bind their legs with fillets of linen; for distinction. Leg bandages as military costume seem to have passed out of date in the fourteenth century; but puttees, or *lingettes*, were part of a French butcher's dress up to the sixteenth century. Puttees came into modern English prominence with the Boer War, recommended by a character obtained in the East. Horsemen wearing cotton or linen bands round the leg had certainly made public appearances in this country earlier than the South African War, but the wider recognition of the article came at that period, since when acquaintance with it has improved. A distinction may be drawn between the puttee, which is a simple strip of cloth with no natural disposition to follow the curve of the calves in the beginning, and the spiral stockinette puttee curved in its manufacture and winding smoothly around the leg without folding. There is again the elastic puttee, made upon the same principle as some surgical bandages from yarns twisted so hard in course of spinning that their constant endeavour is to contract. Except in neatness of appearance, and in the detail of structure, one is much the same as the other, and all of them convey a reminder of the wrappings affected by the Saxons and Danes.

Peruvian Textiles.—Mr. M. D. C. Crawford describes his "Peruvian Textiles" (Anthropological Papers, American Museum of Natural History, 1915) as but an introduction to more exhaustive research, and with this description there is no need to quarrel. The paper relates to the features of fabrics found in the graves of coastal Peru, and gives details pointing to a high degree of manual skill on the part of these primitive spinners and weavers. It is perhaps inevitable that ethnologists, in their examination of ancient processes, should spend a large part of their space upon the rudiments of manufacture and betray some unfamiliarity with technical terms. Mr. Crawford, for example, would have contributed to ease of understanding by calling the weft-carrier a shuttle instead of a spindle. The stick used to carry weft in weaving may be very like the piece of stick used in spinning, but nothing is gained by ignoring the difference of office. Mr. Crawford succeeds in calling attention to the wide range of fabrics made in ancient Peru, and he takes it as certain that these productions owed nothing to outside influences or instruction. "Those great textile masters of antiquity" are lauded for fabrics which "have never been equalled from a technical point of view," and for dyeing work than which "no better has been ever done." These encomiums are perhaps too facile, and a more critical attitude towards the specimens of which the museum is justly proud, and towards some authorities upon whom the author is content to rely, would carry more conviction than Mr. Crawford's fluent enthusiasm. A second paper, in which analyses and diagrams are promised, should give a fuller idea of the excellence of Peruvian workmanship. Manufacturers are, of course, better able to appraise

technical excellence than are ethnologists who may be warned against the pursuit of technical matters to the neglect of their historical duties. It is not so necessary to vindicate the Peruvians, the Egyptians, Persians or Africans, as to present their achievements in their historical sequence as carefully as chance allows.

GENERAL NOTES.

Potash from Kelp in California.—Attention is drawn in *Nature* to experiments conducted by the United States Department of Agriculture of extracting potash from kelp. Before the war the United States imported annually from Germany some 300,000 tons of potash. It is believed that the vast beds of this weed growing along the Californian coast will suffice to furnish all the needs of the country, and large quantities are already being placed on the market from this source. But, according to *California Fish and Game* for July, fears have been expressed that the cutting of the kelp will have an injurious effect upon the fisheries of the State, and this because of the protection afforded by the weed to the braches, and the danger of exterminating the clams and spiny lobsters which live more or less within the protection of the kelp. They also fear that the young fish which are in the habit of seeking refuge here will be driven away, and further that such fish as spawn here will similarly be destroyed. These several objections have now, however, been carefully examined, and it is pointed out that the kelp-cutters do not cut below 6 ft., thus leaving ample shelter. It may be, indeed, that the cutting will prove beneficial, since the weed will be less easily torn up by storms. The species of kelp which is thus being harvested is *Macrocystis pyrifera*, a plant which ranges in length from 100 to 300 ft.

Professional Classes War Relief Council Maternity Home.—In order to assist the wives of professional men hard hit by the war, the Professional Classes War Relief Council maintains, at 13 and 14, Prince's Gate, S.W., a maternity home where expert care and nursing is offered for a nominal fee. This has been made possible by the generosity of the medical and nursing staff, who give their services voluntarily. Since the home was opened in 1915 one hundred and eighty births have taken place there, and the Council has also given considerable outside assistance to a large number of applicants whose family ties have prevented them from leaving their own homes. Applications should be made to the Secretary at the above address.

Cattle for Alaska.—Owing to the extreme rigour of the winters in the interior of Alaska no breed of dairy or beef cattle has as yet been found which can exist there without excessive expense for food and protection against cold. As a result the price of milk is about fifty cents a quart, and the beef consumed in the country consists almost entirely of cold-storage meat imported from elsewhere. In the hope of remedying this situation the Alaska experiment station, according to the *Journal of Heredity* (Washington), has undertaken to cross Galloway cattle with the Yak, an Asiatic ox much used by Mongolians and Tibetans for milk and meat as well as work. It is employed as a beast of burden at altitudes of 12,000 feet or more; it is extremely hardy, pastures through the winter under the open sky in Siberia, and obtains feed from last year's dead grass dug from under the snow. Crosses of the Yak and various breeds of domestic cattle are common in parts of Asia and have been found of much value.

Launch of the largest French Liner.—A new transatlantic liner named the "Paris" was successfully launched at Saint Nazaire on September 12th last. This vessel, which belongs to the Compagnie Générale Transatlantique, is intended for the service between French ports and New York, will, when completed, be the largest vessel in the French mercantile marine. Her length is 233 metres (764 ft. 3 in.), beam 29·60 metres (96 ft.), depth of hold 18 metres (69 ft.), gross tonnage 37,000 tons, and draught 9½ metres (31 ft.). The engines will have 45,000 nominal horse-power. There will be accommodation for 3,000 passengers.

Italian Irrigation.—The construction of two new channels for the irrigation of a large tract of country in the province of Novara is contemplated by the Italian Government. These canals, which will be called the "Elena" and the "Yolanda" canals respectively, would be derived from the River Ticino, and would serve to irrigate the district known as the "Alta Novarese," or country lying too high to be watered by the Canal Cavera.

Cinema Industry in the United States.—An Hispano-American journal, *Las Novidades*, of New York, gives the following statistics respecting the cinema industry in the United States. At the Sixth Congress of Exhibitors of Cinema Films, recently held at Chicago, it was stated that at the present time there are no fewer than 21,000 halls and theatres at which this class of entertainment is given in the United States. These entertainments are attended by no fewer than 25 million persons daily, or say more than one quarter of the entire population of the States. They employ upwards of one quarter of a million operators, whose weekly wages amount to 2,300,000 dollars. The total amount in these undertakings was stated to exceed 2,000 million dollars (£400 million sterling).

CANTOR LECTURES.

VIBRATIONS, WAVES AND RESONANCE.

By J. ERSKINE-MURRAY, D.Sc., F.R.S.E., M.I.E.E.

Lecture II.—Delivered May 8th, 1916.

WAVES IN PONDERABLE MATTER.

When we met last week I pointed out to you that if I could make a vortex ring vibrate sufficiently rapidly you would hear a musical sound. Now it is possible that this is actually realised in the flight of a bullet or shell. You have no doubt seen Mr. Boys's beautiful photographs of a flying bullet, and have noticed that, in addition to the compression waves which slope out from it like the bow waves of a ship, there are many small vortices in its wake. It is quite likely that these may be in sufficiently rapid vibration to act as sources of sound waves, and thus to add to the sound produced by the compression waves.

To-day we tackle the subject of waves in ordinary matter—such waves, for instance, as those of the sea, of clouds in the sky, and of sound. I shall not attempt to deal with breakers, in which the water at the top of the wave actually runs continuously forward in the direction of the wave motion, but shall stick to periodic motions such as those of waves in deeper water or of sound in air or other materials.

The first great thing to notice about a wave is that, although the wave travels steadily forward, any given particle of the material in which it is travelling merely executes a to-and-fro motion. A wave is, therefore, the forward motion of a vibration, but not the forward motion of matter. It is in fact the motion of a motion. There are two principal kinds of waves, the transverse and the longitudinal, these names being given from the direction of the vibration of the medium. In the transverse wave the motion of the material is to and fro at right angles to the direction of motion of the wave. Here, for instance, I have a long strip of corrugated paper lying on the table. I lift one end quickly and bring it down again: a wave runs right along to the far end. Quite obviously the paper does not travel with the wave; it merely rises and falls again at points successively farther and farther from my hand. The wave travels on, however, and is quite as clearly a wave as any other you like to name. Here, again, is a rope stretching from one end of the hall to the other. I give it a transverse impulse by striking it sideways near one end, and you see the wave running along it to the opposite wall, where it is reflected and comes back to me.

In a wave of the sea, *i.e.* a surface wave in a liquid, the vibration is also transverse—that is to say, any particular particle of water moves up and down as the wave passes along. You all know from experience that a cork on water merely bobs up and down and does not travel forward with the wave. If the water went forward, of course, the cork would go too.

Perhaps the simplest way to understand the motion of a water wave is to study the comparatively simple type produced by dropping a stone into a calm pond. In these diagrams, lent me by Professor Silvanus Thompson, we see the progress of the motion. Firstly, the stone strikes the water, pushing it out all round, and, as water is nearly incompressible, the water near the stone has to *rise* to make room for the stone. It cannot go down—there is water there already; it cannot go far sideways because of the inertia of all the water in front of it; so on the whole it must go up. Having risen in a ring all round the stone it is now in an unstable position; there is no permanent force to hold it up, so it falls. In so doing it pushes up the water just outside it, and this in turn falls and pushes up the water farther out. There is thus produced a ring of

raised water of constantly increasing diameter, and this is the circular wave which you see travelling outward in all directions from the point at which the stone fell into the pond. With the exception of a small outward movement in the water close to the stone, the motion of each particle of water as the wave passes is up and down in a narrow ellipse which nearly approximates to a vertical line. The smaller waves which follow the first as a series of concentric rings are due to the inertia of water. Just as in the other vibrations which you have seen, the water raised by the stone does not come to rest when it first reaches the general level of the surface, but goes on in a downward direction, thus making a circular wave of depression which follows the raised ring, and at the same time raises a central peak in the water behind it where the stone fell through the surface. This peak in turn falls down and starts a second raised ring, and the action goes on repeating itself until the energy of the stone's impact on the water has been all used up in producing the waves, and till finally these die out through molecular friction and this energy is turned into heat.

The production of waves by a ship as it is driven through the water is a similar phenomenon. As the wedge-shaped bows of the ship press the water outwards it rises, and in falling propagates a wave which travels outward, just as in the case of the stone dropped into water, but with the difference that the source from which the waves start is moving rapidly—indeed, more rapidly than the waves themselves. Hence the exquisite retreating curves in which the waves spread out on either side of the ship. You can see something of them in the photograph, taken by Mr. Vaughan Cornish, which is thrown on the screen; but it is far better to watch them for yourselves from a height overlooking some calm waterway where ships go to and fro. Why, even London Bridge will do!

There is an interesting case of ship waves which you may have noticed, that of the tramp steamer ploughing her way down Channel with a great foaming wave right across her bluff bows—a "bone in her mouth," as seamen call it. Here the speed of the ship is no greater than that of the wave produced, and instead of curving away like an arrowhead the wave stretches out on both sides, nearly at right angles to her course. In this it is like the stern wave of all vessels, which, rising under the stern, spreads out and settles down after the ship has passed into nearly a straight line.

In this other picture you see a similar type of wave, produced this time by the flow of water over a ridge of shingle. It is the lower end of Loch Lubnaig, in Perthshire, where the stream runs out. The quiet water of the loch flows towards the gravel beaches as they converge to form the banks of the stream, and underneath the surface the spits of shingle are like two ploughs with water flowing past them. You see the waves produced by each are just like those of a steamer, though in this case it is the water that moves and the vessel that is at rest. Such waves as these are seen above a moving submarine, even when it is travelling far below the surface.

The generation of waves by wind is not so simple, though what is produced is, as before, merely an up-and-down motion of every drop of the ocean. But there is this difference—that the longer and harder the wind blows and the further the wave goes, the more the motion grows. Let us see how it starts. In the first place, when one fluid—air—is moving over the smooth surface of another fluid—water—the motion is unstable, and for the following reason. The smallest extra downward pressure of air on a patch of water will cause a slight hollow and, of course, a little rise in front. As the air travels up the rise it will shoot over the top, and just behind the crest there will be a partial vacuum, very slight, but sufficient to encourage the crest to rise a little higher. Thus every time the water rises in its place it will be to a little greater height, and everywhere the up-and-down motion will increase. The result of this will be that each wave which travels off down wind from the initial place of vibration will be larger than the one before, and that the farther the wave goes the larger will it become, for at any position its energy is that of a vibration which has grown in amplitude from two causes: firstly, by superposition of the waves coming down wind to its position; and, secondly, by the action of the wind in its own locality. In the photograph of the Luss Straits on Loch Lomond, which you see on the screen, this growth of the waves under the action of the wind is very obvious. On the left the waves are small, but down wind towards the right they grow both higher and longer from crest to crest as they go.

The explanation I have given you of the growth of waves at sea has not, as far as I am aware, been put so fully in words before, although there is a suggestion of it in a paper of Lord Kelvin's. It accounts for the more obvious phenomena of sea waves and also

throws light on some of those less commonly noticed. I have, for instance, observed the following in watching a rough sea. All the large waves come towards one in a comparatively regular succession and with practically the same speed. If, however, one notes that a certain wave is larger than the others and watches it, one finds that, although it travels in the procession as a wave, it only continues to be unusually large for a very short time—in fact, it loses its characteristic size as it travels, and the wave behind it in turn becomes a large one. The maximum vibration thus travels forward much more slowly than the individual waves. This is a curious observation. It does not mean that a long wave, *i.e.* one which is long from crest to crest, travels more slowly than a short one, for the reverse is true except for small ripples, but that in a series of waves, all of nearly the same length, a wave which is particularly high at one place does not continue to be a high one throughout the whole of its course, but leaves its height behind it as it progresses. That is to say, the place of maximum vibration lags behind the actual wave motion. Since the velocity of a wave increases as the latter becomes longer in travelling down wind, the probable explanation of this phenomenon is that the extra height is due to the superposition of the two wave trains of slightly different wave length, and therefore travelling with different velocities. Their crests will thus coincide and give maximum waves at certain points which travel forward with a velocity less than that of even the smaller waves. This type of phenomenon, due to the difference in the velocities of waves of different length, does not appear to have attracted the attention it deserves, perhaps on account of the fact that in certain media all waves appear to travel with the same velocity.

When the difference in wave length is great, as, for instance, in ordinary sea waves with a ground swell coming in, where each of the longer waves is many times the length of the others, there is a somewhat different effect. Atlantic waves are sometimes considerably over a thousand yards between one crest and the next, and as these come in at about one per half minute, the result is more like a tide than a wave. Apparently the whole sea rises with all the smaller waves on its surface and sinks again. Sitting on the rocks at the mouth of Pornic Cove, in Brittany, I have watched a tide which ebbed and flowed once in every five minutes. The rise and fall totalled about a couple of feet and was quite regular and definite. Two explanations are possible. Either it was an immensely long Atlantic swell coming in, or, what was perhaps more likely, it was the natural vibration of the water in the cove—a deep and narrow harbour running about a mile into the land. Many cases are known of such vibrations of large masses of water: in the Scottish lochs, for instance, they are continually occurring, being started by differences of wind pressure on opposite ends or sides of the lake. A very careful survey of these motions, and of their relations to the depths and forms of the lochs in which they happen, has been made, the results being published in the Proceedings of the Royal Society of Edinburgh. The technical name for such a little tide is the French word "seiche," they having been first observed in the lake of Geneva. The common saying that the seventh wave is always the greatest is probably a recognition of the fact that there is usually on all sea coasts a swell of great wave length in addition to the smaller waves of more local growth.

I shall now show you a simple experiment which illustrates very clearly some of the more important laws of wave motion. Here is a large photographic tray in which there is some water mixed with a considerable proportion of syrup to make its movements slower, so that they may be more easily followed by the eye. I place an arc lamp near it, the light of which is reflected from the water surface and thrown upwards on the screen as an oblong patch. You see that the slightest disturbance causes a ripple in the water, which travels across the tray and is reflected from the other side. If I touch the surface with a small stick, or let a drop of water fall on it, a rapidly growing ring of concentric ripples travels outwards till it touches the side and then is reflected back. Notice that the reflected ripples cross the band of incoming ones without stopping their motion or being in the least distorted themselves, and in fact that each wave travels onwards just as clearly and independently across the others as it would do on a calm surface. You can see clearly that when a band of ripples crosses another band and arrives again in a calm surface, it is quite evident that it has suffered no distortion in the process. The essence of this observation is that waves do not destroy or even confuse one another, but that each goes on its own appointed course as if none other existed. Thus it is that we can hear sounds from many sources at once and distinguish them, and that the ground

swell does not obliterate the cross sea on its surface.

I may now state this as a law of wave motion: Any number of wave motions may co-exist independently in any medium without mutual distortion, and the motion of any portion of the medium is simply the result of the superposition of the waves passing through it.

If I strike the table with my hand you see straight bands of waves starting simultaneously from all sides of the tray. They travel forwards, making a tartan pattern, and, crossing one another at the centre of the dish, arrive at the sides opposite those from which they started quite unchanged. If, instead of giving a single stroke, I continue to beat the table at short intervals, the tray becomes full of these waves, and the result is a fine chequered pattern of bright points and dark lines covering its whole surface. These appear to be merely rising and falling at fixed points, and for this reason are sometimes called stationary waves; but the moment I stop beating the table, you see that they are really just the points where several sets of travelling waves cross one another. One can see an effect like this wherever waves cross one another, and very clearly near a sea wall or stone pier. The reflected waves travel back through the incoming ones, and where two crests meet the compound wave rises to a great height, often breaking into spray. A "jabble" is the technical name, and well describes the apparent wildness and irregularity.

The same effect can be seen in the long stretched rope if I give it a second impulse just as the first has reached the far end. The two then meet in the middle, and, as the reflected one is returning on the other side from which it went out, apparently cancel one another at this point, but pass on nevertheless. By repeatedly striking the rope at intervals, each equal to the time taken by a wave to travel from one end to the other, I can keep this motion going, and the string continues to vibrate in two sections with a quiet spot at its centre.

The speed of a deep-sea wave is proportional to the square root of its length from crest to crest; but in shallow water another rule holds good. If you watch a long swell coming in from deep water over a slowly shelving bottom you will see that the distance between crests is gradually reduced, showing that the speed of a wave in shallow water is less than in deep. The case of waves in a canal is an especially interesting one, and has been calculated by Lord Kelvin. He found that there is a limiting velocity faster than which a wave will not go. This is illustrated very neatly by the way in which the passenger boats used to be run on the canals in Scotland. These were light and shallow vessels, not like the great barges now used for freight-carrying, and were drawn by a pair of horses. At first their speed was that of a walking horse, say four miles an hour, and at this rate they travelled with a large wave always just in front, and it was hard work for the horses. One day the horses bolted, the barge was jerked forward over the top of the wave, and, to the surprise of the driver, continued to move forward quite easily at about ten miles an hour without creating any wave. After this the obvious method of whipping up the team at the start and then keeping them at a steady trot was always adopted. The fact was that they were now going as fast or faster than the most rapid wave possible on the canal. Thus no wave was produced, and no energy to speak of was wasted in churning up the water.

A type of wave which I have not hitherto mentioned is the ripple, by which I mean the little waves less than an inch from crest to crest, which do not mainly depend on gravitational force, but are controlled chiefly by the molecular attractions between adjacent molecules of the liquid. The effect called surface tension is produced by these forces, and its result is as if the surface were a solid elastic sheet. The speed of a ripple, unlike that of a larger wave, is greater as the length is less—a fact very easily observed in water. Here I must remind you that all the water waves with which we have dealt are surface waves in fact, and for this reason are more complicated than internal waves, such as sound waves in air, or electric waves in a large mass of dielectric. There are, of course, surface phenomena in all wave motions at the interface between two media, but in sound and electricity the internal waves exist and are important, while the only truly internal waves in water are either sound or electric, for the ordinary waves are solely due to the fact that above the water there is the air—a fluid of much less density.

Even in the atmosphere itself surface waves are possible, for there are sometimes sharply marked layers of different density. Here is a photograph which shows you a series of long straight clouds lying in parallel lines, just like the crests of a swell. Such, indeed, they are, being the tops of great air waves in which the moisture has become condensed as they rise, thus rendering them visible: they indicate that

in the upper layer the air is blowing across the air beneath it, just as the lower air blows across the sea; but they travel slowly, for the difference of density of the two layers is small, and on this depends their speed. In another of these pictures we see, from above, a wonderful sea of clouds, which at first sight appear to be piled at random away to the farthest horizon; but on closer examination an order is evident, and many parallel ridges are clearly discernible. Now when a fluid surface shows such a definite formation one seeks an explanation, and in this case that of wave motion is the only one which fits. Indeed, whenever a fluid shows a structure in parallel lines the presumption is in favour of a wave motion being the cause.

There is one great set of waves, so large that we do not recognise them as such, which is of the utmost importance to us as an insular people—I mean the tides. If the globe were covered to a uniform depth with an endless sea the tide would be quite a simple motion; but as it is, with the ocean broken up by continents and its depth varying from several miles to a few score feet, it becomes a most complex procession of waves whose periods can only be determined by prolonged observation. But once determined and analysed into their simple harmonic components they can be predicted for years ahead. This sounds remarkable, but really the process is quite simple. First one determines the component simple vibrations by graphical or mechanical analysis of the record of past tides at the station. Then one adjusts each of the vibrators of the tide-predicting machine to represent by its motion one of these component vibrations, and thus the end of the cord, which passes over all the vibrators, performs a complex vibration, and records the form, height and period of the tide required on a moving strip of paper. The tide predictor is a frame in which are set two horizontal rows of pulleys. A cord, fixed at one end and free at the other, passes over an upper pulley, then under a lower one, and so on up and down across the board. At its farther end is a weight with a pen attached. Each pulley can move up and down in a vertical guide, and is made to do so at a properly chosen rate by gearing behind the frame. Hence, as each pulley moves it lengthens or shortens the bight of cord which is round it, and alternately raises or lowers the weighted pen at the free end of the cord. As all of the pulleys are working on the cord at once, the movement of the pen is simply the sum of their separate motions.

I have constructed a simple machine which will show you this composition of harmonic motions, though in this case the vibrations are damped and not uniform, like those of the tide predictor. It consists of two weights hung on helical springs, which are attached by their upper ends to the top bar of a trestle. A horizontal rod is connected by flexible couplings to both the weights; it runs in fact through the rings on them, and is held in position by fine cords. One end of the rod projects beyond the weights, and has a small paint-brush fixed across it horizontally. If I now set the weights in vertical vibration the paint-brush performs a complex up-and-down motion which is compounded of the separate vibrations of the weights, and by drawing a sheet of thick paper steadily past the brush I obtain on it a wavy line giving the form of the compound vibration. Also, by keeping either weight still and letting the other vibrate alone, I get its wave form: so here you have the records, not only of the compound vibration, but also of each of its simple harmonic components. By hanging additional weights on one of the vibrators you see that I obtain another form of record, and that if the frequencies of the vibrations are not greatly different the motion is a curiously complex one. To find how long it will be until the record begins to repeat itself is really a problem in our old school friend the L.C.M., so that hackneyed rule is of use after all; I say to repeat itself, though with this machine this is hardly exact, since as the vibrations are continually dying away they never are repeated in size, although they are in form.

The model, lent me by Professor Thompson, which I now show you demonstrates a very curious type of vibration. As I move it you see that each of the knobs at the top of the rods describes a nearly circular curve in a plane perpendicular to the wave, and that the wave travels forward with a cork-screw motion. In this other model, which consists of a ladder of tape with knitting-needles as rungs, we get what at first sight appears to be a similar wave form; but it is not so, for in this case the ends of the needles reverse their motion and rotate to and fro, whereas the knobs in the first model moved continuously round in circles. The second model shows torsional waves such as are easily produced in rods or masses of elastic material, and are in fact of very great importance in propeller shafts and other structures. I have seen them, for instance, in a long corridor carriage travelling at high speed on one of our

main lines when looking along the corridor from one end to the other.

From the experiments which you have now seen you will realise that the vibrations which generate a transverse wave may be either in straight lines at right angles to the direction of the wave motion, or in curves of any form in planes at right angles to the same. When we have stated the character of the vibration we have defined the property of the wave which is termed its polarisation.

All the waves which we have considered thus far are transverse in nature, and amongst those of this class are also included the waves which we know as electric and as light and heat. There is a smaller but still very important class, in which the motion of the material through which the wave passes is to and fro in the direction of the wave itself. These are called longitudinal waves, and are only found where the medium is compressible either on account of its nature or because the wave is merely carried along a rod which is free to expand or contract in lateral directions, since it is surrounded either by a compressible or by a fluid material. I shall show you examples of both types of longitudinal wave, and, as it is perhaps the simplest to demonstrate, I shall commence with a longitudinal wave on a long rod or cord of elastic material surrounded by air, which, by the way, is both fluid and compressible.

Here I have a long thread of indiarubber, on which I have strung at equal intervals a number of small leaden weights in order that the wave may be slowed down so as to be visible by you. To keep the indiarubber in a straight line, it is supported from a horizontal bar above it by a number of cotton threads; these do not appreciably interfere with or alter the wave motion which I am going to show you. At one end of the rubber a small lever and flag are attached so that those of you who are not close at hand may see the arrival of a wave more easily. I now pull and suddenly release the near end of the rubber cord. You see the impulse running along it made visible by the crowding of the little leaden weights. This crowding, which is in fact a compression wave, runs along to the far end and wags the flag. Keeping your eye on any one of the leaden beads, you see that it merely moves to and fro lengthwise as the wave passes. The wave is thus truly longitudinal, the vibration of any particle being forwards and backwards in the direction of the propagation of the wave. If you watch closely, you will see that the wave is reflected from the far end and returns to my hand just as in the case of the transverse wave on the long rope, and if I give the cord a succession of little tugs at proper intervals I can produce stationary waves with a quiet spot half-way along the indiarubber in the same way as with the rope.

I have said that I loaded the rubber thread with leaden weights in order that the wave might travel more slowly. It is quite easy to show you that adding inertia does retard a wave. This piece of cord, about 30 ft. long, is loaded for 10 ft. of its length at the end farthest from me. If now I start a series of waves so that the cord gets into stationary vibration, you see that, while there are two vibrating segments in the loaded portion of 10 ft., the whole 20 ft. of unloaded cord vibrates as one. Now the length of a segment, *i.e.* the distance between one node and the next, is inversely proportional to the velocity of the wave running along it, for the times in every case are the same, as is also the number of impulses per second. Hence, since the unloaded segment is four times as long as one of the loaded ones, the velocity of the wave in the unloaded part is four times that in the loaded portion. To make this more evident, suppose we cut 5 ft. off the loaded section of our cord. The cord would then be 25 ft. long and there would only be one node, *i.e.* at the commencement of the loaded section, in addition to the fixed points at the ends. Now imagine two impulses starting simultaneously in opposite directions from this node, and travelling to the ends of the cord and back again. Clearly, if the node is to remain a node, *i.e.* a quiet point, the two impulses must again pass simultaneously through the point from which they started. Hence the time taken by an impulse to travel over each segment of the cord must be the same, and, as the unloaded segment is four times as long as the loaded one, the velocity in it must be four times as great. Loading the medium along which a wave passes, therefore, slows its progress. We understand why this is so when we reflect that the rapidity of a wave's motion depends on the rate of the local vibrations which constitute it, and that these are slower the greater the inertia of the vibrating body. The same is, of course, true whether the vibrations be transverse or longitudinal.

I shall now show you by a simple method which I discovered some years ago, the movement of a sound wave in air. On the table a yard or more away from me I place a lighted candle. Standing facing the candle, I hold a

piece of stiff cardboard about 1 ft. square in both hands in front of me. If now I suddenly pull the cardboard towards me, you see that the flame is momentarily drawn over towards the retreating card. I place a second candle a foot or two beyond the first and repeat the experiment. Now both flames move with the motion of the card and, as nearly as can be judged, at the same moment. Clearly, therefore, the rate at which the disturbance travels through the air is high, certainly more than 100 ft. per second, for if it were slower the eye could notice that the near candle flame flickered before the farther one. The disturbance cannot, therefore, be a draught of air in the ordinary sense—that is to say, it is not caused by air actually flowing across the room. What happens is this. Jerking the card towards me leaves a partial vacuum behind it, since the neighbouring air cannot instantly flow in because of its inertia. The air against the card is, therefore, momentarily rarefied. Into this partial vacuum the air immediately beyond it commences to fall, becoming itself rarefied in the process. Then the air immediately beyond this falls in, and so the rarefication travels on until, on reaching the candle flame, this falls in also and shows you the presence of the wave. A very similar action is visible in a large heap of sand or fine gravel when a spadeful is taken out of one side of it. The sand commences at once to fall into the vacancy, and the falling-in process keeps on spreading farther and farther until an equilibrium is reached.

I have called this a sound wave, as in fact it is, although your ears are not sensitive enough to hear it. If I could move the card more rapidly, and thus produce a better vacuum, you would hear a single thud owing to the outward motion of the drums of your ears as the rarefaction came along to them.

If instead of pulling the card towards me I push it suddenly away, I produce a compression wave which travels exactly as does the rarefaction. It is not so easy to show you, however, as one's muscles are not so well suited for a sudden push as for a pull. Probably the greatest wave of this kind on record was that given out by the volcano of Krakatoa. I have already mentioned how it was heard as a loud sound after travelling fifteen hundred miles, and was detected by sensitive barometers after it had gone one hundred and forty-four thousand miles —*i.e.* six times round the globe.

Another interesting case of sound transmission is the submarine bell. In water, on account of its very small compressibility, a sound wave travels about four times as fast as it does in air, and, when once started, it has considerable energy owing to the density of the water. The result is that under water it is no uncommon thing to hear a submarine bell at a distance of sixteen miles, and the more powerful sound of the Fessenden hooter has been heard at fifty-five miles off. The latter is something like an electric motor-car hooter on a very large scale. A steel disc is caused to vibrate rapidly by an electro-magnet carrying an alternating current; it produces a succession of waves of compression and rarefaction in the water, and these are appreciated as a tone in a telephone connected to a microphone which is immersed in the sea. Submarine bells are now very largely used in navigation in all parts of the world, but especially on the eastern coasts of America, where scores of them are located on sunken shoals and as guiding points near the entrances to harbours. Most transatlantic liners are fitted with the receiving apparatus, which consists of a pair of microphones, each enclosed in a box full of water fixed against the plating of the vessel *inside*, on either bow. If the ship is heading straight for the bell the sounds picked up by the microphones are equal in strength: thus the bearing of the bell can be determined and the proper course set. In thick and foggy weather the bells have proved to be of the greatest use.

In my last lecture I showed you that musical tones and articulate sounds are merely certain types of continued vibrations, and since the waves given out by them are really the same vibrations in motion from place to place these waves have the same characteristics. The strange thing is that, although each set of waves is independent of the others in the sense that it travels on its course undiminished and undistorted by the others it may meet, the actual vibration at any particular point, at the drum of your ear, for instance, being the sum of all the pressures and rarefactions arriving at each moment, is in itself merely an alternation of pressure and rarefaction—not a simple harmonic vibration, of course, but a harmonic variation composed of many simple components. It can therefore be represented by one wavy line, apparently irregular, but in reality composed of many simple harmonic motions. This one line represents a motion which is very simple as regards space; it is in fact merely backwards and forwards in one short straight line, but may be infinitely complex in time. Thus it is that the little wavy

scratch on a gramophone disc or the tiny pitted groove of a phonograph may be the completed record of the sound waves of a band of many instruments, of a single human voice, or of the confused babel of a market-place. There is no further mystery in either of these instruments. Inside the box there is only ordinary clockwork, and the reproducer is merely a fine needle attached to a little glass or mica disc. The mystery of the music is wholly in the wavy line. Once you have got some way of making a piece of material large enough to cause audible compression and rarefactions in the air, to move according to the wave forms frozen on the record, you can obtain again the sounds they represent. Here is an ordinary gramophone record rotating at its proper speed. I hold a thin calling card with one corner in the groove. As the record turns the card is forced to vibrate with the wave forms which have been impressed on the groove, and so gives out the sounds—faint, no doubt, for the card does not take so firm a hold as does the needle of the reproducer, but quite clear and distinguishable.

Do not forget that in the air and even at the drum of your ear a sound is nothing but alternate compression and rarefaction, or a mere to-and-fro motion—the music is in your mind alone; it is a picture painted, not in space and colour, but in time and motion, and, like other pictures, pleases or displeases by the conception of harmony which it gives. It was something of this sort that Fourier meant when he said that if one could comprehend at once the laws of the diffusion of heat it would give one the sensation of music, so beautifully do they harmonise.

It might seem a misuse of terms to call the grinding shriek of a tramway car as it turns a corner a musical note, but though unlovely it has something of that quality, and so must be caused by repeated vibrations. To those unaccustomed to associate such sounds with the presence of a uniform vibration the curiously regular flutings so often observed on the surface of tramway rails remained a mystery, and were provocative of all sorts of far-fetched explanations which merely confused the issue. A long discussion on "roaring rails" on railways went on at intervals during many years in our premier engineering institution, while, oddly enough, at the same time the subject of the "corrugation of rails" was chronic in another. Internal evidence from the proceedings of both societies shows that the phenomenon, though known by different names, was one and the same, although the aspects of the two societies were different. In the tramway case it consisted in the appearance of certain bright patches on the surface of an otherwise neutral-coloured steel rail—patches which indicated the development of peaks and hollows on it, which were certain to lead to its early suicide, causing much grief and expense to its masters. On the railways, on the other hand, it was the noise that attracted attention. Each time a train ran over certain sections of the line it roared as if the brakes were on, and worse sometimes. Passengers complained, and the careful permanent-way engineers were even more annoyed than the noisy oyster. I first became interested in the phenomenon when travelling daily from Bushey to Euston in 1907. After studying the rails at various parts of the line, and obtaining permission of the Company, I went out one fine Sunday with a genial foreman platelayer armed with some long rolls of tracing paper about two inches wide to obtain tracings of the markings on the rails which roared. These direct tracings have been transferred to this wall diagram on their full natural scale, and although they were done eight years ago, you are the first audience to see them.

At first sight the markings appeared to be hopelessly irregular, and gave no clue to their origin; but on looking more closely I found a characteristic form repeated itself with slight variations at definite intervals—an almost certain sign that the corrugations had their origin in vibrations. Look, for instance, at the rail marked (A). First you see a row of small bright patches at nearly regular intervals of about an inch; then follow three or four longer and less regular marks; and this complex pattern of smaller and larger markings is repeated again and again along the rail at intervals of about two and a half feet. Now, the longer markings occur on the portions of the rail near its points of support—the chairs—and the shorter ones in the interval where the rail is free: thus, every time a wheel passes over the rail it dances along the unsupported part, and then skids in longer jumps up the minute slope to the chair and over it, repeating the whole performance at every successive sleeper. I have observed miles of this pattern on the London and North-Western line and on others of our best-laid express lines. This observation at once disposes of the suggestions which have been made that the corrugations might be due to soft spots in the metals or to uneven rolling during manufacture, for it is quite beyond all probability that the rails should be soft at regular intervals corresponding to those between

sleepers, and then in so complicated but definite a pattern.

I have also observed that "roaring" rails on railways and "corrugated" ones on tramways occur almost always in places where the conditions are unusually favourable to the production and repetition of a particular vibration. Such conditions are: (1) a tendency for the wheel to slip intermittently instead of rolling—*i.e.* a moderate tangential force between wheel and rail, so that the wheel acts like a bow on a violin string or the exciting stick on one of Gould's bars; (2) a repetition of these conditions of motion for every wheel passing the section of track. Thus the worst corrugation in tramways is generally found on curves, and on these both conditions (1) and (2) exist, for (*a*) the difference in distance travelled by the outer and inner wheels on any axle in rounding a curve involves slipping of the wheels, and (*b*) the fact that there is very rarely a stopping-place on a curve ensures that every car goes over the section at nearly the same speed, unless, indeed, the other traffic is so heavy as to cause frequent delays. Conditions (1) and (2) occur also just before and just after stopping-places, and there also one often sees corrugation, even where the line is straight.

On railways I find that the same conditions are fulfilled on the sections giving most trouble. Where the rolling-stock of nearly every train is of the same type and the speed nearly the same for all trains, it is clear that the vibrating masses and their motions are alike; and I find that it is just in these circumstances that the markings which indicate the roaring rail appear most frequently. Thus on the fast lines of a four-track main line, and particularly where one express train of long bogie carriages follows another at almost exactly the same high speed with the brakes on, corrugations often occur, though these do not appear on the slow lines in the same section. On the latter the rolling-stock is of many descriptions, from passenger coaches to all types of goods and mineral waggons, and the speeds are as various: on them, therefore, the conditions for a definite vibration and its repetition are absent. If a corrugated rail be moved to another section of the track it is not uncommon for the markings to disappear, which, of course, is a further proof that the corrugations are due to a combination of circumstances favourable to vibration and not to irregularities of manufacture. The consideration of a large number of observations on tramways and railways in various parts of the United Kingdom has thus led me to the conclusion that roaring, or corrugated, rails are initially caused by vibration, and, once commenced, the corrugation naturally increases with time, since every wheel that passes deepens the hollows and renders more energetic the vibrations of all that follow.

RUSSIAN ASBESTOS INDUSTRY.

Asbestos is found in insignificant quantities in the Caucasus and in Siberia, but about 99 per cent. of the Russian output is mined in the Ural Mountains. Some of the best asbestos mined in the Urals is produced at mines sixty miles north-west of Ekaterinburg, in a zone of serpentine rocks which extends about six miles and is about 1,400 yards broad. The quality of this asbestos is believed to be as high as that of Canada and Piedmont. The veins are directly broken off, either by hand or by a hard hammer. The operation of mining asbestos in the Urals is of a primitive character, but in some cases the production is being made more systematic.

According to a report by the United States Consul-General at Moscow, the most important of the Ekaterinburg asbestos mines are the Voznesensky and Zoe-Anonsky asbestos mines, situated nineteen miles from the station of Bazhenof, on the Perm-Tiumen Railway. A third of the asbestos produced in the Urals is obtained here, and all the asbestos produced was dispatched abroad, untreated, through Reval. The Shchougy asbestos mines in the village of Mostovsky produce less than the above mines, all the asbestos produced being worked up in the factory, where sheeting, bands, twine, insertion, thread, etc., are made. The Gavorikhinsky asbestos mines lie in a line with the Voznesensky mines, and yielded 3,183 tons of asbestos in 1911. Six miles from the Meivo-Shaitansk factory of the Alapievsky Mining Works are the Kirtanovsky asbestos mines, with a sorting factory where 2,000 tons of asbestos can be sorted per annum. Close to these mines are the mines of the Russo-Italian Asbestos Co., the N. V. Mikhanov Co., the "Uralite" Co., etc. The following figures show the output of the Ural (Ekaterinburg) asbestos from 1906 to 1913: 1906, 8,001 short tons (of 2,000 lb.); 1907, 8,743 short tons; 1908, 10,694 short tons; 1909, 13,129 short tons; 1910, 10,936 short tons; 1911, 15,872 short tons; 1912, 16,584 short tons; 1913, 16,661 short tons. Practically the whole of the output was exported *via* Riga.

North of Ekaterinburg asbestos is found in the Bogolsof mining area, in the Kortiakovsky mines (where the vein is about 2 ft. thick), near the Alapievsky works, the Veniansky works on the River Uktussa, near the Beresovka works, etc. In the Southern Urals asbestos

deposits are found at the Khristogor and Petropavlovsky ore mines, near the Miask works on the River Krasnacht, in the Pavrilof copper mines (of excellent quality), in the Atliansky gold placer, near the River Imian Yurt (in talcous schist); there are veins of asbestos near the Kisnikaievsky copper mine at the foot of the Naralinsky Hills; also amongst the serpentine of the River Kara, near the Kachinsky factory, and along the River Puberle, near the fort of that name.

The best mineral is considered to be that of the Asbestovoy Hill, on the River Sissert, and the asbestos deposits of the Shelkovoy Hill, on the land of the Nizhni-Tagil works, between the Shouralinsky and the Teploy Hills. To the south of the Ural range of hills in the Government of Orenburg there are some exploited asbestos mines—the Natalievsky in the Upper Ural district—the Issergansky in the Orsk district, and the Kholmisty in the Troitzk district.

The following companies have joined the syndicate of Ural asbestos producers:—

	Tons.
1. Voznesensky Asbestos Mines, with an annual output of	3,106
2. Yakovlev Successors, with an annual output of	1,806
3. Poklevsky-Kozell Successors, with an annual output of	5,416
4. Korievo Asbestos Mines, with an annual output of	2,709
5. Girard de Soukanton, with an annual output of	3,611
6. Russo-Italian Asbestos Mining Co., with an annual output of. . . .	1,806
Total . . .	18,454

It is stated that all the companies operating in this district are privately owned and managed. The present transport facilities from the mines are confined to the single-track line of the Perm Railway, connecting with the Northern Railway to Petrograd.

According to official statistics, the exports of asbestos from Russia for the last seven years were as follows: 1909, 9,160 short tons; 1910, 9,689 short tons; 1911, 13,524 short tons; 1912, 15,547 short tons; 1913, 13,669 short tons; 1914, 8,577 short tons; 1915, 975 short tons. These exports before the war went to Germany, Austria, the United Kingdom, Belgium and the Netherlands. Asbestos is produced in the Caucasus in an insignificant quantity, in the Sharopan district of the Kutais Government, at the Vzhinevi asbestos mines. In the same Government of Kutais asbestos is known to exist far from the deposits already named to the north-west, in the Lechgoumsky district in the Savanetsky police circuit. It is also found in the extreme south-eastern corner of the Caucasus, not far from the Persian frontier, twelve miles from the town of Shusha.

In Siberia asbestos is exploited only in the Government of Irkutsk, in the Angar district, at the Angar asbestos mines. In the Government of Yenisei there are asbestos mines on the left bank of the River Kamuisht, near the Saksar and the Ak-kay Hills, near Bishtals Hill, at a distance of twenty-five miles from the village of Askeisk, and on the River Karagan, on the boundary of the Mausky and the Servievsky gold placers. In the Tomsk Government it is found in the system of the River Katum, in the Semiriechensk territory, on the northern slope of the Dzhigla Range, in the Dzuban-Arychsky district, and in the Transbaikal Province, in the serpentine of the Klinchinsky ore mine, near the Shilkinsky factory, and in the neighbourhood of the tin mines of the Nerchinsk Circuit.

On the Mongol-Dabansky gold placers (now worked out), which belong to the Crown, very rich asbestos and mica mines have been discovered. The Mongol-Dabansky gold placers are situated on the River Mongol-Daban, which falls into the River Didi, a tributary of the River Oka. The new mines lie seventy-five miles from the station Zima, on the Trans-Siberian Railway.

HOG-RAISING IN CUBA.

Cuba consumes more than £2,000,000 worth of pork and pork products per annum, but as yet there has been no sustained effort to raise pork for the local demand, or to establish a packing-house industry, although the country is in many respects ideal for raising hogs. There is an abundance of water, forage all the year round, an equable climate, and, in addition, the widespread distribution of the royal palm tree ensures a great quantity of the seeds, called "palmiche," which fall at all seasons of the year and are greatly relished by swine. The palmiche gives the meat a nutty flavour that is very fine indeed, and pork raised on this food is held in great esteem. The animals thrive on it amazingly.

In addition to the palmiche there are other foods growing wild—the guava, which hogs relish, and yuca roots, and many other tubers and roots. Mango trees are distributed over the island, and in season the ripe mangoes that fall are a considerable factor in the food supply. Sugar cane is eaten with avidity, and is found to be remarkably satisfactory for putting flesh on hogs. Cow peas, peanuts, sweet potatoes, soya beans, and the like as special forage and grazing crops grow with little attention. Good land suitable for hog-raising may be had for 10*s.* 6*d.* to £2 per acre, becoming more expensive as the location is nearer the cities.

The native hog in Cuba is very much like the famed "razorback" of the Southern pine woods —mostly head, legs, snout, and ears, swift of foot, but very hardy and thrifty, and does well without any care whatever. According to a report by the United States Special Agent in Cuba, there is as yet practically no effort to raise hogs commercially, except in small herds which range the woods in charge of a herdsman and his dogs. The meat of these semi-wild hogs is in considerable demand on account of its flavour from the palmiche seeds, but the supply is not dependable, and no attempt is made to put it up as hams, bacon, ribs, or sides. This fresh pork sells at 4½*d.* a lb. all the year round, and is scarce at times.

There has of late grown up in Cuba a sentiment in favour of producing more foodstuffs, and hog-raising is receiving considerable attention. The Cuban Agricultural Experiment Station at Santiago de las Vegas is experimenting with various breeds, and is in touch with the more progressive element which intends to devote attention to the growing of better pork. Cholera is known to some extent, but the most prevalent disease with which Cuban hogs are afflicted is called "pintadillo," and is supposed to be a mild sort of cholera. The Cuban Experiment Station is now seeking in the United States a competent chemist to make cholera serum and to study the diseases of native hogs.

In 1913 Cuba imported 10,225 hogs, valued at £26,170, and in 1914, 9,816 hogs, valued at £26,920. The United States furnished the entire number. Duroc-Jerseys, Berkshires, and Poland Chinas appear to be the favourites, and a cross between these and the native hogs produces a thrifty animal which, if not ideal in shape from the packing-house standpoint, carries considerable meat, and is a great improvement on the native wild hog.

Some capitalists of the United States are now projecting a hog ranch and packing-house on 20,000 acres of land in Pinar del Rio Province, about sixty miles from Habana. It is proposed to commence with a capital of £50,000.

OIL-ENGINES IN HONG-KONG.

In spite of the general depression of trade noticeable in all lines, and especially in those lines of trade which depend directly upon Chinese consumption, there seems to be a continued demand in China for internal-combustion engines of several varieties and especially for marine motors. The growth of the trade in normal years has been remarked upon by nearly all trade authorities, the Commissioner of Customs at Canton, in his recently published annual report, saying, for example :—

"The demand that is becoming noticeable for oil-engines, both stationary and marine, is due chiefly to recent improvements in motors permitting the use of crude oil in place of the more expensive gasoline, and a large development of this trade in the near future may confidently be predicted. Crude-oil motors for irrigation purposes were erected during the year in the Ko Ming district on the West River, near Samshui, and larger engines of similar type were also imported for the use of the Fatshan Electric Supply Co. Oil-engines, usually an exact copy of some foreign pattern, are being made locally by the Chinese engineering firms, who are presumably alive to the growing demand for motive power in a handy form."

From a recent report by the United States Consul-General in Hong-Kong, it appears that the manufacture of such motors in Canton, or elsewhere in China, so far has not developed to any considerable extent, nor is it likely to do so for some time to come so long as prices of imported motors are reasonably low. The use of motor pumps for irrigation along the West River has not been very successful, though the outbreak of the war in Europe and the collapse of South China's foreign trade have prevented a fair test of the demand for engines for such purposes.

The war has also directly affected the development of the motor-boat traffic on South China rivers by causing the depression which has existed for months in all lines of Chinese activity. Nevertheless, the trade has continued in fair volume, and with the advent of normal conditions in this field the demand will increase greatly. The type mostly in demand is a simple motor with few working parts and an ability to stand exposure, dirt and neglect, and using crude oil or petroleum as fuel. The demand is mostly for marine motors and motors suitable for small electric light and power plants, and for running very small industrial establishments.

MARBLE DEPOSITS IN BRITISH COLUMBIA.

Among the many natural resources of British Columbia available for commercial and industrial purposes is a fine grade of marble. An extensive ledge of what is designated as Malaspina marble is now being worked on Texada Island, about fifty miles north-west of Vancouver. It is a crinoidal formation, its most attractive feature being the variety and extent of tints and colouring shown in irregular streaks.

Marble from the Texada quarries was used for decorative purposes in the new Vancouver Hotel, completed in 1915, and samples exhibited at the Panama-Pacific Exposition at San Francisco attracted favourable attention. The deposits are found in the southern end of the island adjacent to a land-locked bay, which facilitates the transportation of the product to markets on the mainland.

The value of marble imported into Canada in recent years has averaged about £100,000

annually. In addition to the imported article, marble from Canadian quarries, particularly the green marble of Missisquoi, is extensively used throughout the Dominion. According to a recent report by the United States Consul-General at Vancouver, it is estimated that the marble used in buildings in Vancouver has a total value of £1,000,000, and with the rapid development of the country the prospects for the development of an important industry in the quarries of Texada Island are promising.

ENGINEERING NOTES.

American Gasoline Caterpillars for Drainage Purposes.—The latest development in ploughs for excavating drainage channels of sizes too small to be economically handled by a dredge is the gasoline traction engine, mounted on caterpillars. Many years ago a drainage channel plough was invented. Horses were attached four abreast, and frequently 50 miles of channel 8 ft. wide on top, 3 ft. deep, and 18 in. at bottom width, were let on contract prices at from 5*s.* 2*d.* to 8s. 4*d.* per rod. The gasoline machine which is replacing these outfits consists of an engine supported on two long caterpillars 30 in. wide, which carry a 16-in. diameter cable drum 24 in. long. This drum is driven from the main shaft of the 60-h.p. engine, and is geared to give a rope speed of 14 to 18 ft. per minute, depending on the amount of cable on the drum. About 1,000 ft. of 1⅝-in. wire rope is used. When, on account of difficult ground or for other reasons, the tractor must be set at greater distance from the plough, removable lengths of 500 or 600 ft. of wire rope are attached between the plough and the end of the cable. In operation, the plough, removed from its four-wheel carriage, is left at the starting-point of the channel, the cable attached to its beam. The tractor moves ahead to the proper point on the line of the channel, paying out the cable as it advances. The traction gear is then released and the drum thrown in. As soon as a strain is taken on the cable, two anchor flukes drop to the ground and bite in as the tractor moves backward until the latter is securely anchored. When the plough is drawn to the end of the cut, the drum is thrown out of gear and the tractor thrown in. As the tractor advances, the anchors ride up from the ground and are hooked up in the clear by power. One man and a helper are required to operate the tractor, while another man rides the plough. A team and driver are employed in hauling supplies, and a cabin on wheels, presided over by a cook, furnishes food for the crew. The plough, weighing 4 tons with its removable truck, a waggon loaded with cable and supplies, and the cook waggon are hauled by the tractor over ordinary country roads at the rate of two miles per hour. Although the tractor weighs 15 tons, its large bearing surface enables it to travel over swamp land too soft to support a team. A plough of increased size, which will cut drains 2 ft. in bottom by 9 ft. in width, and 3 ft. 6 in. deep, is used with the tractor. The caterpillars are similar to those that have been applied to the so-called "Tanks" for war purposes.

Niagara Wire-Rope Way.—A passenger cable-way, said to have the longest clear span in the world, has recently been built across the Niagara Whirlpool, at a cost of about £15,000. The passenger car is suspended from a running gear which travels on six parallel track cables of 1 in. crucible steel rope. Each cable is anchored securely at Colt's Point, the starting point, by means of a 2-in. rod bent into an anchorage in a 740-ton concrete block. At the other terminus each track cable passes over a sheave and is fastened to a counterweight or stretcher. Boxes, 12 ft. high by 6 ft. 7 in. wide by 11 in. deep, made of riveted steel, contain cast-iron weights sufficient to make a total of 10 tons for each track-cable counterweight. The boxes move up and down freely in steel guides, maintaining the tension in each cable always at 10 tons regardless of the load on the cables. When the load on the car is increased, the counterweights rise, and sag in the cables is increased until they take such an angle that the sum of the vertical components of the tension at the ends is equivalent to the weight of the car and its load. Each track cable is entirely independent of the others. The breaking of any one of them would not be serious, as the other cables would support all the weight of the car without any increase in their tension. The car would drop several feet suddenly, and, after a few vertical oscillations, would assume a new position of equilibrium. Thus the breaking of one cable would not imperil the passengers, and the breaking of two cables at the same time would be very improbable. The car seats twenty-four passengers and provides standing room in a raised aisle in the centre of the car for twenty-two more, including the conductor. The weight of the car when empty is 3½ tons, and when fully loaded 7 tons. It is 10 ft. 10 in. wide, 24 ft. long, and 23 ft. high. The car is propelled by a ⅝-in. plough steel traction cable fastened to one end. The cable passes over a sheave on Colt's Point, runs back across the whirlpool, over a sheave in front of the Thompson's Point station, the other terminus, and to the driving sheave. From here it passes around three sheaves, to one of which is fastened a 10-ton counterweight box arranged in guides similar to those for the track-cable counterweights, thus creating a tension in the cable which adjusts any slack caused by the rising and falling of the car. The 8-ft. driving sheave is turned by a 75-h.p. Westinghouse motor, through a 30 to 1 worm gear, giving a speed to the car of about 400 ft. per minute when the controller is at full speed. The trip can be made in about 4½ minutes, but it is planned to permit it to occupy 6 minutes by running at half-speed part of the time. To provide against a breakdown of the motor or interruption in the power supply, there is a clutch in the driving shaft, by means of which the motor can be disengaged

and a 5-h.p. gasoline engine engaged both through a worm and through socket wheels. An automatic control stop is provided in each terminal, which stops the car without jar within a distance of 3 ft. 4 in. The traction cable runs longitudinally through the 5-in. pneumatic cylinder and through the centre of the piston. A clamp on the traction cable, just ahead of the car, strikes the face of the piston and also engages with it in such manner that the car cannot slip back from the landing platform. After the traction and track-tower sheaves had been erected, a very long rope was carried around the face of the cliff from Thompson's Point to Colt's Point. This rope was then hoisted over the tops of the trees until it could be pulled taut from point to point. A ½-in. wire-rope was pulled across with the aid of a hoisting engine, and then the ⅞-in. traction cable was pulled into place. The traction cable was used to haul the track cables across. The strength of the track cables is 92,000 lb. each, allowing for bending over the sheaves, and the working tension is 20,000 lb., so that the factor of safety is 4·6. The sag of the track cable unloaded is 47 ft. 6 in.; the maximum sag when loaded with car and passengers is 100 ft. The car will still be 148 ft. above the surface of the water at the point of maximum sag. The grade of the track cable varies from 16 per cent. at either landing to level at the centre of the span. The above description has been abridged from the *Canadian Engineer*.

Lancashire Water Schemes.—Both Liverpool and Manchester are now faced with the urgent necessity of undertaking important schemes in connection with their water supply. In both cases there is ample supply, at Vyrnwy and Thirlmere respectively, and the difficulty arises from the fact that the demand is becoming greater than the existing pipe lines can meet. Last year the average daily consumption at Liverpool was 40,000,000 gallons, but this would have been considerably exceeded had it not been for temporary decreases in consumption for sanitary and other public supplies. The existing pipe lines will deliver only 46,000,000 gallons, of which some millions must be deducted on account of repairs and other contingencies, and the reservoirs which must be drawn upon to meet any demand beyond the capacity of the pipe lines are relatively small, holding no more than four days' supply to the district. In these circumstances, despite the Corporation's resolution of some months ago to postpone action in regard to the laying of another pipe line from Vyrnwy, the water department is putting itself into a position of preparedness to undertake the work as soon as the sanction of the City Council and the Local Government Board has been obtained. The plight of Manchester is similar, and initial steps have been taken to construct a fourth pipe line from Thirlmere, a distance from Manchester of ninety-six miles. When the third line was ordered the consumption of water was estimated at 40,000,000 gallons, but it has passed that figure, and for manufacturing as well as general purposes is increasing so rapidly that the necessity of doing something quickly has led to the opening of negotiations with the Local Government Board. The last pipe was estimated to cost the city £832,000, and in its construction 72,000 tons of cast-iron pipe were used. The *Times* is the authority for the above statement.

The Seasoning of Concrete by Calcium Chloride.—Calcium chloride added to the mixing water to an amount of 4 per cent. by weight will increase by large percentages the rapidity with which concrete gains strength. This conclusion has been reached at the United States Bureau of Standards at Washington, in which the effects of various chemicals were studied in an effort to find a good accelerator for hardening concrete. While the time of setting was not materially affected by adding calcium chloride, there was no difficulty experienced in handling the concrete to which it had been added. Standard 1–3 mortar cubes and standard cylinders of 1–2–4 and 1–1½–3 concrete were tested in compression at varying ages up to thirty days. Tests of the 1–3 standard sand mortar show that the rate of hardening is accelerated most by the addition of calcium chloride, which increases the strength at twenty-four hours by from 155 to 230 per cent. and at forty-eight hours by from 173 to 190 per cent. over the strength of mortar containing no calcium chloride. The best percentage of calcium chloride to use for proportions of concrete is from 3 to 4 per cent. of the weight of the mixing water. The increase in strength at forty-eight hours thus obtained varies from 14 to 275 per cent. for the 1–2–4 mix and from 11 to 110 per cent. for the 1–1½–3 mix. In all but one case the concretes mixed with 4 per cent. of calcium chloride show greater strength for both mixes than for plain concrete, these results being consistent, though variable, for all the ages tested, up to thirty days. This acceleration in strength is believed to be due to the more complete hydration of the silicates and aluminates in the setting of the cement. The use of calcium chloride increases the cost of concrete by 2*s.* to 2*s.* 6*d.* per cubic yard. For best results it is important that the concrete be mixed to a quaking, but not fluid, consistency. Calcium chloride should be used with caution for reinforced-concrete construction, as it tends to accelerate any corrosion of the steel which may occur.

United States of America Government Nitrogen Plants.—According to the *Electrical Review and Western Electrician*, Congress has passed a Bill authorising the development of hydro-electrical power for the electrical fixation of nitrogen, which will be used in the manufacture of munitions of war, and thus make the Government independent of imported nitrates for this purpose. The President is authorised to cause an investigation of the

best means for producing nitrates, etc., by water or other power; to obtain exclusive use of any necessary site for the purpose of the Act; and to provide the necessary equipment, etc. Any surplus product may be sold and disposed of, and may be used in the manufacture of fertilisers. The sum of twenty million dollars is appropriated for the scheme, which will be operated solely by the Government, and not in conjunction with any other industries or enterprises carried on by private capital.

GENERAL NOTES.

Newfoundland Cod Fishery.—The prospects of the present season, according to *United Empire*, are as favourable as any in the island's history. The catches made on the Grand Banks have been somewhat above the ordinary, the shore fishers are doing well, while the reports from Labrador are also satisfactory. This is all the more gratifying because the fishermen are assured of good prices for their fish, owing firstly to the small catch made by the Norwegians this year, and secondly to the greatly increased demand for fish in all parts of the world as a result of the interference with normal conditions due to the war. Buyers from Canada, America, and France are now making contracts for supplies of cod, and in addition there is a very promising outlook for the sales of cod-liver oil. The Norwegian cod fishery has yielded this year about 44,000 barrels of oil, as compared with 48,000 last year. In 1915 the stock was bought by Germany, and used to obtain glycerine for explosives. This year it has been purchased by Great Britain and France. The withdrawal of Norwegian oil from commercial circles will offer a great opportunity to Newfoundland, and dealers are now taking steps to cope with the demand. Some 400 licences for the manufacture of medicinal cod-liver oil have been issued in Newfoundland this year under the terms of a new Act which provides for the Government control of this industry with the object of securing the production of an article equal, if not superior, to the Norwegian oil. At present the price of this oil, which used to average about $10 per barrel of twenty gallons, is about $2 a gallon.

Electro-Chemical Industries in South Africa.—The Development of Resources Committee of the South African Institute of Electrical Engineers have issued a report on the possibilities of establishing in South Africa, on a commercial basis, certain electro-chemical industries. At present the two chief industries of the country, agriculture and mining, require annually more than £2,000,000 worth of chemicals, all of which are imported in the form of fertilisers, cyanide, and nitrates. In order to manufacture these substances successfully, the chief essentials are cheap electricity, abundant coal, limestone, and labour, all of which may be had in South Africa. The report then considers the question of manufacturing certain specific compounds, and concludes that they can be made profitably provided the raw materials are obtainable at reasonable rates. The prospects of starting these new industries appear to be promising, and it is hoped that the report may stimulate activity in this direction.

London Fog and Smoke Deposits.—The City of London Medical Officer, in his report for 1915, states that during the year 1914, with the concurrence of the Sanitary Committee—in conjunction with the Committee for the Investigation of Atmospheric Pollution, appointed by the International Exhibition and Conference in London, 1912—a critical examination of the air in the City was commenced. An apparatus consisting of a large rain-gauge was placed in a convenient position upon the roof of the shelter in Golden-lane, and the rainwater from a known area of surface was collected monthly. This rainwater, containing the soot, grit, and dust washed from the air, has been submitted for examination to the Public Analyst and the results tabulated. A table is given showing the rainfall for 1915, and the amounts found of insoluble matter, tar, soot, and dust, also the soluble matter, together with the sulphates, ammonia, and chlorine in the volume collected. The results as given by the Public Analyst have been recalculated into metric tons per square kilometre during the month. One metric ton per square kilometre is equivalent to approximately 9 lb. per acre or 2·56 tons per square mile. In the month of November only the amount of deposit registered as falling in the City amounted to 21·48 metric tons per square kilometre, which is equal (estimating the City as an area of one square mile) to no less than 55 tons avoirdupois. Of this mass of dirt nearly 35 tons were soluble and included the chemicals mentioned, and 20 tons were insoluble and consisted of tar, carbon, and grit. In addition to the foregoing a daily observation has been made at midday at the Guildhall of the purity of the air by a new dry method by which the suspended matter can be readily demonstrated. The amount of the impurity at noon has varied from a trace to three milligrams per cubic metre of air. This includes times when there has been a slight fog, but no dense fog has yet been tested at the Guildhall.

French Helmets.—Over 3,500,000 helmets have now been made for the French army. They are stamped out of the best sheet steel. Each helmet is made up of four pieces—the cap, the peak, the neck-protector, and the crest; and they are riveted together and sprayed with a grey-blue paint, just sufficient to prevent rust. A helmet requires about 2 lb. of steel and a little aluminium to stiffen the lining.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

VIBRATIONS, WAVES AND RESONANCE.

By J. ERSKINE-MURRAY, D.Sc., F.R.S.E., M.I.E.E.

Lecture III.—Delivered May 15th, 1916.

In my last lecture I gave you some concrete examples of waves in ponderable, or ordinary, matter. I am well aware that in a single hour it would have been difficult to describe even any one of them in thorough detail and quite impossible to have gone mathematically into its particular form of motion; hence I have chosen rather to give you these merely as illustrations of the general laws, and have emphasised their similarities instead of dwelling upon their differences. I have followed, in fact, the plan which I laid down in my first lecture, of treating the subject from the point of view of Natural Philosophy, a plan which indicates that before one can usefully employ the symbols and processes of mathematics one must have a clear conception of the phenomena and of their fundamental laws. This was the method of Sir Isaac Newton, whose great propositions, stated in the plainest of language, form the basis of all modern dynamics. It might be well if our modern mathematicians would bear this more constantly in mind in attempting the solution of physical problems.

To-day our subject is Ether Waves, that is to say, the waves which are called electric, and those of light and heat. Owing to necessary restrictions in time of war I am unable to experiment with the longer waves such as are used in radiotelegraphy; but this may, after all, be a blessing in disguise, for, as ether waves travel at an enormous speed and are usually invisible and always inaudible, it is really better that I should have to demonstrate their laws and properties by mechanical illustrations which you can see and appreciate. These illustrations are not mere analogies, but are simply other examples of the same law. When, for instance, I show you the attenuation of a wave, it is in illustration of an important law of wave motion, and not merely of a particular phenomenon in submarine-cable signalling, telephony or fluid motions; the demonstration is, in fact, a moving picture in which the one thing conspicuously obvious is the law under consideration.

I shall not attempt to go into the question of the molecular nature of electricity since it hardly concerns us in a general survey of wave motions, and shall speak of charges of electricity and their conduction as mere facts, without giving an electronic or other explanation. I do not mean to imply that the theory that electricity moves as a number of small discreet particles is untrue, but only that for our purposes the ultimate nature of its structure is unimportant, the mass result being that with which we deal.

Now I must say something which may appear paradoxical but which is nevertheless true. An electric wave is a moving state of stress in the ether which may cause the motion of electricity in a conductor, but is not itself the motion of an electric charge. For some purposes it is convenient to look upon this changing electric stress, or displacement as Clerk-Maxwell called it, as an electric current, but it is not in itself the motion of a charge of electricity; in fact, completely closed moving rings of it may exist in a medium which is wholly non-conducting. There are, therefore, both free electric waves which travel unguided through a non-conductor, and conducted waves which are guided by a conductor. The electric stress is of the same kind in both cases, but the presence of a conductor profoundly modifies the nature of the wave motion. Suppose that we create a series of electric waves, the wave-length being a few metres as in Hertz's experiments. Such waves in uniform free space will travel in straight lines

outwards from the point of origin; but attach them to a conductor and they will follow it even round the convolutions of a coil of wire a few millimetres in diameter. Again attach them to the earth, as at a wireless station, and they will follow its surface over hill and dale and over the waves of the sea. I do not say that a mountain in their path makes no difference, but experience has shown that it in no sense casts as perfect a shadow as it would do if the waves travelled in straight lines, even allowing for the inward bending of the rays usually called diffraction. We must not, however, consider a conducted wave as something essentially different from a free one; it is not, it is just literally a wave conducted, *i.e.* guided by the surface of the conductor.

In the material of the conductor itself the wave has no longer the simple nature it has outside. As it penetrates the surface it generates conduction currents, and energy is used up in driving these. Also the better the conductor the less stiff is the dielectric in it and the smaller the depth to which the waves penetrate. In a good conductor, such as copper, the generation of the current commences very evidently at the outside, and when a constant E.M.F. is applied along the surface it is, comparatively speaking, a long time before the flow becomes uniform, even to a depth of a few centimetres. The process is in reality one of diffusion, not radiation, and the establishment of the steady state of the current is a matter of several seconds. Thus it is that we have what is called the "skin effect," that is to say, the limitation of the major part of an alternating current to the outer layers of a conductor, *i.e.* to those in contact with the dielectric.

It is important that you should realise the fact that the energy in electrical actions travels *viâ* the dielectric or non-conductor. This is quite clear when we are dealing with free radiation, but not so obvious for conducted waves or for the limiting case of an infinitely long wave which we call constant, or direct, current. It has been proved mathematically by the late Professor Poynting, in an investigation which is fundamental to modern theory but which is too elaborate to give you here. Instead, I shall ask you to consider a simple experiment from which the same deduction can logically be drawn. Suppose that I am in a small room with continuous walls of solid copper a foot or more thick in which there is no crack or opening whatever. Outside the room there is a dynamo or other source of electric power; inside it I have an ordinary electric lamp which I wish to light from the power outside. How can I do it? There is no use soldering both terminals of the lamp to points on the inside of the walls and those of the dynamo to points on the outside, for the walls are thick copper and the difference of potential between any two points on the outside, and still more between those on the inside, will, as you know, be utterly infinitesimal. No, if I want to get the energy in there is only one way to do it, and that is to bore a hole through the copper and run an insulated wire through it to the lamp. The material of the insulation is of little consequence, the essential point being that there must be a continuous tube of insulator from the dynamo through the wall to the lamp. This is a direct proof that the energy travels *viâ* the insulator, and it is at once simple and logically convincing.

It is for this reason that the stresses, whether constant or varying, in a dielectric are of such great importance: they are the means by which electrical energy moves from place to place and fulfils its manifold functions; a conductor may guide, but it does not convey and without a dielectric is useless.

A similar law holds in mechanical things. Suppose we have a large pond into which a jet of water is projected horizontally from a pipe at one end. No appreciable energy will reach the far end, even though the flow from the pipe be of considerable velocity. But if instead of allowing the jet to diffuse itself and mingle with the mass of water in the pond we contain it by making it flow through a hollow cylinder of some material which can permanently support an elastic stress—if, in fact, we continue the pipe across the pond—we shall obtain the energy at the far end in almost its full amount. The pipe, or insulator, has conveyed it along its solid walls.

In order to eliminate the mysterious force called gravity, I have supposed the pipe to be horizontal and uniform in diameter; this being so, there can be no steady flow of water in the pipe unless there is a tension in the walls of the pipe, and more than this, there can be no flow unless this stress decreases along the pipe in the direction of flow.

The flow of electric current in a submarine cable has many points in common with that of water in a pipe. The dielectric, for instance, is a hollow cylinder filled with, and surrounded by, a conductor just as the pipe is surrounded by and filled with a fluid, while its thickness and its electrical rigidity, together with the resistance of the conductor in its core, control the amount

of current under any given difference of pressure between its ends in the same way that the flow of water in the pipe is controlled by the rigidity of the walls and the viscosity of the fluid. Indeed, so similar are the phenomena when considered as questions in the flow of energy that it is possible to employ the one as a useful working model of the other.

On this horizontal board I have laid a thin-walled rubber tube of 4 ft. or 5 ft. long; it is filled with a mixture of syrup and water, and you can see a drop hanging from the far end over the bowl. At the near end the tube is fixed on to the jet of a strong syringe, also filled with the same liquid. Now I press the piston of the syringe firmly and raise a bulge in the tube. The swelling creeps along, but not till it comes to the far end of the tube does any liquid run out. Now this is a true picture not only of the flow of electricity in a submarine cable, but also of the flow of water in any level pipe. In it, however, I have chosen the dimensions and materials so that the time factor is, as it were, magnified. Where the bulge takes several seconds to travel along the rubber tube, it would have flashed from end to end of a steel pipe of the same size in a minute fraction of a second; also it would not have been of visible size for steel is so much stiffer than rubber — but it would have happened all the same. In an electric cable of the same length as the tube the motion would have taken place even more rapidly, indeed the tube represents in this respect a cable of several thousand miles in length.

Note that the moving bulge is a true wave or impulse, not merely a mass of material moving forward, and that in fact the liquid which I put into the tube from the syringe remains at this end, and that the movement of any particular drop of liquid is merely a small distance forwards and outwards as the pressure rises behind it. The pressure travels the whole length of the tube, but the liquid only takes one short step. We have, therefore, a true wave or impulse swelling along the tube. To make the phenomenon obvious to those of you who are not close at hand, I have mounted a number of little flags on wires which are attached to the board at their lower ends and lie across the tube. You see that each flag rises as the bulge reaches it, and that it falls again shortly after. Now this model is very like the electrical case. The elasticity of the rubber walls of the tube is the capacity between the core of the cable and the sea water outside it; and the resistance due to the viscosity of the liquid is the electrical resistance of the core. In neither case is the inertia important, as the motion of the liquid is so slow that it is almost completely dependent on resistance of the liquid and elasticity of the tube, while in the cable the only factors of serious importance are the capacity and resistance. To follow the similarity you have only to recollect the picture I made for you in the first lecture, in which I showed the action of a condenser in terms of an elastic solid in which were cavities containing liquid. In this case, however, the solid is not an infinite mass but is merely a hollow cylinder surrounded by, and filled with, liquid. The greater the capacity, *i.e.* the thinner the walls of the tube, the slower does the impulse travel, and increase of resistance, whether fluid or electrical, produces a similar effect.

The frequency of the waves used in cable telegraphy is about ten per second, and, as the time that an impulse takes to travel from Ireland to Newfoundland is a large fraction of a second, there are several waves on their way along an Atlantic cable at one time.

Waves of all sorts gradually die out as they progress through a medium along a conductor, and short ones do so more rapidly than those of greater length. Technically this decrease in size is called attenuation, and when a compound wave travels its shorter components become more rapidly attenuated than the longer ones. Thus, in a telephone conductor the higher harmonic waves which define the vowel or consonant sounds, as I explained to you in the first lecture, are more reduced in proportion than the fundamental wave. The result is that, although a voice may sound quite loud at the far end of a long line, it may have lost its character, and it may be difficult to distinguish between such sounds as "ee" and "oo." This is the reason why as yet telephony has never been carried out through submarine cables of any considerable length, for in a cable the largeness of the capacity, providing, as it were, a shunt circuit to the sea, causes great attenuation. Even in underground cables, such as, for many good reasons, we have in London, the capacity is much greater than between the wires of an overhead circuit, and it is possible that this is one reason why the telephone operators are instructed to roll their "r's" in a triumphant "thr-r-ree," instead of pronouncing them in the ordinary way. One would not naturally expect that "three" and "two" could be confused, as they sometimes are, but when one

considers the wave forms of "ee" and "oo" one understands the reason. The sound "oo" is practically a perfect sine wave, while "ee" is a similar wave with five small ripples on it. If these disappear there is only "oo" left, and "three" becomes very like "two."

Now I shall show you the attenuation of waves and the distortion, or loss of character, of a complex wave as it progresses. Here is a long piece of the light fabric called butter-muslin, with wooden stretchers across its ends, one of which is attached to the picture-rail on the wall. Holding the stretcher at the free end of the muslin in my hands, I pull it gently towards me until the fabric is pulled up almost to a horizontal plane. Now I move the end of the muslin slowly but steadily up and down, and you see large waves travelling slowly along it towards the wall, which they just reach. Next I make the up-and-down motion much more rapid, and although I am actually giving out more energy than I did when making the long ones, the short waves produced die out long before they have traversed the length of the muslin, and indeed are quite imperceptible beyond a distance of a yard or two; thus the attenuation of the short wave is very much greater than that of the long. Here you have the reason why long waves are preferred to short in long-distance telegraphy of all kinds.

If now I send out both types of wave at once by moving my hands up and down with a rapid vibration superposed on a slower one—in what, for want of a better term, I may call a series of jerks—you see that the compound wave which goes along the muslin soon loses the ripples which give it its peculiar character, and long before it reaches the end becomes quite smooth. There you have an explanation of the difficulties of submarine telephony and, indeed, of all long-distance transmission of complex waves. Even in ocean waves the same effect is to be seen when a long, oily wave comes in over a glassy sea without a ripple on it.

There is one way to reduce the attenuation of short waves along a wire or of pulses along a cord, and that is to add inductance or inertia uniformly distributed along it. Each wave then represents a greater quantity of energy, and as the transverse motion is more rapid in a short wave than in a long one of the same amplitude, the energy is proportionately greater in the short wave than in the long one. Hence the short wave is fortified against the attenuating influence of resistance and capacity, and the complex wave travels on with less distortion. For this reason one more easily obtains "harmonics" on the wire-covered strings of a violin or guitar than on the lighter gut strings, and better articulation on a telephone cable loaded with inductance than on one with a single straight conductor. The Channel telephone cable, for instance, has extra coils of wire inserted in it at short equal intervals along it in order to make speech to Paris possible, and the same arrangement is used in some of the very long land lines in America and elsewhere. The distances between the coils must be short as compared with the lengths of the waves transmitted, so as to approximate as nearly as possible to a uniform distribution of inductance. Adding inductance of course reduces the velocity of the wave along the conductor, but as the energy is not seriously decreased this is of much less consequence than the improvement in the clearness of speech.

If a coil of very great inductance is put in series with an alternating current or telephone line, it may almost entirely prevent any current flowing. Large inductance means large storage of energy as magnetic lines of force in the medium surrounding the conductor, and the actual reflection back along the conductor of much of the wave energy. The introduction of a large inductance in a line in which the distributed inductance is small, therefore cuts down an alternating current, just as an increase of resistance would do; hence, in technical parlance, such a coil is usually called a "choker." I can show you the same wave effect on the long-stretched rope, at a point on which I have fixed a 7 lb. weight. I give one end of the rope a vigorous waggle, but although the wave runs rapidly along as far as the weight it gets no further, but returns towards my hand. Here the mass has so great inertia that the force of the wave is not sufficient to set it quickly in motion, and the rope swings over and returns before it has moved appreciably. Thus the wave is reflected and returns to the origin. In the electrical case the wave has not time to overcome the inertia of the choking coil, due to the large amount of magnetic force which has to be built up during even the smallest increase of current, and its energy is therefore also reflected back to the origin.

At first sight this phenomenon would appear to contradict the law that loading the line reduces the attenuation of waves, but it is not so. The difference lies in the distribution of the inertia. If this be added along the whole line or in small lumps commencing near the origin, there being a considerable number of lumps

each wave length, a wave starting with the same energy is more persistent, for its energy is now largely magnetic, and therefore is not wasted but is returned to the current at each half oscillation. A smaller wave current has therefore the same energy as a larger one on an unloaded line, and since it is smaller there is less loss due to resistance, and therefore less attenuation of the wave, as it proceeds.

It is a general rule that when a wave passes from a less dense to a more dense medium, some part of its energy is reflected back into the less dense medium, and that if the difference in density is very great the reflection may be nearly complete. Thus, when a wave travels along the cord to the end which is fixed to the wall, it is almost entirely reflected. There is no doubt a wave of very small amplitude in the wall itself, but, owing to the mass being so great, it is practically negligible. It is also true that when a wave goes from a stiff into a slacker medium, or *vice versâ*, there is partial reflection. If, for instance, I strike one end of a beam with a hammer, the compression wave goes along to the far end and starts a wave in air which you hear as a sound, but a good deal of the energy comes back in the beam to my end, and is again reflected internally. I can tell that this is so from the mere fact that the beam gives out a definite note, which proves the existence of a succession of waves, although I only gave the beam one stroke.

To eliminate the difference of density one might immerse the log in a liquid of its own density but of a different compressibility, which is not difficult to do, and the result would be similar to that in air.

I have lately noticed a curious case of the production of a musical note by reflection which appears to be analogous to that which one gets on clapping one's hands in a room with bare walls. If one is standing on smooth ground while an aeroplane is passing overhead one hears a rough musical note of fairly definite pitch. On bending down, however, the pitch rises, and if one lowers one's head to about half its usual height the note goes up a whole octave. The effect is very curious, and is particularly marked if one keeps on bowing continuously. A similar sound can be heard, though less clearly, under a tree whose leaves are rustling in a breeze. I noticed it first under an aspen in my garden on a quiet afternoon. The explanation seems to be that each impulse reaches the ear twice in quick succession, once while going down and once when rising after reflection from the ground; thus, though the original series of impulses is probably irregular, particularly from the rustling tree, the fact that each gives, as it were, a little double knock to the ear in passing and re-passing, and that the time interval between the knocks of each pair is the same, gives one the sensation of a musical note. It is curious to think that these definite musical tones of the forest, though heard by countless generations, do not appear to have been recognised or recorded, except perhaps in a general way by some nature poets.

Hertz's first experiments on the production of electric waves were complicated by the very same phenomenon. It is known now that when at the outset he thought he was tuning his receiver to the waves from his radiator he was, in fact, tuning to the interval between the direct passage of an impulse, and its return reflected from the wall. The frequency observed was, in fact, like the hum of the aeroplane, dependent on the distance of the receiver from the reflecting surface.

Here I may remind you of one great generalisation made by Clerk-Maxwell from his mathematical investigations of the laws of electricity. Up till the date of his work it was believed that electrical actions travelled at an infinite speed—that is to say, that a disturbance at any point in space produced its results simultaneously at all other points, however distant. Faraday had an idea that this supposition was incorrect, and tried in many ways to show that electric and magnetic actions took time to travel from place to place, but was baffled, as we now know, by the enormous speed with which he was dealing. Clerk-Maxwell, however, showed that the laws which had been proved to govern the motion of electricity indicated that an electric disturbance would travel through space with the speed of light, and that indeed light and radiant heat themselves conformed to the laws which he had proved for electric waves. For a number of years Lord Kelvin was the only scientific man of note who upheld Maxwell's view, and it was not until Hertz had experimentally demonstrated the existence and properties of electrical waves that the true significance of his remarkable deduction was realised by others.

There is an interesting and fundamental phenomenon of wave motion on which I have not yet touched—it is called diffraction. When a procession of sea waves enters a harbour between the ends of the breakwaters, it does not merely go forward like a column of soldiers marching forward in parallel straight lines

through a gate, but on the contrary the outer end of each wave, as it passes through the opening in the wall, curves round, clinging to the inner side of the breakwater, and thus stretching out the wave into a convex curve which sweeps over the whole surface of the harbour even into its most sheltered corners. Of course, the wave is largest in the direct line of its entrance to the harbour and becomes lower and lower as it curves round into the shelter, but there is no discontinuity, merely a tailing-off in size as the wave gets farther from the line in which it entered. The physical explanation of all this is fairly simple if one recollects that what actually takes place at any given point during the passage of a wave is merely an up-and-down vibration, and that the wave is not material in itself and has no property of inertia independent of the local vibrations which constitute it. When, therefore, a wave comes through the entrance to the harbour the vibrations spread not only forwards but in all directions into the smooth waters, for each mass of water moving up and down communicates its motion to the adjacent water on all sides of it.

By a very simple experiment you can convince yourselves that a similar phenomenon takes place when light waves pass through an opening in an opaque material. Close one eye and look with the other through a narrow slit between your fingers at this candle flame. If the slit be fairly wide open you will see the candle as usual, but on pressing the fingers more closely together, and thus making a narrower slit, the flame appears to become broader and broader until it forms a horizontal band of light. Now the candle flame is itself unchanged; the apparent widening must, therefore, be due to an alteration in the direction of the rays entering the eye. The fact is that when a ray of light enters the eye from any given direction we see the source of it in that direction, whether it really is there or not. This widening therefore indicates that the light has spread out fanwise after passing through the slit, that in fact the waves are curving round into the shadows just as the sea waves do on entering a harbour. The same phenomenon is even more obvious with the longer electric waves such as are used in wireless telegraphy, though in this case it is usually complicated by actual conduction along the earth's surface.

Here I must point out that a conductor, in the common sense of the word, is not the only thing which will guide electrical waves; in fact, an insulator will conduct them along its surface if it has higher specific inductive capacity than the medium surrounding it. The truth appears to be that conduction is not primarily due to the fact that in a "conductor" electric current spreads by a process of diffusion in which there is energy dissipated as heat through resistance, but takes place along such a body because its dielectric rigidity is smaller than that of the air or other dielectric outside. If the body be a perfect insulator of finite specific inductive capacity, it will conduct alternate currents or waves only; but if its nature be such that it cannot permanently sustain electric stress it will also conduct a direct current, *i.e.* a wave of infinite length. It is this latter kind of material which is usually called a conductor; but, as you see, it has not an exclusive right to the name. As an illustration of this subject, I may say that in the conduction of electric waves in air along a water surface the large specific inductive capacity of water is actually of greater moment than the property which is usually called its conductivity. It will make this somewhat difficult subject clearer if I define conduction as the guidance of an electric disturbance by an interface between two media of different specific inductive capacity along a desired path which coincides with this interface. A simple instance will show the value of this definition. Suppose two parallel metal plates in air connected to the terminals of a source of alternating current. Now fit a straight rod of glass or other material of high specific inductive capacity from one plate to the other. The dielectric current, which was originally of practically equal density at all points between the plates, will now be much denser along the glass rod than elsewhere, and is in fact "conducted" by the glass rod. That this is so may be seen by twisting the rod into a curve or helix of which the ends are against the metal plates. The helix will still carry a large proportion of the total dielectric current between the plates in spite of its crookedness. It does in fact guide the electric current. You see, therefore, that conduction of electric waves at least is due to difference of electric rigidity, and that materials may conduct although they are perfect insulators.

In the transmission of electric waves through the atmosphere over sea and land, not only do conduction and reflection play their parts, but there is also refraction at work. Refraction is a change in the direction of a wave as it passes obliquely from one medium to another, or through a medium the density of which varies from

place to place. Suppose, for instance, that a medium decreases in density as one goes upwards and that the velocity of a wave of some kind is greater the rarer the medium; then if such a wave crest travels upwards in a sloping direction, the end of the crest which is highest will gradually gain on the other, slewing round so that the crest forms a curve which is concave in the forward direction. The upper part of the wave will now no longer be travelling in the direction in which it set out, but will be moving in a line more nearly horizontal. It will, in fact, have been refracted in its passage through the layers of decreasing density. The same is true when the wave is travelling in the reverse direction, except that of course in this case the front of the wave is convex in its direction of motion since the lower end is retarded.

In the passage of an electric wave over the earth from one wireless station to another all four phenomena occur. It is conducted by the ground or sea, it is diffracted round obstacles, refracted as it passes upwards or downwards through the atmosphere and reflected from the upper layers of the atmosphere. Of all these actions we have now direct evidence based on a large number of careful observations in different parts of the world. In 1906 I showed by deduction from the experiments of Duddell and Taylor that the conductivity of the earth or sea over which the waves passed controlled the amount of energy transmitted to the receiving station. Some years later I deduced the existence of an upper reflecting layer from observations made by observers at the Canadian stations on the Pacific coast. Both deductions have been amply confirmed by more recent observations, among which I must particularly mention those of Dr. C. J. de Groot, Chief Government Wireless Engineer in the Netherlands Indies. Dr. de Groot's results are extraordinarily interesting, and show, among other things, not only a single reflection from the upper atmosphere, but even a second one, signals from a small station having been heard at distances of 3,000 and 6,000 kilometres, though quite inaudible in the intervening spaces, except of course within a couple of hundred kilometres of the sending station. His observations also indicate a bending of the path of the waves as they travel upwards or downwards through the atmosphere, and go a long way towards explaining the curious variations in the strength of signals which occur daily in all latitudes, though more markedly in the tropics.

In the few moments that remain I shall show you a couple of experiments in the shorter waves known as light. The first proves that a coloured surface only shows up in its proper colour if illuminated by light which contains the wave-lengths proper to that colour. Here is a small lamp in which is burning spirits of wine mixed with common salt. It gives out a pure deep yellow light. Look at my face. You see it is now merely different shades of yellow, from a pale colour down to a dark yellowish grey. The red pigment therefore does not change the rate of the yellow vibrations, but simply fails to reflect them and the surface appears dark; it in fact absorbs all other colours but red, which it reflects.

In this other experiment I shall show you the difference between a light in which waves of all lengths are mingled, as sound waves are, in a comprehensive noise, and one in which there are a few definite waves as when one strikes a chord on the piano. On the screen you see three parallel bands of colour, the top and bottom ones showing a continuous gradation from deep red through all the colours of the rainbow to the faint heliotrope beyond the violet. These come from the upper and lower carbons of the arc lamp, and their continuity shows that the complexity of the vibrating particles in a white-hot solid is so great that all wave-lengths are given out. The middle band is the light from the arc itself, and instead of being continuous it is merely a ladder with rungs of brilliant colours, here a deep red line and there two green ones, and farther on there are others less well marked. This light comes from the free particles of hot gas between the carbons, and, as you might expect, their freedom is manifested by the radiation of definite and characteristic vibrations, no longer modified by the constraints of close aggregation as in a solid.

ONTARIO NICKEL MINES.

An interesting account is given, in "Canada the Country of the Twentieth Century," * of the nickel mines of the Sudbury district of Ontario, which are said to be the greatest in the world and to supply over two-thirds of the world's consumption of nickel. The town of Sudbury lies about thirty-five miles north of Georgian Bay. It may be reached from Montreal by a journey of about 440 miles westward on the main line of the Canadian Pacific Railway, or from Toronto by a journey of 260 miles northward on the Canadian Pacific or the Canadian Northern Railway. The nearest

* Published by the authority of the Minister of Trade and Commerce, Ottawa.

nickel mines are about two miles to the north and three miles to the west of the town. The smelting is for the most part carried on at Copper Cliff, a short distance from the town of Sudbury.

The nickel region has sharply defined geological boundaries, all the ore deposits being connected with a single great sheet of eruptive rock, roughly boat-shaped, having its interior filled with sedimentary rocks. The basin is thirty-six miles long, and sixteen miles wide, and the known ore deposits are all either along the edge of the sheet or less than four miles from it. The nickel deposits are not distributed uniformly around the basin. There are rich portions separated by barren intervals. Along a somewhat irregular line of thirty-three miles on the southern margin of the nickel-bearing eruptive rock, seventeen mines have produced ore, and within two or three miles to the south of it ten other mines have been worked. While some of the deposits appear to be pockets, there are a number of extensive bodies of ore. It is believed that the Canadian Copper Company has enough ore in two of its mines to last for sixty years, while there are a number of other mines supposed to contain great quantities of ore. The whole nickel basin includes an area of 550 square miles, divided among twenty-four townships. Mining has taken place in eight of these townships, and important ore deposits are known to exist in several others.

The Sudbury ores are sulphides, containing on an average about 40 per cent. of iron, 3·09 per cent. of nickel, 2·12 per cent. of copper, and small quantities of cobalt, gold, silver, platinum, and palladium. Bessemer nickel copper matte contains from 2½ to 7 oz. of silver, 0·02 to 0·3 oz. of gold, and 0·17 to 0·5 oz. of platinum and palladium per ton.

The iron content of the ore is thrown out and wasted in the smelting process, the aim being to produce a nickel-copper matte suitable for shipment to the refineries in the State of New Jersey and in Wales.

The Sudbury ores all contain large quantities of sulphur, and the first process to which they are subjected is roasting to remove part of the sulphur. They are then smelted in water-jacket furnaces, producing a matte which is resmelted in Bessemer converters, making a matte containing from 75 to 80 per cent. of nickel and copper, of which less than half is copper. In the roasting process the sulphur thrown off is entirely wasted. It destroys all vegetation in the neighbourhood.

In the year 1913 the mine-owners valued the nickel-copper matte as it was shipped abroad for refining at $7,076,945. After refining the nickel alone was valued at $14,903,032, and the copper at over $3,950,000, while the platinum and palladium were worth about $43,800—a total of nearly nineteen million dollars.

Large quantities of Canadian nickel have been used in making nickel steel for armour plate on warships. Nickel steel is also much used in the manufacture of motor-cars. It is coming into use for structural steel in bridge-building, as it has been found that steel containing from 2½ to 3½ per cent. of nickel has greater tensile strength and greater elasticity than the ordinary structural steel. Another alloy of nickel, known as monel metal, contains from 62 to 72 per cent. of nickel, with the balance copper, except for trifling quantities of iron, sulphur and carbon. It can be produced directly from the nickel-copper matte at a cost not greatly exceeding that of copper. It is silver white, takes a brilliant polish, which slowly turns greyish on exposure, melts at 1350° C., has the same specific gravity as copper, and can be cast or rolled and treated in various ways like copper or steel, but is distinctly stronger than ordinary steel or than manganese bronze.

BRITISH COLUMBIA TIMBER.

Some particulars of the principal woods of British Columbia, the Douglas fir, the red cedar, the hemlock, and the British Columbia spruce, given by Mr. H. R. Hamilton, Chief Forester of British Columbia, are quoted in "Canada the Country of the Twentieth Century."

The Douglas fir, of which there are many billion feet now standing, has remarkable strength and elasticity, as shown by the severest tests in competition with other woods, and yet it is 22 per cent. lighter in weight than the next best soft wood structural timber. Its use for general housebuilding, railway cars, packing houses, bridge and trestle work for railways, ships, barges, scows, docks, wooden pipes, and warehouses, where it is subject to moisture, rapid changes in temperature and great stress and strain, have proved its high resistance to decay. The ease with which it absorbs creosote and its natural hardness make it an ideal paving-block material. Sawn edge-grain, it makes a superlative floor, taking a high polish, never splintering, wearing long and evenly. Its strength, ease of working, and cheapness have made it popular in sash and door factories. Its beauty of grain, hard surface, ease of working, resistance to warping, shrinking or swelling, and its ability to take stains and paints, make it especially suitable for finishing.

The British Columbia red cedar reaches a maximum size of 200 ft. in height and 15 ft. in diameter, averaging from 100 to 150 ft. in height and 3 ft. in diameter. It is exceptionally light, weighing 23 lb. to the cubic foot kiln-dried. It is a soft wood of close, straight grain, takes stains and paints and holds them well, while changing conditions of weather, such as heavy rains or snows, with alternating dry, hot weather, do not cause it to warp, twist, or decay. These qualities make it eminently suitable for outside walls, porch roofs, columns or posts, or for construction of lattices, trellises, pergolas, arbours, and summer-houses. It makes a peerless roof, which is cool in summer, warm in winter, will not sweat, leak, or crack, and requires only light supporting framing. Most beautiful effects on both roofs and sides of buildings can

be obtained with fancy-stained shingles. British Columbia red cedar shingles are sawn edge-grain, and for this reason lie flat and will not warp or twist. By wetting shingles twenty-four hours before laying, and using zinc, copper, or galvanised nails, the life of the roof will be doubled. Its durability, suitable taper, great lengths, and its resistance to decay at the ground line, make it ideal for posts, telephone poles, and trolley poles. Its high resistance to weather action, and the long, wide, clear lumber obtainable, make it unequalled for row-boats, canoes, and motor-boats. The beautiful distinctive grain and smooth, high finish of British Columbia red cedar, and the fact that it takes and holds stains so admirably, while it never warps, splits, or twists, and can consequently be used in wide panels, make it an interior finish material second to none where it is not subjected to rough usage. Its odour, so pleasant to human beings, is obnoxious to moths and similar insects, and makes it a desirable lining for closets and store-rooms, and it will not soil or crack like plaster.

British Columbia hemlock is quite different from the eastern hemlock. It is of fine grain, soft, light, and strong. It reaches a maximum height of 200 ft., with a diameter of 5 ft., averaging 130 ft. in height and a diameter of 2 to 3 ft. It weighs 32 lb. per cubic foot, kiln-dried, and has only 12 per cent. less strength than the Douglas fir. It is specially suitable where ease of working, handsome finish, strength, lightness and tastelessness are desired, but needs paint or other preservatives when exposed to the weather. For framing and shelving it serves as well as Douglas fir. It makes an excellent flooring when cut edge-grain and used in dry places. It finishes smoothly on account of uniform texture, and wears evenly. Containing practically no pitch, having a beautiful grain, and taking stains readily, it can be used for inside finish, and when properly dried will not swell or shrink under normal conditions. It presents a comparatively hard surface, and consequently it makes good, cheap box material, but it is not adapted for direct contact with foodstuffs except where dry. It makes good laths, and is commonly used by western farmers for rat and mouse-proof building and receptacles. Exhaustive tests have shown that it is suited for all but the heaviest construction work, and it has been found satisfactory for piling on the British Columbia coast.

The British Columbia spruce is the largest of all the spruces, having a maximum height of 200 ft., with 10 ft. diameter, while it averages, when fully developed, 150 ft. in height, with a diameter of 4 to 5 ft. The weight is 26 lb. per cubic foot, kiln-dried. The wood is white in colour, odourless and tasteless, of rough fibre, does not warp, and is free from resin and pitch. It does not split easily in nailing even when worked to the least possible thickness for the manufacture of boxes, and its light weight gives it a low transportation cost. While not sufficiently strong for heavy structural work, it is well suited for many uses in general building. Its ease of working, light weight, and ability to take and hold nails, particularly adapt it for framing, sheathing, shelving, and sub-flooring. Its whiteness, tastelessness, and freedom from resin and pitch, make it particularly suitable for sink and laundry boards in houses and hotels, refrigerators, and the lining of refrigerator cars, and it is the most popular wood used in the construction of containers for the marketing of food products, such as butter and cheese, lard, meats, fish, berries, dried and canned fruits, and baking products. As a finish material it is soft and easily worked, takes and holds paints well, and has an attractive, cloudy appearance when stained. It is obtainable in large widths and lengths. Being tough, of light weight and sufficient strength, it is used for the manufacture of large doors for garages, freight warehouses, and dock buildings.

THE ROAD BOARD.

The sixth annual report of the Road Board shows that, in spite of the fact that its main source of income—the taxes on road traffic—has been diverted to the National Exchequer, the sum of £135,000 per annum is still left, and this is being laid out on the tar-treatment of the main roads of the country.

The Board is satisfied that "a surface dressing of tar is generally the most effective and cheapest method of preventing disintegration, and thereby prolonging the effective life of a road crust, provided that the surface is in sufficiently good condition to justify the application of the tar dressing."

After the war there will be a great amount of reconstruction work to be done on neglected roads. Just what kind of surface should be adopted in various situations may be settled, in many cases, as a result of the work done on the Road Board's road-testing machine at the National Physical Laboratory, which is described in the report.

The results of the more recent tests afford valuable information to which the attention of road authorities, engineers, and surveyors may be called. In addition to showing that bituminous surfaces, when carefully made and laid, are likely to be durable and economical, the tests appear to throw light on several of the causes of past failures.

The road-testing machine consists of a revolving frame supported on wheels running on a test path. The circular test path is 34 ft. diameter, and has a working width of 2 ft. The road material is laid down on a concrete foundation. On the surface to be tested the machine revolves at any desired speed, but when steel tyres are used, as has hitherto always been the case, this must not exceed seven miles an hour.

The road machine framework is supported by eight wheels, each 3 ft. 3 in. diameter by 3-in. tyre width. Each of these eight wheels is driven by its

own electric motor, so that the action on the test surfaces is nearly the same as that of a driving wheel of a motor lorry loaded to the same weight. In most cases the weight per inch of tyre width has been about 470 lb., but during the consolidation stage this has been sometimes increased to 750 lb.

The test surface may be kept either perfectly dry, or it may be sprayed to any desired degree of wetness, and as wetted surfaces can be tested to destruction sooner than when the track is kept dry, the wet test has now become the standard of comparison. During a wet test the whole of the material worn off by attrition can be collected and weighed, and thus the loss of material from actual wear can be accurately measured. The temperature of the test-room may be maintained at any desired point between that of the summer and winter seasons, and as bituminous materials soften and show the least resistance to deformation during the summer months, a temperature approaching that of summer has generally been maintained.

The tests are now carried out in the following manner: A manufacturer of road material or a road authority desiring to have his material tested sends about three tons of it ready mixed, in a motor waggon, so covered and protected from loss of heat that it can be delivered at a sufficiently high temperature, which is usually from 300° to 330° F., to be soft and plastic enough to be properly laid and finished. The hot material is filled into the track, then levelled by raking to the depth required to consolidate it to a finished carpet 1½ inches thick; the consolidation is then carried out by rolling it with the machine, or by hand rolling, or by tamping, as makers prefer.

At the time the track is laid, test samples are made in separate moulds and preserved for reference. The machine is then started and run on the new surface with a gradually increasing load, until about 4,000 to 6,000 tons per yard of width have rolled over it—this is called the consolidation period.

The test proper then commences—the machine is run at a load of 470 lb. per inch of width and at a rate of about 2,200 tons per yard of width per hour; the running hours are about eight per day, the track being kept wet all the time. The condition of the track is observed twice a day or oftener, and any defects which may appear are entered on the test sheets. The material worn off by attrition is collected as mud, dried and weighed. In most cases with good material a well-laid surface remains smooth and polished and but slightly marked until about 200,000 tons per yard of width have rolled over the track. Generally about this stage wave-like markings begin to appear. These gradually extend themselves until at 400,000 tons the surface becomes considerably waved, so that the vibration caused and communicated to the machine and building is excessive, and the test is then considered complete. Plaster casts are then taken to record the shape and the condition of the road surface—usually one of these is taken at the worst point where the surface is most waved, and another at the point where it is smoothest. Test pieces are cut out and their density compared with the first set of samples, so that the increase of density during the test can be recorded.

This appears to be a mode of testing which in some respects affords a more accurate means of comparison of certain qualities of road material than is possible when the material to be tested is laid in the open, exposed to the varying conditions of moisture and varying temperature of our climate and to irregularity of traffic, for these varying conditions render accurate comparisons difficult, so that the comparisons which can be made between the materials tested are necessarily uncertain and largely a matter of individual opinion.

RHODESIAN TRADE.

In the course of a paper on "The Development of Rhodesia from a Geographical Standpoint," which appears in the October number of the *Geographical Journal*, Mr. H. Wilson Fox makes some interesting remarks on the character of the European population of the country and the extent of its trade. "The settled areas in Southern Rhodesia," he says, "have a European population now exceeding 30,000 persons. In Northern Rhodesia the European population is only about 2,000, while settlement has been practically confined to three centres in the vicinity respectively of Livingstone, Lusaka, and Fort Jameson.

"Of this population I need only say on the present occasion that they are of the stuff of which empire-makers are made, and that they have always exhibited those virile qualities of courage and endurance without which the special difficulties of a new country cannot be overcome. The numbers of this population are at present small, some 32,000 in all, men, women, and children; but the results to which it has contributed are so striking as to require for their proper understanding a right appreciation of the part played by Europeans in what are primarily native territories, where the part of the European is, broadly speaking, to organise and supervise labour. Let me give you some figures. The total exports of Rhodesia during the ten years ended December 31st, 1914, represented a value of £25,928,481, and the corresponding value for imports is £30,484,384, showing a total trade during that period only of £56,412,865. The high-water figure was reached in the year preceding the war, when the exports from Rhodesia (North and South) amounted to about £4,500,000, and the imports to about £3,500,000, giving a total trade of approximately £8,000,000. A very important fact is that of this total trade at least £6,000,000 took place with Great Britain. Is it not very remarkable that the effect of establishing 32,000 persons in this new territory should have given rise in so short a time to a trade of such dimensions? You will perhaps think it even more remarkable when I tell you that the

annual value of the total trade of Great Britain with Germany before the war was about £130,000,000, or only about twenty times as large. Has not this fact a most important bearing on the real value to Great Britain of its territories overseas? On the one hand 30,000 of our own race give us a trade of about £200 annually per head of European population, while 70,000,000 Germans give us only £2 per head. Much of their trade, too, has been deliberately designed to injure us. Facts like these afford much food for reflection. They confirm the view which I have long held, that the chief value to Great Britain of its tropical and semi-tropical possessions is not that they supply an outlet for surplus population, but that they provide the trade which enables an increased number of our people to live at home."

THE OIL-SHALE FIELDS OF NORFOLK.

In a paper on "The Norfolk Oil-Shales," which was read before the Institution of Petroleum Technologists on October 17th, Mr. William Forbes-Leslie drew attention to the possibilities of a very important and comparatively little known oil-bearing district.

There is little doubt, he said, that a large oil-shale basin exists in Norfolk. The evidence for such belief rests upon an analysis of the structure of the east of England when brought into alignment with known tectonic conditions within the area. Its geographical extent has not yet been completely demonstrated, although its visible geological features have been traced for many miles north and south, and for considerable distances on the dip. The possibility of the Kimmeridge series being cut off against the edge of the chalk has not been lost sight of, but all research work in this direction goes to prove that the Kimmeridge beds dip underneath the chalk. No signs of faulting, such as cuts the Kimmeridge beds, and brings them against the chalk at Ridgeway, in Dorset, can be observed in the eastern section of the Wormegay basin. The boring at Holkham, 743 ft. deep, is said to have terminated in Kimmeridge clay, although another version makes it terminate in Lower Greensand. Nevertheless, adjacent and available data lead to a belief in the permanence of the Kimmeridge beds, beneath and seaward of the chalk shore line at Holkham and Hunstanton.

With a proved thickness of 6 ft. of oil-shale in Smith's series, and 6 ft. in the Puny Drain series, or a total of 12 ft., every acre of ground should yield something like 24,000 tons of shale, and half a square mile may be considered as providing for a 1,000 ton output per day for twenty years.

But with every indication that this estimate will be quadrupled or more, and with a possible extension of the basin very far beyond its present indefinite limits, it is obvious that the oil contents of the Norfolk end of the Kimmeridge outcrop will add very considerably to the oil resources of the United Kingdom.

Such a conclusion, which is borne out by careful examination of all authentic data, and by patient and laborious research in the field, implies that England is not so entirely destitute of oil resources as many people suppose. In the near future, the oil-fields of the Kimmeridge outcrop may be supplying a considerable bulk of the oil and petrol consumed in this country, and will enable the large amount of gold sent abroad every year to pay for foreign oil to be considerably reduced. This in itself is a matter of great importance from the view of national finance. The whole question of the English Kimmeridge measures demands investigation, for where one great productive basin exists in the south extremity of the Kimmeridge outcrop, and another great basin at the other, there is no adequate reason yet presented why there should not be other large productive basins in existence between these two geological terminals.

It is a national question. Private individuals have done much to demonstrate great deposits of oil in specific parts of these measures. The State, through the exigencies of war, is approaching that communal ideal when it may be called the mother of its citizens. Let it deal therefore with this most important economic question, the question of an internal supply of oil fuel, which more and more tends to underlie industrial efficiency, military and naval power, and might in the immediate future of the race comprehend even the basis of national existence.

RATTAN FURNITURE INDUSTRY IN HONG-KONG.

In reference to the note on this industry published in the *Journal* of August 11th, the following details regarding the processes used in preparing the canes for the industry may be of interest.

The sorting, cleaning, grading, and stripping of the canes is not done for the most part in Hong-Kong, but at villages in the neighbourhood of Canton, where labour is cheaper. The rattan must be thoroughly dried before treatment. After this is done the processes used may be summarised as follows:—

First the nodules, or bases of the leaf spathes, are pared off by women and girls, using knives fashioned like old files sharpened on one long edge. Next the rattan is sorted for sizes and grades. Those of certain diameters are taken out to be stripped for the cane and reed. Large pieces suitable for framework are specially imported in long bundles, undoubled. The rattan is then immersed in a vat containing water and sand. Some of the latter is picked up with a handful of wet coir (coconut husk), and this, when rubbed vigorously lengthwise over the surface, removes all foreign substances and brings out the real colour of the skin. Finally

if the rattan is stripped, unless it is intended to be used whole, the cane removed is bleached. If not stripped, it is bleached immediately after washing. This process is carried out in wooden boxes rather taller than a man and about 10 ft. wide, with two tiers of doors across the front. A quantity of sulphur is ignited in the bottom, and the rattan subjected to the fumes for about twenty-four hours. In stripping, the cane is removed by hand with a heavy clasp knife. It is gauged for thickness and width by drawing it between two vertical knives placed close together. The reed may then be split into as many strips as desired, the latter being rounded by drawing through holes in a sheet of iron. No machinery whatever is employed.

Five or six grades of the cane are recognised for most purposes. The first is of an even straw colour and thoroughly flexible; the second and third are less perfect in these respects, while the others lack an even colour and are little used for furniture, though suitable for binding purposes. The classification of the peel depends also on its flexibility and the evenness of its colour, and on the extent to which it has been cleaned. The care with which this grading is carried out marks an important difference between the handling of rattan in Hong-Kong and in the Philippines, and the indiscriminate sorting in bundles which is usual in the latter place forms undoubtedly an obstacle to the development of the industry there. Another obstacle in the Philippines appears to be the non-employment of suitable methods of washing and of any bleaching process, for without these no satisfactory classification based on the colour —and this is the most important of all—can be made.

The best demand is said to be for furniture covered with the reed, and next for the sea-grass product, while that for the types covered with cane is rather small. The principal export markets are the United States and South Africa, but a great deal of furniture is also sold in the China coast cities and in the various British possessions in Asia.

THE DRUGS AND SPICES OF SIAM.

Among the crude drugs produced in Siam is the well-known gum benzoin, a resinous exudation of a tree similar to *Styrax benzoin* of Sumatra. The Siam benzoin is gathered in the most northern forest regions of the country, and is highly esteemed for its delicate perfume, being used locally in the preparation of toilet waters and incenses, and in foreign countries chiefly for preparing compound balsamic tinctures. During the fiscal year ended March 31st, 1915, 52,251 lb. of crude benzoin, valued at £5,658, were available for export (against 17,824 lb., value £2,409, for the previous year), and the shipments were destined for the United Kingdom, Germany, Singapore, and Indo-China.

Gamboge is a yellow resin obtained from *Garcinia hanburii*, a tree which grows in the eastern Siamese Lau Provinces, and is used locally in the preparation of a golden-yellow ink, but abroad for medicinal purposes. Its export for 1914-15 amounted to 33,811 lb., valued at £2,353, as compared with 36,307 lb., value £2,664, for 1913-14, the United States, United Kingdom, Germany, France, Hong-Kong, and Singapore being the purchasers.

Cutch, the bark of *Acacia catechu*, or *Nauclea gambier*, is used medicinally and as a substitute for the areca nut in betel chewing, and also for tanning purposes. The export of cutch is confined to Oriental ports, and for last year amounted to 9,709 lb., valued at £46, against 21,729 lb., valued at £115, for 1913-14.

The cardamom classified as "best" in the Customs list and cultivated in the eastern provinces of Siam is the fruit of *Amomum xanthioides* and galanga, and is used by the natives in the preparation of curry, and is also employed for medicinal purposes. The amount available for export in 1914-15 was 4,595 lb., valued at £547, as compared with 32,577 lb., valued at £4,683, for 1913-14.

Another variety of cardamom, known as the "bastard," grows in eastern and northern Siam and is the fruit of *Amomum villosum*. This cardamom is used exclusively for medicine, and of this 33,886 lb., valued at £612, were shipped to Hong-Kong in 1914-15, against 235,200 lb., valued at £4,260, to that port and Singapore in the previous year.

Pepper is extensively grown in the province of Chantabun and in the Siamese Malay Peninsula and the amount available for export during 1914-15 was 3,283,780 lb., valued at £77,890, as compared with 2,568,813 lb., valued at £64,602, for the previous year. The bulk of the pepper exports go to the United Kingdom and the United States, the former taking 1,050,152 and the latter 770,670 lb. in 1914-15.

According to a report by the United States Vice-Consul at Bangkok, a number of other products of Siam's jungles and fields besides those mentioned above may also be had in quantities for export, namely, the wild cinnamon (*Cinnamomum silvestre*) of northern Siam; nutmeg (*Myristica fragrans*) from the province of Puket; cloves, ginger, tamarind, anise, liquorice, turmeric, til or sesame seed (*Sesamum indicum*), exported to Europe, and the oil extracted therefrom, said to be used for adulterating olive oil and for soap-making, but locally the oil is used medicinally; niger seeds (*Guizotia abyssinica*), which are used for the same purpose as sesame seeds; lotus seeds, which are mainly used for food during a scarcity of rice; arachis or groundnut, which is abundant in Siam, and the oil of which is used medicinally, for preparation of perfumes and cosmetics; pungtalal or jelly fruit (*Sterculia scaphigera*), which has a decidedly mucilaginous character, and is used locally in the preparation of cooling and medicinal drinks and for making jellies.

ARTS AND CRAFTS.

THE ARTS AND CRAFTS EXHIBITION AT BURLINGTON HOUSE (FIRST NOTICE).

An Arts and Craft Exhibition at Burlington House marks an epoch in the history of the Arts and Crafts movement. When the first exhibition was held in 1888, people did indeed talk of the possibility of craftwork being shown some day at the Academy, but the most hopeful of them only looked forward to its inclusion in the summer exhibition. A special exhibition, opened by the President of the Royal Academy, was beyond their wildest dreams. It says a great deal for the energy and enthusiasm of the members of the Arts and Crafts Exhibition Society, and still more for their foresight, that they have been willing to undertake so large an enterprise at the present time, when not only are many of the artists and craftsmen turned for the nonce into soldiers and sailors, but the difficulties of labour are almost insuperable. In spite of all this, Mr. Wilson and his committee have embarked upon an exhibition on a really grand scale. The walls of many of the rooms are decorated with paintings by well-known artists; the large room has been altered almost out of all knowledge; the sculpture room is turned into a group of small chapels adorned in various ways; and parts of several of the other galleries have been partitioned off, and decorated and furnished to represent bedrooms, a nursery, and the like—and all this without interfering unduly with the display of such objects as do not easily fit into such schemes of decoration.

The first room is devoted almost entirely to works by Morris, Crane (the two first presidents), Philip Webb, and Burne-Jones, and special rooms are set aside for jewellery and small metalwork, writing and book production, pottery, etc. The work was not completed by the opening day and the catalogue has not yet appeared, so that it is only possible at present to notice the exhibition in its main outlines; but enough is completed to show, what those who had seen the British Arts and Crafts section at Ghent suspected, that Mr. Wilson is a real genius in the conception and arrangement of exhibitions of this kind. There is only one respect in which the result seems somewhat disappointing. It has been said repeatedly that the justification for holding an exhibition of Arts and Crafts just now is the desire to show what English artists can do and to help British manufacturers to realise that, if they will but use the artists, they will in the future be able to meet with greater success foreign commercial competition. Still, in spite of the interesting little show arranged by the Art and Industries Association, consisting entirely of pottery produced under ordinary trade conditions, the present exhibition has, at first sight at any rate, very little bearing on this problem. One can imagine a manufacturer going round the galleries and remarking, "All this is very beautiful, but where do I come in?" On the other hand, there is evidently an abundance of excellent craftwork, and in the eyes of the ordinary visitor that will more than make up for any deficiency in exhibits more closely connected with industry and trade.

CORRESPONDENCE.

PINEAPPLE INDUSTRY IN THE AZORES.

I have read with interest the very excellent article in the *Journal of the Royal Society of Arts*, dated June 23rd, 1916, upon the question of pine-growing in the Azores. The writer is quite right in pointing out that these markets are now over-supplied with Azorean pines, but this is not only due to over-production but to the fact that the Continental markets—and chiefly Hamburg, which, according to the article, took 65 per cent. of the products—are now cut off.

The facts disclosed in the article in no way affect the question of production and sale of the South African pine. The latter, from a commercial point of view, is an entirely different article: it is about a third or half the size of the Azorean pine, its outward appearance is not so nice, but it is of better flavour, and on account of its small size and good colour it is better canning fruit; it can be produced for one-tenth of the price, and sold at 4*s*. per dozen landed here against 2*s*. 6*d*. each for Azorean pines.

For these reasons it appeals to a different section of the trade, and is a far more commercial article.

The following section of the article is of particular interest to me:—

> "When the production reached 50,000 cases annually, or 600,000 pineapples, fancy pineapple stock still brought 6*s*. to 8*s*. each in the London market. To-day, when the production is more than 2,300,000, the producers are obtaining only 6*d*. to 1*s*. 9*d*. each for their fruit."

Imagine 600,000 pines being sold at 6*s*. to 8*s*. each! I would like to get an order to supply 600,000 *dozen* of South African pines at less than that per dozen. The writer of the article complains that the producers are now obtaining only 6*d*. to 1*s*. 9*d*. each for their pines; well, the producers of South African pines will be very happy to get that price *per dozen* for their pines on their farms, and would produce millions of dozens at that price.

CHAS. P. CHIAPPINI,
Trades Commissioner.

Government of the Union of South Africa.
Trades Commissioner's Department,

GENERAL NOTES.

PAPER FROM HENEQUEN BY-PRODUCTS.—According to a report by the United States Commercial Agent at Vera Cruz, a machine has been invented for obtaining paper-pulp stock from henequen stalks and waste. The inventor, a Mr. George Taylor, states that he had been experimenting with henequen for two years for the purpose of obtaining a paper stock that would be equal in quality to that known to the trade as "kraft" stock, to be used in the manufacture of wrapping paper and paper bags. After he had obtained a pulp from henequen that met his requirements in every particular, he constructed a small experimental paper-making machine and produced a paper that was equal to, if not slightly better than, the paper manufactured from imported kraft stock, and that could be produced and marketed at a price considerably lower than that quoted for kraft paper. Several American manufacturers of paper bags and wrapping paper appointed one of their number to investigate the matter, and he accompanied Mr. Taylor to Yucatan to witness a practical demonstration of the new process in the field. This demonstration was held, and it was shown that the samples produced in the field were in every respect equal to the samples previously submitted by Mr. Taylor. As a result, a company has been organised to build and operate a pulp mill, which will have a capacity of 30 tons daily.

CHICLE INDUSTRY OF MEXICO.—Chicle is obtained by tapping the sapodilla (*Acras sapota*) trees, which grow wild in the forests of the State of Vera Cruz. The industry is controlled almost entirely by the Huasteca Indians, who sell the chicle in the markets of Tuxpam and Tampico. From two to four trees are generally found on an area of one acre of average virgin forest land in the Tuxpam district. In certain districts in the States of Campeche and Yucatan the average is much higher. The trees should be from twelve to fifteen years old before being tapped for the first time, and even then, unless great care is exercised by the tapper, they will die. It is said that the Indians, who use a machete, kill about 25 per cent. of the trees they tap. The trees in the Tuxpam district average from 1 lb. to 1¾ lb. of commercial chicle at each tapping; but they should be tapped only once a year, the best time being the winter months. According to a report by the United States Vice-Consul at Tampico, land containing sapodilla trees can be obtained in the vicinity of Tuxpam, but labour is expensive on account of the development of the oil industry. At present, however, owing to the depreciated currency, good Mexican labour can be secured for 1s. a day. During the year 1915, 347,815 lb. of chicle, valued at $57,728 (U.S.), equivalent to about £11,860, were shipped from Tampico to New York. Most of the chicle exported from Tampico is produced in the Tuxpam district.

COTTON IN UGANDA.—According to the annual report of the Department of Agriculture, Uganda, the cotton crop for 1914–15 was the highest on record, amounting to about 18,000,000 lb. The quantities exported were 107,139 cwt. of ginned cotton, valued at £320,486, and 30,188 cwt. of unginned cotton valued at £33,660, while the cotton seed exported amounted to 180,334 cwt., valued at £18,172. In consequence of the war, during a part of the period under review there was no market for the cotton, and the growers were unable to provide adequate storage accommodation. The result was disastrous, as many cotton plantations were neglected; in some cases the cotton was actually destroyed, as the planters despaired of being able to sell it. The area under cotton in the period 1914–15 was over 100,000 acres, of which more than three-quarters was in the Eastern Province.

PAPAYA PEPSIN IN THE PHILIPPINES.—It appears, from a report by the correspondent at Manila of the United States Department of Commerce, that an effort is being made to develop in the Philippine Islands an industry in the dried juice of the papaya (*Carica papaya*) for medicinal use as a substitute for pepsin. The preparation of this product is represented by the Bureau of Health officials, who are endeavouring to stimulate its production, as very simple. The fruit is hung above a bowl, and longitudinal cuts are made in the fruit from which the juice drips, hardening soon after it falls into the bowl. After being thoroughly dried in the sun it is put in sealed cartons for shipment. Papayas may be grown in almost every part of the islands. The native variety is small compared with the Hawaiian variety, which has been introduced and is now grown extensively for the table.

CLOTHING FOR THE BRITISH ARMY.—Some remarkable figures are quoted by the *Textile Mercury* showing the enormous quantities of goods ordered between August, 1914, and March 31st, 1916, for clothing the British army. Of woollen and worsted cloths the total was 117,000,000 yards, or sixty-one times the established peace average. Of flannel there were 84,000,000 yards, or enough in twelve months for forty-one years by old reckonings. Of cotton cloth of various kinds the total was 194,000,000 yards, or 175 times the average. 19,800,000 blankets had been placed on order, and 54,500,000 pairs of socks, 23,000,000 drawers, 8,750,000 vests, and 7,500,000 cardigans and jerseys.

FRIDAY, OCTOBER 27, 1916.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICE.

EXAMINATIONS.

The results of the 1916 Examinations have now been published in a pamphlet of 124 pages, folio, which can be obtained at the Society's offices, price 1*s*., or by post 1*s*. 3*d*.

Copies have been sent to all examination centres.

The results had previously been communicated to all the candidates.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

VIBRATIONS, WAVES AND RESONANCE.

By J. Erskine-Murray, D.Sc., F.R.S.E., M.I.E.E.

Lecture IV.—Delivered May 22nd, 1916.

In my earlier lectures I have given you many instances of the generation of waves by the vibration of a fixed oscillator; I come now to the converse process, namely, the conversion of the energy of a stream of waves into the vibration of an oscillator on which they impinge. It is here that the principle of resonance becomes of such immense value, for if it were not possible to absorb and store a small increment of energy from each wave as it comes along, adding them all up until the resultant vibration of the receiver becomes of appreciable magnitude, wireless telegraphy and telephony would be extremely limited in range and utility, and such achievements as the transmission of speech from Washington to Honolulu and the Eiffel Tower would not have been possible.

Here is a simple experiment which illustrates this action mechanically. This long lath, fixed vertically in a vice, and having an adjustable weight on it, is connected to a point on a long rope stretched across the room by an india-rubber band. I waggle the rope so as to cause a wave to travel forwards and backwards from end to end, and as each wave passes a small jerk is given to the rubber cord and thus to the lath. If the position of the weight on the lath is such that these impulses come just in time with its natural vibration it commences to vibrate, and as the impulses succeed one another the vibration becomes more and more energetic. If now I alter the height of the weight so that the rate of vibration no longer is the same as that of the incoming waves, the lath no longer gains in energy of motion but merely gives, from time to time, a few irregular movements of very small amplitude. The effect of tuning the receiver to the waves received is thus made manifest.

When we come to mechanical vibrations which are sufficiently rapid to be appreciated as sound, many striking demonstrations of resonance are possible. Have you ever thought why "intoning" is so commonly practised in large churches, and why the clergyman who strikes the right note can make his voice carry so much further than one who does not? It is simply a question of resonance. In one case advantage is taken of a natural rate of vibration of the mass of air in the part of the building where he stands; in the other there is no resonance, and instead of the radiation of sound waves from the whole mass of air from floor to roof there are only those which come direct from the mouth of the speaker. One can get the same effect very easily in any room of which the floor is bare, and in which there is but little furniture. Sing a slowly ascending scale, passing gradually from low to high without intervals, and you will find, if the room be bare enough, that at a certain pitch the sound swells out without effort on your part, and even the faintest note uttered of this pitch seems to fill the room and lasts long after you have ceased

to sing. Higher or lower notes are dead in tone by comparison and do not give the same satisfying sensation. On that note your voice was in tune with the natural vibration of the air in the room, and every vibration of your vocal chords added to the wave in the air just at the moment which helped it most.

Other experiments we have in plenty. Here, for instance, are two tuning-forks of the same pitch or rate of vibration. I sound one with the bow, and after holding it near the other for a short time I stop it vibrating. You can hear that the other has taken up the vibration and is now going. For those of you who are further off I have arranged this large glass bead on a thread which just rests against the side of the second fork. If I repeat the experiment, you see the bead begin to jump outwards from the fork and hear it clicking against it as it falls back and is thrown off again. I now put a small cap of lead on one of the prongs of the second fork, lowering its pitch a note or so as you see when I bow it. Again I try to make it resonate, but this time there is no sound and the bead no longer jumps. The forks now are out of tune.

The resonance of a column of air is well shown by holding a vibrating fork over this jar, which I gradually fill with water. As the water reaches a certain level the sound swells out and dies away again as more water is put in. There is thus a certain length of air column corresponding to each note, and the note is that which would be given out if the column of air were that of an organ pipe. These pear-shaped brass vessels in my hand have been made of such size and shape that the air in one of them resonates to this large fork, and that in the other to the small one. If I sound both forks while you put one of the resonators to your ear you notice that the sound of the corresponding fork appears to have become much louder. The amount of sound entering your ear has indeed become greater, for the resonator absorbs much more energy from the air waves than your unaided ear would do, for the simple reason that its natural rate of vibration is such that each wave arriving applies force in the direction in which the air is moving at the instant, and thus energy is absorbed in the most favourable circumstances.

There are, of course, air waves so slow that they are inaudible and others so fast that they also cannot be heard. At one time I lived near a deep railway cutting, so deep that but little was heard of the trains as they passed. Every now and then, however, the glass door of the verandah would commence to rattle slowly, a crescendo clack, clack, clack—about four clacks per second; then it died away. On listening outside one could hear that a train had just left the station and that the puff, puff, puff was now going faster than the door could vibrate. Each puff had been a long and almost inaudible wave, and as their rate increased it had for a short time coincided with the natural vibration of the door. Sir Hiram Maxim has written a pamphlet on the bat in which he discusses the use of the rose-like frills of skin which form so distinctive a feature of the faces of so many bats. These he suggests are organs for the detection of long air waves such as must be produced by the bat's own wings, and are therefore useful in enabling the animal to recognise the presence of trees and buildings through the waves reflected from them. The suggestion seems a reasonable one, and there is no doubt that the small vertical tongue which stands at the entrance to the bat's outer ear must have a frequency of vibration of the same order as the flapping of its wings, and should, therefore, be sensitive to the waves produced by them. Be this as it may, there is no doubt that there must be many inaudible "sounds" in the atmosphere which we could appreciate if only we had properly tuned receivers.

The use of tuned or monotone telephones, *i.e.* of telephone receivers which have very definite rates of vibration and therefore respond only to one note, has made it possible to send quite a large number of telegraphic messages simultaneously over the same line. At the transmitter a number of tuning-forks act as interrupters of the current, and each sends a steady stream of impulses over the line when its particular telegraphic key is pressed down. At the receiving end only that telephone sounds which is tuned to the fork used at the transmitter; and even if several messages are being sent at once on the different keys there is no confusion, for each receiver gets only the signals sent by the fork to which it is tuned. A system of this kind, invented by MM. Mercadier and Magunna, is in use in France and elsewhere, which, in addition to utility, forms a fine example of what can be done by resonance when there is perfect synchronism of the vibrator and resonator.

An interesting application of the same principle is in use by the Clyde Lighthouse Trust at Roseneath and Fort Matilda, near Greenock. The problem there was to start a light or an acetylene fog-gun by wireless control from a

station a few miles away. It was solved by controlling the transmitter by means of a pendulum so that it sends out an impulse at each beat of the pendulum, while at the receiver there is a similar pendulum which gets gradually into motion as each impulse, received by the wireless set and converted into a direct magnetic pull on the pendulum, adds its quotum of energy to those which have previously arrived. Finally, when the pendulum has got a large enough swing on, it makes an electrical contact and fires the gun.

Although the energy transmitted in the two cases just described is electrical the resonating arrangements are purely mechanical, and depend on the proper adjustment of the vibrations of masses of matter. In electrical resonance the result is obtained by proper choice of the electrical constants of the circuits concerned, and if—as is almost invariably the case—both circuits can oscillate freely, by the equalisation of their natural rates of vibration.

Here is an electrical oscillating circuit. I cannot energise it for fear of disturbing the Admiralty wireless station, but I can tell you how it acts. It is, as you see, very simple—merely a piece of wire with a plate on each end. To give it more inductance, *i.e.* to add to its inertia, it is usually coiled up into a helix or spiral, thus. This increases the magnetic energy of the current. To add to the capacity, and therefore increase the charge and energy for a given difference of potential, the flattened ends or plates are brought near to one another so that there is only a thin wall of dielectric between them. These processes also diminish the frequency and increase the length of the wave given out, the wave length being proportional to the square root of the product of capacity into inductance. If the plates are close together there is but little radiation from the circuit; for the purpose of radiating energy, therefore, as in wireless, instead of being comparatively small plates close together they are made very large, and are as far apart as is conveniently practicable, the upper one being the aerial wires and the lower the earth itself. We can thus obtain a circuit which, though tunable to a definite frequency, will also radiate a certain proportion of the energy of each oscillation in it.

Here I may note that although it is quite properly called a circuit, no electrical oscillator is a complete *metallic* circuit; it must have in it a section where energy is stored potentially, as well as one in which the storage is kinetic. The potential or static storage takes place in the dielectric between the plates and the kinetic in the medium surrounding the conductor during the passage of the current, and these, of course, take place alternately, first one and then the other. Its frequency of oscillation can thus be adjusted by variation of either inductance or capacity, or both.

This apparatus on the table is an electric circuit containing a small electric lamp, a condenser and a variable inductance in series; it is coupled electromagnetically to the alternating current supply from a central station. You see that by varying the inductance, and therefore the natural rate of oscillation of the circuit, I can find a point at which the lamp lights up brightly, although for neighbouring values of the inductance it is quite dark. The brightness, of course, indicates a large current through the lamp, and therefore shows that for this value of the capacity and inductance the circuit is in resonance with the alternating current of the supply.

In a wireless station the transmitter, as a rule, contains two circuits in resonance, the primary and the aerial, and often the low-frequency circuits are also tuned. The receiver has two tuned circuits at least, the aerial to the aerial of the transmitting station, and to one or more local circuits on the detector side. Resonance thus plays a very important part in wireless; its advantages are two in number: it enables one to work with a long train of waves of comparatively low voltage and still receive a considerable amount of energy, and at the same time ensures that waves which are not of the proper frequency do not actuate the receiver unless they are overpoweringly energetic. The simultaneous working of a number of stations in the same area is thus rendered possible and the range of transmission is increased.

Photo-chemical effects, including ordinary and colour photography and many other phenomena, are probably due to the resonance of molecules to light waves, a vibration being built up in the molecule which grows until the agitation is so great as to overcome attractions. The absorption of certain colours by certain pigments and coloured glasses and, in fact, all colouring in nature and in art, almost certainly depend directly or indirectly upon the same principle of resonance. If time permitted I would show you some of the beautiful demonstrations which are possible, but as it is I must content myself with showing you, before we part, a couple of experiments which summarise, in a simple way, some of the more important points in these lectures.

Stretched tightly across the room you see this cord, and hanging from it, near each end, a pair of vibrators, each just a spiral spring with a weight attached. I start this pair in motion and you notice that one bobs up and down more rapidly than the other; the weight is smaller or the spring stiffer. At the other end the vibrators have been carefully adjusted to have the same frequencies as these. Note the effect when I start one at this end, the slow one for instance. Almost immediately the slow one at the other end commences to move up and down and after a few swings is going strongly. The other keeps almost quite still. The vibration having ceased, I start the quick one, and immediately the corresponding one at the other end commences. Each answers only to the timed impulses sent along the cord by that which is "in tune" with it. Now I start both vibrators and both those at the other end respond. I alter the rates of vibration of either pair by adding or subtracting weights, and now, beyond a few feeble and erratic waggles, there is no response at all.

Here is the demonstration in a slightly different and even more interesting form. Over each end of this long watertrough two vibrators are suspended from firm supports. As before, they are in pairs, a rapid and a slow one at each end. The weights are partially submerged in the water, and if I move one up and down it sends out waves which you can see travelling along the trough. In a few moments you see the corresponding vibrator at the other end begin to move, and as before each is actuated only by the one of its own frequency. If both are started both respond, and if the frequency of either is altered there is no response.

Here, then, we have a vibration producing a series of waves, and, if there is a vibrator whose frequency is that of the incoming waves, an absorption of energy by resonance. We have also a proof that if the vibrator is not tuned to these waves the energy is not absorbed. Again, there is the proof that two sets of waves can co-exist in the same medium without mutual destruction, for when both vibrators at one end were started both those at the other answered to them and the only connection between them was the water, on whose surface both waves must therefore have existed simultaneously. In like manner we can see how two or more pairs of wireless stations can be worked independently and without interference in the same district; and how, as in Squier's "wired-wireless" system, a message in high-frequency currents can be signalled along a wire on which a telephone conversation is going on, without either set of waves interfering in the slightest degree with the other, indeed without the one message being even perceptible in the instrument used in receiving the other.

To the many and strange actions with which we have dealt, I must add the suggestion of another. When two particles, one positively and one negatively charged, revolve round one another they give out an electric wave whose period is that of their revolution. Thus there is reason to suppose that the waves of light, each a very small fraction of a millimetre in length, given out by a molecule of heated gas may originate in this way. Now the sun is probably positively charged while the earth is negative, and the one revolves round the other in a year; so, radiating from our system through interstellar space there are probably electric waves whose period is a year. Think of the length of them. They travel at three hundred thousand kilometres a second and each wave is a whole year long. Three hundred thousand times the seconds in a year is its length in kilometres. I leave the calculation to yourselves.

THE UNIVERSITIES OF LEEDS AND SHEFFIELD AND THE TECHNICAL PRESS.

Last May an invitation was given to the Circle of Scientific, Technical and Trade Journalists to visit the Imperial College of Science. A similar step was recently taken by the Universities of Leeds and Sheffield, which invited the Circle to form a party to visit these cities, as the guests of the Universities, on October 8th to 10th.

On arrival at Leeds the party, about twenty-five in number, were received by the Vice-Chancellor of Leeds University, Professor M. E. Sadler, and made welcome by representatives of the local press, and on the following day they proceeded to the University, where an inspiring address was delivered by Professor Sadler. The visitors were then conducted through the various departments of the University, and had an opportunity of seeing some of the valuable work carried out, much of it bearing directly on the local industries of Leeds. Since the outbreak of war many drugs previously only obtainable from abroad have been produced in the University, which is also acting in co-operation with National Dyes, Ltd. The section of the University devoted to textile work and dyes is stated to be unique in Western Europe, and the relations with local industries are close and cordial. As an instance of this recognition of the work of the University the visitors were shown the special research laboratory erected by

the leather industries as a tribute to the work of Professor Procter, the head of this department, on behalf of the leather trade. In this department, apart from the experiments constantly being conducted on processes involved in the manufacture and testing of leather, useful work on culture media for bacteria, on colloids and other subjects is constantly going on.

The visitors were subsequently entertained to lunch by the Leeds Luncheon Club, where an address on "India and the Empire" was delivered by Mr. H. A. L. Fisher (Vice-Chancellor of Sheffield University), and the Chairman said a few words in welcome to the party, for whom Mr. A. J. Mundella (Chairman of the London District of the Institute of Journalists) responded.

The afternoon was devoted to visits to several local factories concerned in the manufacture of boots and khaki garments for the Army—these industries being selected as being specially associated with the work of the University. Afterwards the party were entertained to tea by the Lord Mayor, leaving for Sheffield in the evening.

Here another excellent programme was arranged, the visitors being received and addressed by the Vice-Chancellor of the University, who explained that, although among the youngest of the leading educational institutions in this country, Sheffield University is already doing most useful scientific work. After passing through the chemical and medical departments an account of the work carried on in the department devoted to metallurgy was given by Dr. Ripper, the Dean of the Applied Science Section. Much of this work is closely associated with the war and is conducted by the University for various Government departments. It is interesting to notice that the University has been made the centre for meetings of the local Committee on Munitions. Over 1,000 students have been trained for munition work in the great Sheffield armament works. While the work of this department is chiefly associated with the production and testing of iron and steel, a non-ferrous department has recently been added, which has carried out useful researches on the production of cupro-nickel. In addition to this, many experiments have been conducted on problems arising in local metal industries since the outbreak of war. Two enterprising steps have also been recently taken by the University—the formation of a lectureship in Russian, and the organisation of a new department to investigate glass technology, the latter with the support of the Yorkshire Glass Association.

During the remainder of the day visits were paid to the works of Messrs. John Brown & Co., and of Messrs. Thos. Firth & Sons, where the operations are on a gigantic scale. Lunch was taken at the former works, where, in the unavoidable absence of the Master Cutler, an address was given by the general works manager and director, Mr. A. W. Dixon. Mr. Dixon emphasised the fact that Sheffield steel firms are fully alive to the benefits of applied science, and added that the provision of hygienic conditions for the workers received their constant care. Mr. Gilbert Wood and Mr. L. Gaster (Chairman of the Circle) replied for the visitors.

The visitors were deeply impressed by the evidence presented of a growing appreciation of the value of scientific methods in these two cities and the general recognition, on the part of manufacturers, of the good work the Universities are doing—a recognition that promises well for the industrial development of Leeds and Sheffield.

THE STRAW HATS AND BRAIDS OF TUSCANY.

The manufacture of straw hats and braids on a commercial scale is a comparatively modern industry in Florence, being slightly over one hundred years old. The growing of the fine thin straw that must be used is an industry peculiar to this part of Italy. Attempts have been made to grow it in other parts of the world, particularly Japan; but, although care was taken to get the proper seed and to plant it in soil similar to that in which the straw is grown in the Florence district, the results up to the present have been unsatisfactory.

From a report by the United States Consul at Florence it appears that the seed, which is obtained in the Apennine Mountains, between Bologna and Florence, is sown in the hill country which lies between Lastra-a-Segno and Empoli. The ground is prepared to a slight depth and the seed broadcasted by hand on the surface, where it is left uncovered to sprout. The thicker the seed is sown the more spindling the straw grows. The sowing is done in November and in May.

Just as the seed is coming into milk the entire plant, roots and all, is pulled from the ground. The stalks are laid out on the field to dry in the sun and turned from time to time. After this drying process is completed the crop is stacked or housed. During the autumn and winter the top joint, including the seed, is pulled out by hand, the remainder of the stalk, including the root, being kept by the farmer for his own use. The top joints are then gathered together and the seed part is carefully cut off. This is also put aside by the farmer and is used for reseeding or for feeding. That part of the top joint which remains is then cut into two sections, the upper, called "punta," being one-half or two-thirds the length of the lower, called "pedal."

The "punta" and "pedal" straws are then separately bunched and brought to the market, where they are purchased by manufacturers through "fattorini" (agents), or, in many cases, by the "fattorini" themselves. In order to get straws or

strands of a size they are sorted by a machine, the meshes of which are so arranged that by passing the bunched straws over the meshes those of the same size fall in the same bin. "Punta" and "pedal" straws are sorted separately. From the "punta" straws the fine so-called Leghorn hats are made; the "pedal" straws are made into what are known as Milan braids.

Leghorn braids are composed of nine, eleven, or thirteen strands, the braids being from one-eighth to nine-thirty-seconds of an inch in width, and 82 to 131 ft. in length. In general it may be said that the length is governed by the size of hat as determined by fashion experts. If the style calls for very large hats, it is sometimes necessary to splice two braids much in the same way as ropes are spliced. Milan braids are composed of five or seven strands, the braids being from one-fourth to one-half an inch wide, and of length to suit the size of hat wanted.

"Truciolo" straw is made into braids at Carpi, a town near Modena. These braids are employed for "chip" hats. The material used is not straw at all, although it is sometimes known as "rice straw." Great numbers of white poplar trees are grown in the River Po region in the Provinces of Reggio Emilia and Ferrara especially for the manufacture of this "straw." Four or five years after planting the trees are felled. All straight trunks and branches are cut into lengths of 20 to 24 in., the bark removed, and the piece squared and planed. The pieces are then passed through a special machine that cuts them into strands of any desired width and thickness. Three of these strands are used to plait a braid. The braids can be coloured or bleached to any desired shade.

Carpi has become renowned for "truciolo" braids, and besides utilising the home supply of poplar, its manufacturers import poplar and willow in 48-in. pieces from Bohemia and Russia. Although occasionally whole pieces are imported, it is more usual to import the strands. Bohemian "truciolo" straw is of a brighter colour, and has a more satiny finish; it is used for making women's hats. In the past, exportations of braids and hats were very heavy, but of late years, not only have fashions changed, but Japanese braids have cut heavily into the trade with the United States. Children's chip hats are still worn, and exports are confined almost entirely to goods adapted for such use. A three-strand braid is plaited from rushes or osiers, but this is seldom in demand.

Braids are also made of hemp imported from the Philippines. Although the Florence district produces great quantities of the fibre, the strands of Italian hemp are not considered strong enough to use in making hat braids. Hemp braids are also imported from Japan, and the hats are made in Florence. "Neapolitan" or horsehair hats are not made in the Florence district; these come from Canton Aargau, in Switzerland, and the hair used is either Swiss or Austrian. Depending upon the whim of fashion, braids are also made of twisted straw, of mixed straw and hemp, and of mixed straw and chip.

Generations of Tuscan women have braided straw, and seem to do the work mechanically. They are wonderfully deft, never looking at the strands, braiding while talking or walking or while carrying bundles upon their heads. Braid-making furnishes an occupation to thousands of women and girls and is a home industry, to be taken up or put down as circumstances require. The Italian peasant woman is never idle. The work is paid for by the piece, and earnings range from 4*d.* to 1*s.* 8*d.* per day, the latter amount being for the most expert workers.

In making Leghorn hats the braid is sewn edge to edge with straw of the same size. The braid used in making Milan hats is intended to be lapped. The projecting rough straw ends in the Leghorn plateaux are removed by rubbing two plateaux together. Before being made up the braids are bleached by means of a chemical wash.

The hats known as "Mountain," "Casentino," and "Marche" are all of the same kind; but these are made of straw after the thrashing has been done, only the first joint from the top being used. The braids are sewn together without lapping, just as Leghorns are made. They are really rough Leghorns except that the entire first joint of the straw is used as one piece, and is not cut into "punta" and "pedal" straws.

The United States offers the most extensive and best market. Many of the plateaux are blocked into hats in Florence, where this trade has passed down from father to son. While the plateaux are supposed to be of the same size when ready to be blocked, the sizes are, as a matter of fact, somewhat irregular. Florentine blockers are used to this and make the proper allowances; but in New York blockers find these slight irregularities a source of annoyance and trouble.

The value of straw hats and braids exported from Florence to the United States during 1910 was £241,000; in 1911, £230,000; in 1912, £254,000: in 1913, £178,000; and in 1914, £203,000.

The number of women and girls available for hat and braid work has been considerably reduced because of the higher pay that can be obtained in making clothes and uniforms for army contractors. As a consequence, hat and braid workers are scarce, and prices show a rising tendency. So, too, the cost of bleaching braids has risen 75 per cent., as chemicals can no longer be obtained from Germany.

THE VEGETABLE DYES OF INDIA.

Since the outbreak of the war in Europe investigations have been carried on in India jointly by the Departments of Industries in Mysore and Madras with a view to determining to what extent the present shortage of synthetic dyes could be made good by reverting to the natural dyestuffs of vegetable origin that were formerly employed.

The work has been carried out mainly in the laboratories of the Applied Chemistry Department of the Indian Institute of Science, and with Professor Sudborough have been associated Dr. H. E. Watson and Dr. F. Marsden, the tinctorial expert of the Government of Madras.

Dr. Marsden's report has recently been submitted to his Government, and is reproduced in the official *Indian Trade Journal*. The materials dealt with in the investigation included chay root, nunà, ventilago bark, *Rubia cordifolia*, red sanders wood, sappan wood, cutch, divi-divi and other tannin materials, annatto, kapila, lac and *Wrightia tinctoria* leaves. Concerning annatto, Dr. Marsden says :—

"The dye obtained from Jabara seeds was tested upon bleached mercerised cotton, upon which it gives a pleasing rich orange shade. The method of dyeing is simple, consisting in working the yarn in a warm alkaline bath made by extracting the dye from the dried seeds with water, and then adding a little carbonate of soda or potash. The dyeing is finished by giving a weak bath of acid and rinsing.

"It is generally assumed that the shades given by annatto are not fast; but I find that the fastness properties are equal to those of many of the bright aniline dyes which have been so largely used here, and there is no reason why, if the shade is liked, the material should not find a more extended use upon silk and cotton materials in which brightness of colour is a consideration."

THE WILD SAGE OF THE ADRIATIC.

Sage (Salvia) is an indigenous perennial shrub, growing in profusion on the mountains and hills in Croatia, Dalmatia, and the islands of Veglia and Cherso, in the Quarnero Gulf. The same species is said to grow naturally from Spain along the Mediterranean coast to and including the east side of the Adriatic. It is found mostly where there is a limestone formation with very little soil, but seems to grow in all kinds of places. Some of the barren hills in the region of Fiume have very little vegetation other than this wild sage. Its leaves are used in pharmacy, and its technical name is *Salvia officinalis*.

In appearance the wild sage is much like the common garden sage, although more shrubby in appearance. It generally grows to a height of 2 ft. and has narrow greenish-grey wrinkled leaves and purple flowers, variegated with shades of red and blue, that appear in whorls on stems, rather short and bushy in appearance, but tapering slightly towards the top. It has a more penetrating odour and is more bitter, spicy, and astringent than the cultivated plant.

This wild sage, says the United States Consul at Fiume, is the kind that is exported from the Adriatic region. It is chiefly gathered for that purpose in Dalmatia and on the islands, where the people do not have as many other sources of revenue and employment as in other districts of this region, where it grows naturally. Trieste is the centre of the export trade. A comparatively small amount is exported at any time from Fiume.

The best kind, it is stated, grows near Malinska, on the Island of Veglia, where the surrounding district is known as the sage region. There it is gathered before blooming, and by cutting the stem rather than pulling the plant up by the roots, as is the practice in some parts.

While wild sage seems very plentiful in the vicinity of Fiume, the business of gathering it commercially has not been taken up except on the near-by islands of Cherso and Veglia. During its blooming season the bees gather the nectar, and genuine sage honey commands the highest price, owing to its flavour.

In the region where this sage grows its leaves are boiled in vinegar and used as a tonic. A decoction is also made from it for darkening the hair. It is used more as a domestic remedy than by physicians. As a home remedy it has many reputed uses. It is given in the form of a tea for night-sweating and diarrhœa, and is used as a gargle for bleeding gums, catarrh, and to prevent an excessive flow of saliva. The oil is used for removing heavy collections of mucus in the respiratory organs. Its fresh leaves are used as a tooth wash, and it is a common ingredient in tooth powders. The dry leaves are used for smoking as a remedy for asthma. The domestic consumption accounts for a very small proportion of the crop, as it is gathered chiefly for export.

The leaves are harvested from May to September, but those plucked in midsummer are considered the best. The general opinion is that it should be gathered before the bloom opens, but the Austrian Pharmacopœia says it is best when gathered during bloom.

The only treatment given to the leaves intended for export is drying. They are separated from the sticks and stems, and are generally spread on shelves in the peasants' cottages and left until they are thoroughly dry, as any dampness proves injurious through heating and fermentation. Some of the more prosperous pickers have frames made with a galvanised-iron wire netting or screen bottom. The leaves are placed in these frames to a depth of about 3 in., and the frames are stacked one above the other and left until the drying is complete. Most of the pickers use shelves as first mentioned, being too poor to purchase the screen-bottomed frames. The leaves must not have sunlight while being dried, hence drying is done in the cottages of the pickers. There is no systematic gathering, as it is only done by people who do not have a more profitable use for their time.

When thoroughly dried the woolly, hairy dust of the leaves is removed by sifting. It is estimated that 9 lb. of fresh leaves produce 2 lb. of the dried herb. After drying, the leaves are sorted and generally pressed into bales of 100 to 300 kilog. (220 to 660 lb.) and bound with iron bands.

Three classes are recognised by the trade of Fiume: (*a*) large leaves that keep their shape and their green colour; (*b*) small leaves that curl and pulverise, losing their natural colour (if these are not dried in masses, but are spread out thin enough to prevent heating they become silvery); and (*c*) medium size and quality leaves prepared by the same process. The dry leaves should be kept in practically air-tight receptacles to preserve their strength. Those having a silvery-grey appearance are considered the best.

An essential oil is obtained by steam distillation of the fresh leaves, producing from 1·3 to 2·5 per cent. of oil.

The price of sage has advanced about 300 per cent. because of inability to get it. Large quantities were formerly sent to Germany, whence a good deal was shipped to Great Britain and the United States.

The wild sage of this region should not be confused with the other wild sages of Southern Europe and the Orient. *Salvia sclaria* (muscatelle sage) is a two-year growth in Southern Europe and in the Orient. It is often cultivated in gardens and appears wild in some places. Its plant and leaves are said to be added to wine to give it a muscatelle taste. Fermented with sugar and yeast it produces "clary wine."

Salvia pomifera is a shrub which grows in Greece and in Syria, with oval, notched, greyish, felt-like leaves, wave-like at the edges, and with flowers white spotted on the underside lip. As a result of stings of wasps, it produces round fleshy grey growths, about 5 centimetres in diameter, which are reputed to have a pleasant spicy taste. The stalks with leaves and flowers are used to make a tea, said to be popular in Greece.

COMPRESSIVE STRENGTH OF MORTARS AND CONCRETES.

A publication has been issued by the United States Bureau of Standards on the "Compressive Strength of Portland Cement, Mortars and Concretes" which will be of interest to contractors and engineers and, in fact, to all users of cement.

Concrete differs from most structural materials in that it is not manufactured at a mill or plant according to chemical formula, under the observation of skilled specialists, subject to rigid inspection and test, and such control as to produce a uniformly homogeneous product; nor is the process of manufacture completed in a few hours or days as in the case of steel products. Furthermore, concrete is made from materials obtained from sources differing widely in characteristics which affect its quality. The proportions of the ingredients, the amount of water used in mixing, the thoroughness of mixing, the manner of placing, the atmospheric temperature and humidity, exposure to sun, rain and wind, immersion in fresh water, sea water, or other natural solutions, all affect the quality of the concrete. All these matters are discussed in the Bureau's publication, which contains the results of some 20,000 tests. The general effect of variation in the methods of preparing the concrete is shown, and suggestions are given as to the proper methods to follow in order to obtain the best quality of concrete.

The paper states that certain generally accepted methods of testing aggregates and proportioning mixtures are incorrect, and suggests methods of selecting concrete aggregates, proportioning the mixture, mixing, placing, and curing. Copies of the publication, Technologic Paper No. 58, may be obtained free upon request to the Bureau of Standards, Washington, D.C.

MANUFACTURE OF BAR-LE-DUC JELLY.

Bar-le-Duc jellies and jams take their name from the town of Bar-le-Duc, capital of the Department of Meuse, which specialises in their manufacture. They are prepared with currants specially chosen on account of their size, but which are not produced by any particular variety of currant bush. The following outline of the method of preparation, contained in a report by the United States Consul in Paris, may be of interest:—

During the month of July each year trained workers receive from the factories quantities of currants, which they take home for the purpose of removing the seeds. In this process the berry is held in the fingers of one hand and the seeds are removed by means of a goose-quill sharpened to a fine point. The work is exceedingly difficult and requires considerable dexterity acquired by long practice. As soon as the currants are returned to the factory, sugar is added and the fruit cooked. The quantity of sugar used is much greater than in ordinary jams and jellies, owing to the fact that the jelly boils for only a short time in order to avoid the oversoftening of the berries. (Softening would cause them to lose their attractive appearance, which is the speciality of the Bar-le-Duc product, the whole berry being seen through the glass jar.) When prepared, the jelly is placed in small pots closed with a metal cap, and the pots are placed in boiling water to ensure the keeping qualities of the product. As Bar-le-Duc jelly is prepared chiefly for the export trade, this latter is essential.

Five firms at Bar-le-Duc manufacture jelly in normal times. It is doubtful whether the jelly is now being made, owing to the fact that the district is in close proximity to the firing line, and that many, if not most, of the civilians have left the region.

French statistics do not show the quantity of this jelly exported, but, upon examination of the total exports of jams prepared either with sugar or honey, it is found that the French export trade has decreased but little since the war, 1,005 tons of such jams having been exported in 1915, as compared with 1,025 tons in 1914 and 1,132 tons in 1913.

ENGINEERING NOTES.

Mechanical Milking.—The *Daily Telegraph* intimates that much saving would be effected by the extension of this process. On an up-to-date farm in Herefordshire a milking machine, in charge of one man, deals with seventy cows, which, were hand-milking in vogue, would require at least five expert milkers. The plant includes a vacuum pump driven by a 1½ h.p. motor, and connected by pipes to the milking machines that are placed in the cows' stalls. The machinery has a capacity for dealing with eighty-eight cows, the cost of operation being but a mere fraction of the wages of the men who would otherwise be employed. There need be no milk famine and no requests to the tribunals for the exemption of milkers, if only farmers would adopt the mechanical process. It is one that has everything to recommend it. Apart from reducing the cost of milk, the use of this plant tends to give cleaner milk since human hands and clothes do not come in contact with the animals, whilst if electricity is used for lighting the further possibility of contamination of the milk through the paraffin lanterns usually employed is avoided. A divisional traffic superintendent of the Great Western Railway has stated that the general adoption of mechanical milking would be the means of helping the railway companies out of a difficulty for which, up to the present time, no solution has been found. The question of acceleration of railway traffic in the early mornings really necessitates earlier milk trains—a proposal that has met with strong opposition from agricultural districts, as the farmers are unable to get the milk conveyed any earlier to the stations owing to the dislike of the farm hands to start milking operations before the usual hour. The general adoption of milking machinery, driven either by electricity or by an internal combustion engine, would enable milking to be carried out at the same time all the year round, no matter how many cows were kept, thus easing the railway companies' early morning traffic problem, besides giving many more men to the Army, and reducing the cost of one of the chief necessities of life.

Hydro-electric Power in Spain.—According to recently compiled statistics, the United States Consul-General Hurst at Barcelona reports the hydraulic power available in Spain is estimated at over 5,000,000 h.p. There are 110 large hydro-electric plants exploiting a total power of 281,490 h.p. and a large number of small plants; so that the whole amount of power in use may be reasonably estimated at 300,000 h.p. This total will probably be increased to 500,000 during 1916, when important installations are expected to be completed. The total potential horse-power controlled by the 110 large enterprises referred to is 1,020,790, and consequently 739,300 of their total power remains to be developed. Independent of this amount, numerous paper, spinning, and flour mills, and other manufacturing plants are run by water power not transformed into electricity. In Catalonia, North-Eastern Spain, the textile industries alone use some 200,000 h.p., about one-half of which is natural water power. The estimated power of the streams of the Pyrenees running through Catalonia amounts to 1,135,000 h.p., and the concessions have been granted for the exploitation of only 800,000 h.p. The water power of the rivers of Spain has been estimated as capable of producing horse-power as follows: Ebro and affluents, 1,300,000; Duero, 900,000; Guadalquiver, 750,000; Tajo, 700,000; Guadiano, 370,000; Mino, 250,000; Jucar, 190,000; Segura and affluents, 100,000; and others, 600,000; making a total of 5,160,000 h.p.

Influence of Hours of Work on Output of Munitions.—There is an interesting remark on this subject included in the report by the Committee of the Ministry of Munitions by Dr. H. M. Vernon referring to the health of workers. Experiments covering a considerable period fully justify the recommendation previously made by the Committee that the hours of work should not exceed sixty-five to sixty-seven hours for men and sixty hours for women; in many cases even a smaller number of hours per week would give the best results. Some striking examples of the effect of continued fatigue in diminishing output are recorded. Thus, in the case of some youths of fourteen to seventeen years, working on steel base plugs, a rise of 16 per cent. in hourly output took place after the Christmas holidays, and subsequently, when the hours of labour were reduced from 70·3 to 57·0, an increase of 42 per cent. was obtained. Thus, in spite of the diminution in the number of hours worked, an increase in total output of about 19 per cent. was reached. These and other results show that it is possible to be engaged for longer hours and yet do less work.

Docks for American Battleships.—The *Times* says that the new construction programme of the United States Navy Board, involving the expenditure of over £63,000,000 for new battleships and battle-cruisers, has, as might have been anticipated, brought with it the need for undertaking additional dry dock construction. It is well known that it was only the limitations imposed by wet and dry dock accommodation which, in days when merchant shipbuilding was pursuing a normal course, prevented the design and construction of yet larger ships than the huge liners which were put in service shortly before the war. The same considerations limit the increase in the size of battleships, which under the conditions of naval warfare must

have behind them at easily accessible points ample graving dock accommodation. In the case of the United States, the proposals which have been put forward for these facilities have been affected by the fact that the possibility of making the passage through the Panama Canal cannot under existing conditions be relied upon at all times. If for this reason, as some assert, the United States must provide both an Atlantic and a Pacific Fleet, it is equally certain that dry docks must be available on both seaboards. The scheme put forward includes the provision of several docks each of 1,000 ft. or more in length, one in the Hawaiian area, one in conjunction with a commercial enterprise on the Pacific coast near San Francisco, and a third at a point south of Hatteras on the Atlantic seaboard, while the fourth would be furnished by the enlargement of an existing dock. The decision to co-operate with commercial interests is significant, and it may be recalled that similar proposals, by which privately owned dry docks at British ports would have been enlarged to battleship dimensions in consideration of a financial undertaking by the Government, were not in past years favourably received by the Admiralty.

Fire Resistance of Reinforced Concrete.—A report has been issued by Mr. F. J. T. Stewart, the chairman of the Executive Committee of the National Fire Protection Association of the United States, on the fire which occurred at the Edison Phonograph Works, West Orange, New Jersey, in December, 1914. This is said to be the first time that a fire of great severity and wide area in buildings of reinforced concrete has been under careful technical observation. The ordinary brick, frame, and corrugated iron-clad frame buildings involved in the fire were mostly totally destroyed with their contents. But as regards the reinforced concrete buildings the panel walls withstood the fire excellently, and there was no case of individual collapse of a floor slab, beam, or girder, except in the basement of one building, where concrete and reinforcement were apparently melted away, causing failure of three beams and a floor slab. All other failures, including the complete collapse of a portion of one building, are attributable to the columns, the action of which was not so satisfactory as that of the other concrete members. All of them, except in one building, were square and reinforced by twisted bars placed at the four corners 2 in. to 4 in. below the surface. The conclusion is drawn that square reinforced concrete columns are not adapted to resist severe fire, and that these columns, together with variations in design or construction from present-day practice, must be held accountable for a large part of the structural injury produced. The complete absence of fire walls and other fire-resisting construction, coupled with inadequate fire-extinguishing apparatus, permitted large buildings to burn freely throughout, thus subjecting every portion of the concrete to long-continued severe heat, which produced excessive expansion stresses. The collapse of the columns is directly attributed to these expansion stresses, and it is pointed out that severe structural damage is liable to occur whenever buildings of this type of construction, with large unbroken areas filled with combustible material, are allowed to burn unhampered.

A Novel Gas Turbine.—In a recent issue of *Power* there was a description of the following combination introduced by the Detroit Gas Turbine Corporation. Its principle of operation consists in compressing a charge of the mixture, firing it at constant volume in an explosion chamber, which results in a very high pressure, and allowing the products of combustion to impinge on a series of moving and stationary blades. The arrangement shown consists of eight radial gas-compressor cylinders, which compress the gas mixture to about 90 lb. per square inch prior to its discharge into firing chambers round the periphery of the turbine, from which the products of combustion at high pressure impinge on two rows of moving blades separated by a row of stationary blades. The moving blades are carried on the outer casing, which revolves about the driving shaft on ball bearings, and is geared to the shaft through a three to one reduction, giving a shaft speed of 3,000 revolutions per minute, which corresponds to 24,000 explosions a minute. The rotor diameter for a 200 h.p. turbine is said to be 21 in. and the weight 335 lb.

The Motor Ship "Peru," with her two Sister Vessels.—In spite of the submarine menace, the motor ship "Peru," launched recently at Copenhagen by Messrs. Burmeister and Wain, has started on her maiden voyage to South Africa and Australia. These sister vessels—the "Peru," "Colombia" and "Chile"—have a length between perpendiculars of 425 ft., a beam of 55 ft., and a depth of 30 ft. 6 in., and a draught of 26 ft. 5 in. Their dead-weight capacity is 9,500 tons. Their propelling machinery consists of two six-cylinder Diesel engines, driving twin screws. The engines are designed to develop a total of 3,100 h.p. at 125 revolutions, and to give the ships a speed of 11·15 knots. The great difference which may characterise the performances of two sister ships, engines, or machines has often been remarked upon, and is well illustrated in the case of the "Peru" and the "Chile." On her trial trip the "Chile" engines, running at 136 revolutions, developed 3,318 indicated horse-power, and gave the ship a speed of 11·39 knots. The "Peru" on her trial trip developed 3,685 indicated horse-power at 139·3 revolutions, and showed a speed of 12·74 knots. The consumption of fuel oil on the

"Chile" was 147·6 grammes per indicated horse-power hour, and on the "Peru" 144·8 grammes. It is to be noted that the trial trip of the "Chile" was run during very cold weather, and that, as her bronze propellors were not ready in time for the trip, cast-iron screws were used in their place. Even so, the difference of 1¼ knots in the speed of the two vessels is remarkable.

Hong-Kong Harbour Works.—According to the report of the Governor of Hong-Kong for last year, the Mongkoktsui breakwater and contingent works were completed. The breakwater is 3,325 ft. in length, and encloses an area of 165 acres. Entrances to the refuge are provided at both ends of it, the southern one being 390 ft. in width and the northern 300 ft. The work also comprised a concrete and masonry pier, 450 ft. long by 30 ft. wide, and a reclamation extending over a rocky shoal near the northern entrance. The reclamation has an area of 187,000 sq. ft., and is protected partly by a pitched slope and partly by a concrete and masonry sea-wall. A short pier-head projects from the reclamation. The depth of water at the entrances at l.w.o.s.t. is 18 ft. The depth within the shelter varies from 9 ft. to 18 ft., 82 per cent. of the enclosed area having a depth exceeding 12 ft. at l.w.o.s.t. and 56 per cent. of depth exceeding 15 ft. The breakwater consists of a rubble mound 192 ft. wide at the base and 20 ft. at the top, with a height of 44 ft. Above low-water mark it is faced with concrete blocks on the outer side and coursed-granite pitching on the inner. The top is paved with concrete blocks. Before the rubble was deposited a trench with an average depth of 9 ft. was dredged in the harbour bottom for the whole length and width of the base of the breakwater. The rubble mound is composed of stones varying in weight from ½ cwt. to 5 tons, the total quantity deposited being about 850,000 tons. In all 12,453 concrete blocks, weighing two tons each, were used in the work, 11,379 being pitching and paving blocks, and the remainder principally foot-blocks for the inner slope. The foot-blocks for the heads of the breakwater are of granite encased in concrete, and are much heavier, weighing over five tons each. The foot-blocks for the outer slope are wholly of granite and weigh 3½ tons each. The granite pitching stones for the inner slope average half a ton in weight, 17,098 being used.

OBITUARY.

SIR JOSEPH BEECHAM, BT.—Sir Joseph Beecham, who was elected a Fellow of the Royal Society of Arts in 1913, died suddenly at his residence in Hampstead on October 23rd.

He was born in 1848, and in 1866 he joined his father, the late Thomas Beecham, the founder of the well-known firm of pill manufacturers. He claimed to be the greatest newspaper advertiser in the world, his yearly expenditure in this direction amounting to upwards of £100,000. Apart from his business interests, he was devoted to philanthropy and music. He and his son, Sir Thomas Beecham, were responsible for many operatic enterprises in London and the provinces, and for the season of Russian opera at Drury Lane, in recognition of which the Czar conferred on him the Order of St. Stanislaus. He was also the proprietor of the Aldwych Theatre, at which grand opera is being now produced. In 1914 he purchased the Covent Garden estate, which formerly belonged to the Duke of Bedford. He served for three years as mayor of St. Helen's, the town in which his works are situated. He was created a Knight in 1912, and a Baronet two years later.

NOTES ON BOOKS.

JOSEPH PENNELL'S PICTURES OF THE WONDER OF WORK. London: William Heinemann. 7*s.* 6*d.* net.

Some four years ago Mr. Pennell read a remarkable paper before the Royal Society of Arts, in which he gave forth his theory of art: "Work to-day is the greatest thing in the world, and the artist who best records it will be best remembered." From his youth he has devoted himself to the study of work—or should it be "works"?—and has found his favourite subjects in great chimney stacks, pillars of fire and clouds of smoke, huge cranes, skyscrapers, and monstrous dumps. The present volume contains a selection of fifty-two drawings—one of them made as long ago as 1880. A number of these were shown on the screen when Mr. Pennell read his paper here, and a few appeared in the *Journal* of December 20th, 1912. The collection deals with subjects in the United States, especially Philadelphia, Pittsburgh, and New York, and also in Europe, especially Italy, our own "Black Country," France, Belgium, and Germany. Mr. Pennell was in the last-named country when war broke out, and not the least interesting of the pictures in this book is the sketch of Krupp's works, Essen, where a great gun in process of manufacture is being swung on a crane across a workshop. It is perhaps to be regretted that none of Mr. Pennell's famous drawings of the Panama Canal are included in this collection, but the reason, no doubt, is that they have already been published in a separate volume.

Mr. Pennell's position as an artist is so secure and so well known that it would be superfluous to attempt to define it here. Probably no one can get a finer black-and-white effect than he from clouds of smoke and fire, or can render more artistically the bold lines of a cantilever bridge or a great factory. But

he has done well to publish this collection of drawings, as when they are studied all together they give one an increased sense of his power and versatility as a draughtsman; for although a similar thread runs through all the pictures, the subjects are enormously varied, ranging, as they do, from Pittsburgh Steel Works to the Carrara marble quarries and the rebuilding of the Campanile, Venice.

THE MIGRATIONS OF FISH. By Alexander Meek, M.Sc. London: Edward Arnold. 16s. net.

The importance of fish as a food has led of late years, and especially during the last two decades, to a wide and close study of their habits; and although the subject is so vast that up to the present a comparatively small portion of it has been covered, we do now know fairly definitely a certain amount concerning the biology of certain fishes, their habits, their reproductive powers, their spawning grounds, and their rates of growth. Much of the information which has hitherto been collected, however, is scattered about in various papers and periodicals, and the time is ripe for setting down in systematic form what is known of fish migrations at the present time. This is the task which Professor Meek has set himself in the volume before us.

The author has dealt with nearly all the various families of fish, but naturally—both on account of their greater practical importance to us and the fact that they have been more closely studied—the food fishes of the Northern Hemisphere have been most fully treated. Especially full and interesting are the chapters which describe the migrations of herring, salmon and trout, conger and other eels, cod, and the flat fishes. As Director of the Dove Marine Laboratory at Cullercoats, Professor Meek has had special facilities for studying the movements of herring, which annually visit the east coast of this country in enormous shoals, and it would appear that our knowledge of the migrations of these very valuable food fishes is now becoming fairly complete.

A word of praise must be given to the illustrations, which are numerous and excellently reproduced, while the maps, showing the distribution of the various fish families are of remarkable interest. In fact, the whole work is a scientific and masterly exposition of a most important branch of biological study.

GENERAL NOTES.

A PAPER FIBRE.—Tambookie, or tambootie, grass, which grows luxuriantly over vast tracts of land in the Transvaal, is said to have a promising future in connection with the manufacture of paper. The *Bulletin* of the Imperial Institute says that this grass has been proved to yield, under the same conditions, more pulp than Algerian esparto grass, but a little less than Spanish esparto. Not only is the yield high, but the pulp is of good quality, and can be easily bleached. Paper-making trials at the Imperial Institute show that a satisfactory paper of fairly good strength can be made from tambookie grass pulp. The most remunerative use for the grass will probably be to convert it in South Africa into "half-stuff," which can be exported to Europe or used for paper-making locally. Specimens of the grass and of paper made from it may be seen in the South African Court of the Imperial Institute.

TRADE IN NORTHERN MANCHURIA.—The *London and China Telegraph* quotes some interesting points concerning the commercial situation in Northern Manchuria during 1915 from a recent report by the United States Consul at Harbin. Hitherto all trade has been on a long-credit basis—a system established by the Germans. Now credits are everywhere refused. It was supposed trade could not readily revive because not enough cash could be found to finance it on a cash basis. But to the surprise of commercial circles the Chinese found money readily enough, and for the first time in its history trade in Northern Manchuria during 1915 was conducted on a strictly cash basis. One of the most interesting developments of the year was the success of the Japanese in making Harbin a distributing centre for both import and export trade with Russia. They were quick to see the natural advantages of its geographical and trade-route position, and to grasp the opportunities that proximity, cheap labour, and direct railway and shipping connections gave them. By far the largest foreign product imported in Northern Manchuria for domestic use is cotton piece goods. A few years ago American piece goods occupied easily the first place in the Manchurian trade, with British and Japanese goods fighting for the second place. To-day Japanese piece goods have practically driven every competitor from the market. Japanese business houses are now endeavouring to achieve the same result with articles of clothing, canned foods, manufactures of hardware and leather—in fact, with a remarkable variety of articles.

CHINESE BEAN "MILK."—Bean "milk" has long been known to the Chinese under the name of to fu chiang, or bean-curd sauce. It is made from the small yellow beans from which the Chinese bean curd and chiang yu or soy are made. The beans are soaked and then crushed between two stones. The crushed mass is allowed to run off into a tub, and is then strained through cheesecloth and diluted with water and boiled. After boiling it is again strained, and the white milk run off into bottles. An analysis of the bean-curd milk shows that it has a specific gravity of 1·020 and a fat content of 3·125. To the eye, according to the United States Consul at Changsha, the product looks exactly like unskimmed cows' milk. It has an odour of raw beans, and is said to be not unpleasant to the taste.

Swiney Lectures on Geology.—A course of twelve lectures on "The Mineral Resources of Europe" will be delivered by Mr. John S. Flett, F.R.S., at the Royal Society of Arts, on Tuesdays, Thursdays, and Fridays, at 5 p.m., beginning Tuesday, November 14th, and ending Friday, December 8th. The lectures will deal with coal, petroleum, iron, copper, tin, manganese, lead, the precious metals, and salt.

School of Art Wood-carving.—The School of Art Wood-carving, South Kensington, has been reopened after the usual summer vacation. Some of the free studentships maintained by means of funds granted to the school by the London County Council are vacant. The day classes of the school are held from 9 a.m. to 1 p.m. and 2 to 5 p.m. on five days a week, and from 9 a.m. to 1 p.m. on Saturdays. The evening class meets on Monday and Friday evenings from 7.30 to 9.30 p.m. Forms of application for the free studentships and any further particulars relating to the school may be obtained from the Registrar.

Deaths from Wild Animals in Bengal.—There was an increase in the total number of persons killed by wild animals in Bengal during the last year, the figure being 423 against 332 in the preceding year. This increase is shared by all divisions, except Chittagong. Deaths from snake-bite rose from 4,356 to 4,709. This large increase is due to excessive floods which drove snakes to take shelter in human habitations. Some 4,185 head of cattle were killed by wild animals and 188 by snakes. A total of 2,769 wild animals were destroyed, of which 275 were tigers and 496 leopards; 11,893 snakes were destroyed last year. The amount paid in reward for destruction of wild animals was Rs. 17,977.

Philippine Shrub Perfume.—According to a report by the correspondent at Manila of the United States Department of Commerce, the perfume known in trade circles as "cassie," manufactured for the most part in France, is found in abundance in the Philippine Islands in the *Acacia farnesiana*, a shrub which grows near Manila and throughout the dry parts of the islands. This shrub has small spiny leaves and produces a short black pod. The flower from which the essence is obtained is very abundant and of a golden colour It is known locally as "aroma."

Fuel Economy.—Owing to the high price of coal in the south of France, old newspapers and other waste paper are being used for making fire-balls for burning with coal or anthracite in close stoves for heating purposes. The paper is soaked in water for twenty-four or forty-eight hours, and then kneaded and pressed into shape to about the size of a golf or tennis ball, and then dried in the sun. When the fire is well alight the balls can be used in the proportion of one-quarter to one-third of the coal.

MEETINGS FOR THE ENSUING WEEK.

Monday, October 30...Farmers' Club, at the Surveyors' Institution, 12, Great George-street, S.W., 4 p.m. Professor T. H. Middleton, "The Farmer's Task."

Tuesday, October 31...Photographic Society, 35, Russell-square, W.C., 7 p.m. Mr. S. Routledge, "Incidents in an Exploratory Voyage of 100,000 miles in the yacht 'Mana,' and the Great Images of Easter Island."

Anthropological Institute, 50, Great Russell-street, W.C., 5 p.m. Mr. A. Trevor-Battye, "The Gurkhas and their Country."

Röntgen Society, at the Institution of Electrical Engineers, Victoria-embankment, W.C., 8.15 p.m. Presidential Address.

Wednesday, November 1...Public Analysts, Society of, at the Chemical Society, Burlington House, W., 8 p.m. 1. Mr. T. E. Wallis, "Quantitative Microscopy." 2. Mr. C. C. Roberts, "Formula for converting Zeiss Butyro-Refractometer readings into Refractive Indices." 3. Messrs. C. Revis and H. R. Burnett, "Criticism of Vaubel's Bromine Values."

Thursday, November 2...Linnean Society, Burlington House, W., 8 p.m.

Chemical Society, Burlington House, W., 8 p.m. 1. Mr. E. Newbery, "Overvoltage tables. Part IV. —The theories of overvoltage and passivity." 2. Messrs. C. A. Seyler and P. V. Lloyd, "Studies of the carbonates. Part II.—Hydrolysis of sodium carbonate and bicarbonate, and the ionisation constants of carbonic acid." 3. Mr. M. Nierenstein, "The synthesis of hydroxyquercetin." 4. (*a*) Mr. E. G. J. Hartley, "The reaction between methyl iodide and some metallic cyanides"; (*b*) "Some reactions produced by mercuric iodide." 5. Messrs. H. M. Dawson and T. W. Crann, "The dual theory of acid catalysis. A comparison of the activities of certain strong acids."

Friday, November 3...Chadwick Public Lecture, at the Royal Society of Arts, John-street, Adelphi, W.C., 5.15 p.m. Dr. W. Stirling, "Fatigue, and its effects on Industry and Efficiency." (Lecture II.)

Mechanical Engineers, Institution of, at the Institution of Civil Engineers, Great George-street, S.W., 6 p.m. (Thomas Hawksley Lecture.) Mr. H. Jones, "The Gas Engineer of the last Century."

THE LIBRARY.

The following books have been presented to the Library since the last announcement. Except where otherwise stated they have been presented by the publishers:—

Ballhatchet, Albert V.—Electrical Apparatus-Making for Beginners. London: Percival Marshall & Co., 1916.

Barnes, Alfred A.—Hydraulic Flow Reviewed. London: E. & F. N. Spon, Ltd., 1916.

Batliboi, Jamshed R.—Advanced Accounts. Bombay, 1916. Presented by the Author.

Batsford, Herbert.—English Mural Monuments and Tombstones. London: B. T. Batsford, Ltd.

Beaumont, Professor Roberts, M.Sc.—Standard Cloths. London: Scott, Greenwood & Son, 1916.

Bell, Edward, M.A., F.S.A.—The Architecture of Ancient Egypt. London: G. Bell & Sons, Ltd., 1915.

Benn, Ernest J. P.—Trade as a Science. London: Jarrold & Sons.

Brown, Thomas, and Vincent E. Collinge.—Arithmetic and Book-keeping. Part I. Sir Isaac Pitman & Sons, Ltd., 1916.

Buxton, Charles Roden.—Towards a Lasting Settlement. London: George Allen & Unwin, Ltd., 1915.

Cross, C. F., and E. J. Bevan.—A Text-Book of Paper-Making. Fourth Edition. London: E. & F. N. Spon, Ltd., 1916.

Cucchi, C. P.—New Italian Grammar. London, 1912. Presented by the Author.

Cundall, Frank, F.S.A.—Historic Jamaica. London: West India Committee, 1915. Presented by the Author.

Dhari, Alakh.—(1) The Growth of Currency Organisations in India. Bombay Chronicle Press, 1915; (2) Co-operative Credit in Gwalior State. Lucknow: Newul Kishore Press, 1915. Presented by the Author.

Dunk, John L.—Hyperacoustics: Division I. Simultaneous Tonality. London: J. M. Dent & Sons, Ltd., 1916. Presented by the Author.

Enock, C. R.—(1) The Tropics; (2) Can we Set the World in Order? London: Grant Richards, Ltd., 1915 and 1916.

Higgins, S. H., M.Sc.—Dyeing in Germany and America. Second Edition. Manchester: University Press, 1916.

Hoffman, Frederick L., LL.D.—The Mortality from Cancer throughout the World. Newark, New Jersey: The Prudential Press, 1915.

Ibbotson, Fred, B.Sc., and Leslie Aitchison.—The Analysis of Non-Ferrous Alloys. London: Longmans, Green & Co., 1915.

Jennings, Arthur Seymour.—Paint and Colour Mixing. Fifth Edition. London: E. & F. N. Spon, Ltd., 1915.

Johnstone, Sydney J., B.Sc.—The Rare Earth Industry. London: Crosby Lockwood & Son, 1915.

Kingsbury, J. E.—The Telephone and Telephone Exchanges. London: Longmans, Green & Co., 1915.

Magnus, Leonard A., LL.B.—The Tale of the Armament of Igor, A.D. 1185. Translated from the Russian. Oxford University Press, 1915.

Meek, Alexander, M.Sc.—The Migrations of Fish. London: Edwin Arnold, 1916.

Oil Seeds and Feeding Cakes. Imperial Institute Monograph. London: John Murray, 1915.

Palmer, A. Risdon, B.Sc., B.A., and James Stephenson, M.A., M.Com., B.Sc.—Commercial Arithmetic and Accounts. Two Parts. London: G. Bell & Sons, Ltd., 1916.

Parrish, Samuel L.—Historical and Descriptive Catalogue of the Art Museum, Southampton. New York, 1912. Presented by the Author.

Peddie, J. Taylor.—On the Relation of Imports to Exports. Second Edition. London: Longmans, Green & Co., 1916.

Pennell, Joseph.—Pictures of the Wonder of Work. London: William Heinemann, 1916.

Rawlinson, W. G.—The Engraved Work of J. M. W. Turner, R.A. Two Vols. London: Macmillan & Co., Ltd., 1908 and 1913. Presented by the Author.

Science Française. Two Vols. Paris: Ministère de l'Instruction publique, 1915.

Smith, Henry H.—Book-keeping and Commercial Practice. London: Sir Isaac Pitman & Sons, Ltd., 1916.

Stephenson, James, M.A., M.Com., B.Sc.—(1) The Principles and Practice of Commerce. (2) Principles of Business. Vol. II. London: Sir Isaac Pitman & Sons, Ltd., 1916.

Swarbrick, John, A.R.I.B.A.—Robert Adam and his Brothers. London: B. T. Batsford, Ltd.

Tedesco, Giulia Hoffmann, and Michele Tedesco. L'Opera. Milan: Alfieri & Lacroix. Presented by Professor M. Tedesco.

Whitley, William T.—Thomas Gainsborough. London: Smith, Elder & Co., 1915.

Willings, W., B.Sc.—A Junior Chemistry. London: Blackie & Son, Ltd., 1916.

Winton, Andrew L., Ph.D.—The Microscopy of Vegetable Foods. Second Edition. New York: John Wiley & Sons, 1916.

Year-Book of Wireless Telegraphy and Telephony, 1916. London: The Wireless Press, Ltd., 1916.

The following were presented by the Director of the London School of Economics and Political Science:—

Bannington, R. G.—English Public Health Administration. London: P. S. King & Son, Ltd., 1915.

Matthai, John.—Village Government in British India. London: T. Fisher Unwin, Ltd. 1915.

Mills, Richard Charles, LL.M., D.Sc.—The Colonisation of Australia (1829-1842). London: Sidgwick & Jackson, Ltd., 1915.

Moore, Margaret F., M.A.—The Lands of the Scottish Kings in England. London: George Allen & Unwin, Ltd., 1915.

Proud, E. Dorothea, B.A.—Welfare Work. London: G. Bell & Sons, Ltd., 1916.

London: Printed by WILLIAM CLOWES & SONS, LTD., Duke Street, Stamford Street, S.E., and published for the Royal Society of Arts by G. BELL & SONS, LTD., York House, Portugal Street, W.C., in the Parish of St. Clement Danes, in the City of Westminster.—October 27, 1916.

Journal of the Royal Society of Arts.

No. 3,337. VOL. LXIV.

FRIDAY, NOVEMBER 3, 1916.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICE.

ARRANGEMENTS FOR THE SESSION.

The Opening Meeting of the One Hundred and Sixty-Third Session will be held at 4.30 p.m. on Wednesday, November 15th, when an address will be delivered by DUGALD CLERK, D.Sc., F.R.S., Chairman of the Council, on "The Stability of Great Britain."

The following arrangements have been made for the meetings before Christmas:—

ORDINARY MEETINGS.

Wednesday afternoons, at 4.30 p.m.:—

NOVEMBER 22.—LESLIE URQUHART, "The Economic Development of Russia and Britain's Share therein." The RIGHT HON. LORD CARNOCK, G.C.B., G.C.M.G., G.C.V.O., K.C.I.E., British Ambassador in Russia, 1906-1910, will preside.

NOVEMBER 29.—

DECEMBER 6.—C. M. WHITTAKER, B.Sc., "The Coal-Tar Colour Industry."

DECEMBER 13.—H. WILSON FOX, "The Development of Imperial Resources."

DECEMBER 20 (at 4 p.m.).—A. C. BENSON, C.V.O., Master of Magdalene College, Cambridge, "Classical and Scientific Education."

INDIAN SECTION.

Thursday afternoon, at 4.30 p.m.:—

DECEMBER 14.—JOHN ALTON TODD, B.L., Professor of Economics, University College, Nottingham, "The World's Cotton Supply and India's Share in it."

HOWARD LECTURES.

Monday afternoons, at 5 p.m.:—

JOHN S. S. BRAME, Professor of Chemistry, Royal Naval College, Greenwich, "Coal and its Economic Utilization." Three Lectures. November 27, December 4, 11.

JUVENILE LECTURES.

Wednesday afternoons, January 3 and 10, at 3 p.m.:—

ALAN A. CAMPBELL SWINTON, F.R.S., "Electricity and its Applications." Two Lectures.

A further announcement will be issued in the next number of the *Journal*.

PROCEEDINGS OF THE SOCIETY.

EXAMINATIONS, 1916.

The Society's examinations have now been conducted on their present system for just sixty years. They were established in 1856, it was in 1857 that the first provincial examination was held, and in 1858 the system was established under which local committees were appointed to supervise examinations worked from a single centre.

At that time there was a craze for examinations. In 1854 "selection by examination as a method of appointment to posts in the English public service was first substituted for the patronage system."* The first competitive examination for the Royal Military Academy was held in 1855, though it was not till 1870 that the principle of open competition for the Civil Service was generally adopted. The Oxford and Cambridge Local Examinations were established in 1858, and the Science Examinations of the Science and Art Department in 1861.

The scope of the Society's examinations at first was very wide, and included practically all the subjects of general education, but the field was restricted as other agencies took up various parts of the work. The establishment of the University Local Examinations induced the Society to abandon its purely literary subjects, while the examinations of the Science and Art Department led to the giving up of the scientific papers. The result was that only the commercial subjects were retained, with the addition of—for some years—Domestic Economy and —down to the present date—Music.

On two occasions, in 1871 and in 1879, it was proposed to discontinue the examinations, and on both the idea was abandoned in consequence of pressure put upon the Council by local institutions.

From time to time subjects have been dropped out as they came to be dealt with by other agencies, and new subjects were

* From the excellent article on "Examinations" in the eleventh edition of the "Encyclopædia Britannica," by P. J. Hartog and Arthur Watson. This article, complete as it is in most respects, seems entirely to ignore the Science and Art Department's Examinations, continued from 1861 to 1911.

introduced to meet the demands of commercial education.

Changes have also been made in the general classification or arrangement of the grades of examination. At first the examinations were only of one grade with three classes. In 1897 an Elementary grade was added of a single class only. This arrangement went on till 1905, when it was recast, and the present system introduced with its three stages—Advanced, Intermediate, and Elementary—the two upper stages being divided into two classes, first and second, and the Elementary consisting of a single class only. On the whole, therefore, it will be seen that the original system still remains, with no organic change and with only reasonable development and growth, so that it may certainly be said to have stood the test of time remarkably well.

Up to 1880 the examinations were free, and the Society expended a large amount of money on their development. When in 1882 the idea of abandoning the examinations was given up, it was determined to try whether they could not be made self-supporting. It was believed that a fee of 2*s.* 6*d.* for each candidate would be sufficient at all events to prevent any serious loss. In practice this anticipation proved accurate, and from that date to this year, this fee has been charged.* When it was first determined upon it was only intended to minimise the loss, and the Society was quite prepared to expend a certain amount annually on the examinations. But their enormous development from 1883 to 1914 has enabled them, since the number of entries became large, to be carried on without loss, and in some years even to bring in a small margin of profit. Of course many departments of the examinations have always been unprofitable. But the profit on those subjects for which very large numbers enter was just sufficient to make up for the loss on the non-paying subjects, and so long as the Society was not called upon to provide amounts which would be a serious tax upon its moderate resources, the Council was perfectly content to carry on a useful public work, without much consideration as to whether the actual result was a small profit or a small loss.

Previous to 1880, when the examinations were free, the largest number of candidates in any year was a little over 2,000. This number was reached and surpassed in 1890. During the next ten years there was a steady annual increase, till in 1900 there were nearly 9,000. The effect of the Technical Instruction Act of 1889 sent the numbers up in 1901 to over 12,000. In the following year there was a trifling increase. In 1903 they passed 16,000, in 1904 they nearly reached 18,000; and in 1905 they exceeded 21,000. In the next three years there was a moderate increase up to 22,000; and in 1909 they shot up to more than 25,000. In two years more they passed 27,000; and in 1914, after a decrease for two years, they reached their highest point, 29,000. This growth of the examinations since 1900 is shown in diagrammatic form on page 847.

As was naturally to be expected, the carrying out of the Society's examinations this year has been a work of considerable difficulty. The staff, never quite large enough to compete satisfactorily with the increase of the work, has had to supply its quota to the Army, but, fortunately enough, the clerks engaged on the examinations were not called up until all the preparations for both divisions of the examination were completed, and so the only real harm done was that there has been a not very serious delay in the publication of the results and the issue of the certificates. Not only was there a deficiency in the working staff, but several of the examiners were occupied with war work, and others had lost the help of clerks and assistants on whom they had previously depended.

The local educational authorities also had their own difficulties, caused by lighting regulations, diminution of railway facilities, and other like matters. These were met by authorising the holding of the examinations at earlier hours when necessary, due precautions being taken to preserve the secrecy of the papers of questions.

On the whole, it is satisfactory to be able to report that none of the anticipated difficulties were found insurmountable; so that, as above mentioned, the only matter demanding an apology is that the printed results were not published at quite so early a date as usual.

As regards the number examined it is disappointing, but not unexpected, to have to report a diminution again this year. This is to be attributed certainly and solely to the war, and perhaps it ought to be considered a matter for congratulation that the numbers have kept up as well as they have.

It was confidently anticipated in 1914 that in consequence of the new arrangements under which a double examination was held, instead of all the examinations being held at one period of the year, the rate of increase would have been still more rapid, and that the numbers for 1915 would have been larger than ever. These calculations, however, were upset by the war, and

* A lower fee is charged for the Elementary Stage.

there was, instead of the expected growth, a considerable diminution in numbers. It was certain that a further loss would be felt this year, but there was some hope that the falling-off might have been comparatively small, and this was encouraged by the fact that, compared with last year, the entries for the first division of the examinations, held in April last, showed an increase of some 1,500. For the second division, however, held in May and June, the falling-off was very large and amounted to nearly 7,700.

The examinations this year, as last, have, in consequence of the falling-off in numbers, caused the Society a considerable financial loss. The same was the case last year, and the matter was fully discussed in last year's Report. The Society's Financial Statement for last year (1914-15) shows a difference of £875 to the bad, and this year (1915-16) there appears a difference of £1,035. This statement, as was explained, is unduly unfavourable in consequence of the time of the year when it is made up, which prevents the cost and the receipts of the same examination coming into the same balance-sheet. If similar figures are taken over a period of years it is possible to arrive at an accurate estimate of the cost of the examinations. Thus, taking the ten years before the war, a careful calculation shows that there was an average annual profit of about £100 during that period, and it was the existence of that profit which was thought to justify the Council in adopting the more expensive system of holding the examinations in two divisions in 1914.

But though the statement still holds good that in recent years the examinations have been made self-supporting, it is also the fact that the losses of the past two years have more than absorbed any previous profits, and, under existing conditions, the Society cannot undertake to provide a considerable annual subsidy to the examinations.

The Council have therefore felt justified in raising the fees by the addition of 6*d*. in the two lower stages, and 1*s*. in the Advanced Stage. The fees are still extremely moderate—3*s*. 6d., 3*s*., and 2*s*. 6*d*. respectively for the three stages, and it is not expected that any serious objection will be taken to them, or that the addition will have any appreciable effect in discouraging the entry of candidates.

The total number of entries for this year's examinations was 25,979—15,940 for the April examinations and 10,039 for those in May and June. The total shows a falling-off of 6,150 as compared with last year, when there were 32,129 entries. It should be understood that these figures represent, not the number of individual candidates, but the number of papers applied for. It will be noted that the entries for the first division of the examinations shows an increase of 1,523, and those for the second division a deficiency of 7,663.

The number of candidates who actually came up for examination was 19,315. These 19,315 candidates worked 24,002 papers—Advanced 2,797, Intermediate (including Theory of Music 230) 8,650, and Elementary 12,555. Comparing the number of papers worked with those applied for we find a difference of 1,977 or 7·2 per cent. It has always been rather a mystery why it is that so large a proportion should fail to present themselves after entering and paying their fees. The percentage this year is rather smaller than usual. Last year it was 8·1.

The numbers of papers worked were divided between the two examinations as follows :—

	April.	May-June.	Total.
Advanced Stage .	1,343	1,454	2,797
Intermediate Stage	4,315	4,335	8,650
Elementary Stage.	9,125	3,430	12,555
	14,783	9,219	24,002

In addition to the 19,315 examined in the annual examinations there were 380 candidates in Colloquial Modern Languages. The total number of candidates who were examined in all subjects by the Royal Society of Arts during the year ending July last, was, therefore, 19,695. Last year there were 23,722.

The general results of this year's examinations are given in Table A (page 842), and a comparative view of the numbers in the higher stages for the last six years (1911-16) is given in Table B (page 843). Tables C and D (page 844) show the percentage of successes and failures in all subjects of the two higher stages for the present year; while the percentage of successes and failures in all stages for the past six years are to be found in Table E (page 844). Table F (page 844) gives the number of candidates, papers, and subjects in the Elementary Stage since 1905. Table G (page 844) shows the number of papers worked in all stages during the last twelve years. Tables H and I (page 845) show the percentage of failures in the different subjects of the two higher stages for the last six years. Table K (page 846) gives the numbers of candidates examined during the same period. In Table L (page 846) are shown the results of the Viva Voce Examinations held at various centres during the current year.

The commercial subjects included Book-keeping, Accounting, Banking, Shorthand, Typewriting, Economic History and Theory,

Précis-writing, Theory and Practice of Commerce, Commercial Law, Company Law, Economic Geography, Arithmetic, Commercial Correspondence, etc., Handwriting, etc., English, French, German, Spanish and Italian. The other subject of examination was Music, divided into Rudiments of Music and Harmony.

It was announced in last year's Programme that it might possibly be necessary to discontinue the offer of medals and prizes during the continuation of the war. After consideration of the subject, the Council reluctantly decided to abandon the money prizes; but they were enabled, by the liberality of the Court of the Clothworkers' Company, to continue the offer of medals as usual. For many years the Clothworkers' Company has presented the Society with the sum of £40 to be expended in prizes for certain specified subjects, and the Court very kindly acceded to a request from the Council that they would permit their grant to be applied generally for the purpose of providing medals in all the subjects, instead of special prizes in selected subjects.

The Society was therefore enabled this year to award nineteen Silver and thirty-three Bronze Medals, the former in the Advanced Stage and the latter in the Intermediate. The scholarship offered annually by the London School of Economics was not awarded this year.

It was always a source of complaint that candidates had to wait a long time before they could know the results of their examinations. A new system of publication of the results of the examinations was started last year, and as it was much appreciated it has been continued. The candidates fill in a counterfoil attached to the paper on which they do their work; on these counterfoils the result of the examination is marked, and they are returned to the centres as soon as possible. By this means candidates are informed of the result of their examination some weeks sooner than in former years, when they had to wait until all the papers had been reported on and classified, and the printed results issued.

The results of the April examinations were sent to the centres concerned—the Advanced on June 21st, the Intermediate on June 30th, and the Elementary Stage on July 20th.

The results of the May-June examinations were issued—the Advanced Stage on August 2nd, the Intermediate on August 18th, and the Elementary on August 24th. The complete list of all the results, classified under localities, was published in October.

No alterations of importance were made in the Programme for last year; but after its issue two interesting additions were made an examination for English prisoners abroad and one for Belgian refugees. After a good deal of negotiation, it was found possible to provide examinations for some of the interned prisoners at Ruhleben, in Germany, and at Groningen, in Holland. In both cases no fees were charged.

As regards Groningen there was no special difficulty, and examinations were arranged for both divisions of the examinations. In both cases the papers of questions were sent over by the Foreign Office to H.M. Minister at the Hague, who kindly undertook to transmit them to the committee formed at Groningen for the supervision of the Examinations. 29 candidates entered—11 for the Advanced Stage, 13 for the Intermediate, and 5 for the Elementary. They worked 34 papers, of which 29 were passes and 5 failures. The subjects were Accounting, Book-keeping, Music, French, German, and Spanish.

At Ruhleben the conditions were more difficult; but the difficulties were overcome by the kind help of the Board of Education, who were able to get the packets of papers through without their being opened by the Censor. The local arrangements were not completed in time for the April examination, but for the Second Division, held in May and June, 31 candidates entered—17 Advanced, 11 Intermediate, and 3 Elementary. There were 41 papers, and only a single failure. The subjects were Book-keeping, Shorthand, English, French, German, and Spanish. Some of the work done was extremely good, and all was satisfactory.

In response to a suggestion from one of the local centres, an examination in English was arranged for Belgian refugees, and this proved extremely successful.*

It was thought better to charge the usual fees. But the work of setting the papers and marking the answers was done gratuitously, and the fees usually paid to the examiner were handed over to a Belgian charity.

In last year's Report an attempt was made to ascertain the comparative number of male and female candidates. The result was to show a percentage of 52·85 male and 47·15 female on the whole list; while in London the percentage was 52·50 female and 47·50 male. It has not been considered necessary to make a similar detailed examination of the present list; but a general estimate seems to show that the proportion of female names is much larger than last year, and now considerably exceeds that of male names. As regards London, the

* See infra, page 839.

number of females is considerably ahead of the number of males, and shows a great advance on last year.

It is also interesting to note that of the 52 medals awarded by the Society this year, 27, or more than half, were taken by women—who obtained 7 of the 19 Silver Medals awarded in the Advanced Stage, and 20 of the 33 awarded in the Intermediate.

The most popular subject is still Book-keeping, although the number of candidates in this subject (6,687) is not very much more than half the number of two years ago, when there were nearly 12,000 candidates. Last year the numbers fell to 8,960, so that there is a diminution of over two thousand in the present year. The examiner reports that the general standard in all stages was fully maintained, or on the whole a little improved.

As is always the case, the next most popular subject was Shorthand. In this 5,532 candidates were examined, as compared with 6,539 last year and 7,815 the year before. Roughly speaking, this shows a loss each year of a thousand. In Stage III. the percentage of passes, both first and second class, was considerably higher than last year. In Stage II. the standard seems to have been very much the same as in 1915, there being a slight falling-off in the number of first-class certificates and a slight improvement in the number of second. Stage I. also shows a little advance.

The entries in Typewriting this year show a slight increase upon last year, there being 2,638, or 72 more than the 2,566 of 1915; but they are still behind 1914, when they were 2,806. This was the largest number ever examined. In the Advanced Stage the work was on the whole excellent, and showed a marked improvement upon previous years; but as regards the Intermediate Stage the quality of the work submitted was much below that of previous years, and the same remark applies to the Elementary Stage. This result is curious and a little difficult of explanation.

In Arithmetic there had been before the war a steady and satisfactory growth in the numbers entering. Last year there was a falling-off of 419; this year the deficiency is larger, and amounts to 580. The actual numbers are 2,226 for the present year, 2,806 for last year, and 3,225 for 1914. On the whole, the working of the papers generally does not show any improvement.

English last year showed an actual increase in the number of papers worked; but this year there is a serious falling-off, as there were only 559 candidates as compared with 816—a loss of 257. It is very satisfactory to be able to report that the examiner considers that the average of the work done in all three stages compares favourably in quality with that of last year.

The new subject of English for Foreigners was added this year as the result of a suggestion from the Bradford educational authority that such an examination would be very useful to a number of the Belgian refugees in this country. Arrangements were therefore made for an examination in this subject to be held in Stages I. and II. at the April examinations. The result was extremely satisfactory, for 197 entered for the Elementary and 85 for the Intermediate Stage. As it was difficult to know what the standard of education would be, the paper in Stage I. was rather easy, and the result was that of the 197 candidates 165 passed. A considerable proportion of these papers were extremely good, and the candidates could easily have taken the Intermediate Stage. 85 entered for Stage II., and of these 23 obtained a first-class and 44 a second, while 18 failed. The result of this examination seemed to show that there might be a demand for an Advanced Stage paper for the May-June examination, and accordingly one was set. It appears that the fact was not very well known among the candidates, for only 12 entered. Of these only half passed, three taking a first-class and the other three a second. The paper set was really a rather difficult one, and apparently it was above the powers of most of those entering. For Stage II. there was a large entry—204. Of these 23 did not succeed in passing, 36 took a first-class, and 145 a second. For Stage I. 49 entered and 41 passed. On the whole, the result of the experiment was a distinct success, and the examination in this subject will be repeated next year.

It is not, perhaps, a matter for surprise, but it is certainly one for regret, that in nearly all what may be looked upon as the higher subjects in the Society's examinations the falling-off in the number of candidates has been very marked. This falling-off without much doubt is to be attributed to the fact that the candidates who entered for these subjects are all, or nearly all, young men of the age called upon for military service. The class of papers referred to includes those in Economics, Law, and Finance.

In Economic Geography there were not enough candidates in the Advanced Stage to justify the setting of a paper, and only 23 entered for the Intermediate. Last year was not quite so bad, as there were 18 in Stage III. and 38 in Stage II. In the Elementary Stage the deficiency is less noticeable—there were 157

against 190 last year. The total number of candidates is 180, or a deficiency of 66 on the 246 of last year. The quality of the work on the whole appears to be a little, but not very much, inferior to that of last year.

In Economic History there were no candidates at all—at least, there were not enough to justify the setting of a paper. Last year there were 103 in Theory and 24 in History—127 in all. This year we have only 46 in Economic Theory —18 in Stage III. and 28 in Stage II. The work was, on the whole, of fair quality and of a good general average.

For Commercial Law there were 57 entries, less than a third of the number last year. For Company Law there were only 49. The total number of entries in these two subjects, therefore, only amounts to 106. In 1915 there were 288, and in 1914, before the division of the subject into two, there were 308.

In Accounting there were 163 compared with 384 in 1915. In Banking there were 49 this year and 125 last. The total number in these two subjects, therefore, amounted to 212, whereas last year there were 509, and in 1914 the one subject of Accounting attracted 488. In Accounting the work, on the whole, was fairly good; several of the papers were excellent. In Banking the work appeared to be about the average, but there were no papers of particular merit.

In the important subject of the Theory and Practice of Commerce the results were more satisfactory than in the subjects just dealt with. For Stage III. there were 64 compared with 83 last year. For Stage II. 162 compared with 150 last year, this being one of the few instances of an increase in any stage of any subject. The total number of entries, therefore, was 226; last year there were 233. The character of the work, on the whole, is reported as quite satisfactory. Though the number of first-class papers is small, the number of absolute failures is not excessive.

For some years past the subject of Précis-writing has shown a steady decline, which, in the present year, is accentuated. In 1914 there were 198 candidates; in 1915, 138; and in the present year, 74, of whom 18 were in Stage III. and 56 in Stage II. In 1911 there were as many as 362 candidates entered.

The number of entries for Commercial Correspondence and Business Training was higher last year than in either of the two years previous, as it reached 606. This year there is a falling-off to 463. The corresponding subject, Handwriting and Correspondence in the Elementary Stage, still attracts a large number of candidates, but the falling-off last year from 1,912 in 1914 to 1,666 has been repeated this year, the number being 1,384. In response to several applications it has been determined to include this subject in Stage III., and a paper will therefore be set in it next year. The title has been altered, and the subject in future will be known as "Commercial Correspondence and Office Organisation" in all three stages.

With regard to the examinations in modern languages, they show a falling-off in numbers very much corresponding with that of last year. In French the deficiency is considerably greater, as there were 500 less than last year, when there was a falling-off of 170. The total number of entries for 1916 was 2,285. As before, the numbers have decreased in all three stages. Naturally one would have expected that French would have shown a smaller diminution than other languages; but this has not been the case, and it is rather difficult to suggest a reason. Six years ago there were 3,647 candidates, and it looks as if the diminution is not wholly due to circumstances connected with the war. The character of the work appears to show an advance. Last year the examiner reported that the standard was rather higher than usual, and the same seems to be the case again this year.

Last year the number of German papers diminished by some 50 per cent., and the falling-off this year is practically the same. Only 270 papers were worked, the deficiency being 192. The diminution appears in all three stages. Such a falling-off in German, of course, is what was to be expected, and the question has been considered whether the examination should not be dropped entirely. It has, however, been thought best to continue it, and the subject will hold its place in next year's Programme as usual.

In Italian it is a little remarkable that there is actually an increase, though the numbers are still small. Last year there were 44, and this year there were 61. The work on the whole in this subject, as it generally has been, is good.

In Spanish there were 149, as compared with 227 last year. The examiner reports favourably on the work in the two lower stages, but that sent in in Stage III. was disappointing.

The results of the Russian examination are remarkable. For nearly thirty years we have had examinations in Russian, but the number of entries has always been very small, and last year the examination was discontinued in consequence of the paucity of candidates. This year, however, classes were established under the London County Council and by independent institutions in London;

and so a special notice was sent round to the various Russian classes drawing the attention of the teachers to the Society's examination. The result was that 127 candidates entered—24 in the Intermediate Stage and 103 in the Elementary. No examination was held in Stage III. 82 of these passed, and 45 failed. The large proportion of failures is not remarkable, considering that practically all the students commenced their study of the language last year. The results, however, show much promise for future years.

Two interesting additions were made to the list of Modern Languages in which Viva Voce Examinations were held this year. For the benefit of Belgian refugees an examination was held in English for Foreigners, and, as a consequence of the increased study of Russian in this country, the experiment was tried of holding one in Russian. Both were held only in London, as no provincial centre was able to find a sufficient number of candidates for a local examination.

As was the case last year, there were also oral examinations in French, German, and Spanish, all in the London district—except at Manchester, where a small number of candidates were examined in French. In all 380 candidates were examined, 10 in Manchester and the rest in London; of these 321 passed, 141 with distinction, and 59 failed. The numbers in the different languages were—French 259, German 34, Spanish 15, Russian 19, English 53. In former years there were also examinations in Portuguese and Italian, and at Liverpool, Birmingham and Bristol.

The total number, 380, is much the smallest of any recent year, and shows a falling-off of 48 as compared with the 428 of 1915.

The oral examinations were started in 1902, when 280 candidates were examined. The numbers rose to 681 in 1905; after that there was a small diminution, the numbers varying slightly year by year, and falling to 583 in 1911, then they increased again to 688 in 1913, and this was the highest point yet reached, as in 1914 there was a drop to 628. Table L (page 846) gives in detail the results of this year's examinations.

The oral examinations are held at any of the Society's centres where the necessary arrangements can be made, at any date convenient to the local committee. The examination includes dictation, reading, and conversation, and is so arranged as to test efficiency in colloquial knowledge of the language, without laying too much stress on minute grammatical accuracy. Candidates who are reported upon as highly qualified by the examiners receive a certificate of having passed with distinction.

The examinations in Rudiments of Music and Harmony were carried on as usual at the same time as the Commercial examinations, and the results appeared as part of the results of the Intermediate Stage. The total number of candidates was only 230, less than half the number, 509, of last year. So sudden and serious a diminution may without doubt be attributed to the war; but as noted in last year's Report, the falling-off in the number of candidates attracted by this subject has been steady and continuous for many years. This is clearly shown by the figures, which were quoted last year, and may now be repeated. They are—509 in 1916, 587 in 1914, 617 in 1913, 688 in 1912, 691 in 1911, 619 in 1910, 699 in 1909, 716 in 1908, 641 in 1907, and 637 in 1906.

In Rudiments of Music 116 candidates presented themselves; last year there were 254. In Harmony there were 114, as compared with 255. Of the 116 candidates in Rudiments of Music, 90 passed and 26 failed. Of the 114 candidates in Harmony, 80 passed and 34 failed. The results show a falling-off from the standard of recent years. So it looks as if the candidates were not only less numerous, but less efficient.

The Examination Programme for 1917 was issued early in October. In it will be found the fullest possible information about the examinations, a syllabus of each stage of each subject, and the papers set in May-June, 1916.* The attention of both teachers and students may be drawn once more not only to the syllabuses but also to the remarks of the various examiners on the results of last year. It will be found that these contain many valuable and helpful suggestions, and the work of the candidates year after year shows that far too little attention is paid to them. Teachers especially are earnestly recommended to study these remarks, as they ought to be guided by them in the instruction they give to their pupils.

The regulations for the Examinations in the Theory of Music, and those for the Viva Voce Examinations in Modern Languages, are also given in full length.

* The price of the Programmes for 1914, 1915, 1916, and 1917 is 4*d*. each, post free 6*d*. Copies can be obtained on application to the Secretary of the Royal Society of Arts, Adelphi, London, W.C. Programmes containing the papers set from 1905 to 1912 can also be obtained (price 3*d*. each year, post free 4½*d*.). The papers set in March, 1915, and April, 1916, are not included in the 1916 and 1917 Programmes. They are printed in separate pamphlets, price 2*d*. each (post free 3*d*.). The regulations and syllabuses for the present year can also be had separately (without the papers), price 1*d*., by post 1½*d*.

TABLE A.—DETAILS OF THE 1916 EXAMINATIONS.

Subjects.	Stage III.—Advanced. Papers worked.	Stage III. 1st class certificates.	Stage III. 2nd class certificates.	Stage III. Not passed.	Stage II.—Intermediate and Music. Papers worked.	Stage II. 1st class certificates.	Stage II. 2nd class certificates.	Music Certificates. Higher.	Music Certificates. Inter-mediate.	Music Certificates. Elemen-tary.	Stage II. Not passed.	Stage I.—Elementary. Papers worked.	Stage I. Passed.	Stage I. Not passed.	Total number of papers worked in all stages.

DIAGRAM SHOWING PROGRESS OF EXAMINATIONS, 1900-1916.
The solid line shows the number of candidates, the dotted line the number of papers worked.

THE DEVELOPMENT OF THE TEXTILE INDUSTRIES.

Industrial Intelligence.—It must be hoped that in their own good time the ruling authorities will see fit to summarise for publication the new facts gained from their several inquiries into the state of the textile industries. These inquiries have had reference in especial to the textiles necessary for war, and they have elicited much that previous returns have not contained. Details of the number and kind of machines, their maximum capacity and average output, have not hitherto been obtainable, and these will be of no less interest than the statements of the quantities of materials on hand at given dates. Traders have been at considerable pains to provide the information, and they should not be deprived of the benefit of reading the outcome in print and of correcting their ideas accordingly. The competent authorities will have to decide whether the periodical renewal of such inquiries is a necessary part of the future national organisation for war. Conceivably it will be found that the form of the census of production, or of the factory returns taken up at ragged intervals by the Home Office, require some change.

British "Inefficiency."—Apart from their other uses, closer particulars of the work done in British textile factories may do something for the British name for efficiency. The new book "Eclipse or Empire," reproduces a sadly fallacious set of tables from which the reader is asked to believe that in productive power the American textile operative is the equal of from one and a half to three English wage-earners. It is stated, for example, that the net weekly produce of a silk worker in the United Kingdom is £1 1*s.* 2*d.*, against the average £3 9*s.* 3*d.* in the United States. Even if the figures are as accurate as the industry of census compilers can make them, they are valueless for comparative purposes, because they do not relate to the same form of work. The similarity between the American and English silk industries is in their name, not in their nature, and there is no possibility of illumination from comparisons which fail to distinguish between such essentially different commodities as silk yarn and silk cloth. In the same way there is no excuse for treating American and British cottons as identical articles. The same chapter in the glossary of the book avers that in the use of the most modern and most perfect labour-saving machinery, the American cotton industry was far ahead of the British five years ago. The basis of this extraordinary assertion is a comparison of the number of automatic looms in use in the two countries; but the outsider may be assured that the Lancashire manufacturer is still pursuing his policy of using that machine which gives the best return for his money. If American experience runs counter to English, something must be allowed for local circumstance. It does not follow that either party is in the wrong.

Marine Silk.—The question has been asked. "What is marine silk (*byssus*), the exportation or re-exportation of which has been prohibited from France?" The answer is indiscoverable in the ordinary way of trade, and it cannot be affirmed of knowledge that the material has any modern use. Porter, in his Treatise, quotes a writer of 1782, who had seen "a strong, brown silk, belonging to some sort of shell, of which they make caps, gloves, stockings, waistcoats, etc., warmer than the woollen stuffs, and brighter than common silk." The description makes it seem the more singular that so meritorious an article should have dropped out of use, and it may be supposed that the account is in some ways deficient. Aristotle knew byssus, and described it as the beard of the pinna, which is a large shell-fish of the mussel family. The pinna secretes a viscid matter in innumerable filaments, and by means of these steadies itself against the movement of the water. Byssus was manufactured in the kingdom of Naples and in Palermo, and it is recorded that in 1754 marine silk stockings were presented to Pope Benedict XIV. Snuff-boxes are not necessarily of one size, but it is said that a pair of byssus stockings could be easily contained in a snuff-box. The article is mentioned presumably by force of habit in French proclamations in company with the recognised sorts of silk.

The Next Carpets.—Fashion in carpets is apparently on the brink of change, the Persian *motifs* having been exhausted nearly as thoroughly as the variants upon Voysey's acanthus leaves. The new sources of inspiration are also Eastern, and as they open up a rich lode of adaptable material it is probable that they will provide a long run. Springtime is the season at which new carpets appear before the public, but the preparations for that period are well forward, and it can be said that the drawing-room carpets for next year will include a choice of Chinese and Egyptian designs. There will be willow-pattern Axminsters in blue and white, and tawnier carpets with recognisably Chinese figures for ornament. The sphinx is an obviously adaptable object for carpet designs, and there is material enough associated with the Nile to allow innumerable changes to be rung upon Egyptian themes. Apparently "verdure" carpets with black or grey backgrounds will again be prominent. Carpets are both up in prices and down in quality, as judged by peace standards, and the deterioration is in part involuntary—a consequence of the inability to get the same yarns and colours as before. Materials are so dear that a good deal has been deliberately taken out of the fabrics to bring them within the limits of the purse, and it rests to be seen whether the old standards will ever be restored. The expense of double dyeing

has put an end temporarily to the production of improved printed carpets for bedrooms, in which a relatively high standard of taste was applied to a cheap kind of goods. Manufacturers note a steady but slow progression towards higher art in carpets for the artisan's home. New patterns in printed carpets cost a large sum of money, and must sell in quantities in order to become profitable. The producer is thus tied to the greatest common measure, and is not free to consult only the most advanced sections of his public.

Textile Research.—The Textile Institute continues its semi-annual congresses, and in its latest session at Leeds discussed principally science in its industrial application. Mr. J. H. Lester's paper bore the most directly upon textile as opposed to chemical manufacturers' problems. Scientists tend to be too abstract and manufacturers too concrete, so that it is advantageous to hear one who doubles these capacities. A chemist who for many years managed the Chamber of Commerce Testing House, Manchester, and is now scientific director of one of the largest Lancashire cotton firms, should be able to see from both sides. Mr. Lester's paper distinguished between the position of textiles and that of the magneto, optical glass and colour industries, and all its tenour was against haste and the expectation of quick returns from a sudden devotion to scientific research. He sketched a picture of confraternities of research workers in physics and chemistry worthily housed in the local centres of the industries they are to serve, and united less by mechanical organisation than by fellowship. Mr. Lester left it to others to formulate a definite scheme. It is, however, to be desired that some one should supply a picture of these researchers at their work, showing what they would do from day to day, with specimens of the kind of fact they would accumulate, and illustrations of the use to which their rarefied data would be put. The more actual the prospects can be made, the more enthusiasm they will evoke among the apathetic.

Current Difficulties.—Complaints are rife about the inattention of workpeople and the impossibility of maintaining discipline when any discharged worker can find new work at any moment. Carelessness quite openly breeds carelessness. Yarn comes in from the spinners with more than its due allowance of knots and thick places, and the effect is not to make the weaver more careful but less. It is said that standards of excellence have been relaxed, and that customers have to be thankful for such goods as may be sent; but to reach even these debilitated standards gives a large amount of trouble. Extra processes have to be employed to bring the resultant goods up to the mark, and these all occupy time and intensify vexation. The best-laid plans are sent awry, and manufacturers who thought they had protected themselves and their customers by allotting their production strictly *pro rata*, and by refusing to sell any goods they did not feel well able to deliver, find themselves three and four months behind their programme. The plight may not be universal, but at all events it is common; and it is a trying one for the health and temper, relieved though it may be by the facts of the balance-sheet.

OBITUARY.

Sir John William Pitt Muir-Mackenzie, K.C.S.I.—Sir John Muir-Mackenzie died at his residence in London on October 25th.

Born in 1854, he was educated at Eton, and passed into the Indian Civil Service in 1874. In 1883 he was deputed to study agriculture at the Royal Agricultural College, Cirencester, and ten years later he was sent to Réunion and Mauritius in connection with Coolie labour questions. He became Under-Secretary to the Government of India in the Revenue and Agricultural Departments, and subsequently Director of Agriculture. He also acted as Chief Secretary to the Government of Bombay, and Commissioner in Sind. He was a member of the Executive Council of the Government of Bombay from 1905 to 1910, when he retired from the Service, and he acted as temporary Governor in 1907. He was created K.C.S.I. in 1909.

Sir John became a member of the Royal Society of Arts in 1900, and he occasionally took part in discussions at meetings of the Indian Section.

Walter Hancock.—The Society has lost one of its oldest members by the death of Mr. Walter Hancock, which took place on October 17th.

Mr. Hancock was born at Aylesbury in 1831. He came of a remarkable family. His father, Charles, was well known as an artist and particularly as a painter of animals; but he was perhaps still better known for his work in connection with gutta-percha. He was the first to devise special machinery for cleansing and purifying the raw material, and he also took out the first patent for its practical application. It was at the Society of Arts that he obtained his first specimen for experiment, a piece having been given him at the *conversazione* held here in the winter of 1843-44 when Dr. Montgomerie's specimens were first exhibited.

Charles Hancock's two brothers were also well known in their day. Thomas's name was intimately associated with the earliest steps in the manufacture of india-rubber, for he was the inventor of the vulcanising process, which he patented in 1843. He also took a number of other patents in connection with the subject. The other brother, Walter, was an engineer who did much to promote the use of steam carriages on common roads, and also improved the machinery for india-rubber manufacture. The late Sir Frederick Bramwell was one of his pupils.

Walter Hancock, the subject of this notice, was educated at a private school, where one of his keenest competitors was James (afterwards Sir James) Knowles, the editor of the *Nineteenth Century*. At the age of fourteen he entered the engineering works, at Stratford, of his uncle, Walter Hancock. Young Hancock naturally devoted himself to machinery for gutta-percha manufacture, and was associated with his father at the works at West Ham and Smithfield. Subsequently he was connected with the India Rubber, Gutta Percha, and Telegraph Works Co., Ltd., and designed and built their gutta-percha factory and plant at Silvertown.

Mr. Hancock became a member of the Society of Arts in 1859, at the suggestion of Mr. Thomas Webster, Q.C., father of the late Lord Alverstone, who, like his son, took a very deep and active interest in the Society's work. He spoke for the first time in the Society's room in 1863, when he took part in the discussion on a paper on "Submarine Telegraphy," by Mr. Webster, and thenceforward he was a frequent speaker here, especially on papers connected with india-rubber, gutta-percha, and telegraphy. His last appearance in the meeting room was made in 1913 (exactly fifty years later), when he came to hear a paper by his son, Mr. Walter C. Hancock, on "The Physical Properties of Clays."

Mr. Hancock was an early member of the Institution of Telegraph (now Electrical) Engineers, and he served on the council of that body. He also took a deep interest in the work of the Self-Propelled Traffic Association, and was one of the deputation sent by that body, under the leadership of Sir David Salomons, to Mr. Henry Chaplin, President of the Local Government Board, in 1896. As a result of this the Light Road Locomotives Act was passed in that year, and the development of automobilism in this country was rendered possible.

GENERAL NOTES.

Kaolin Deposits in Paraguay.—According to a report by the United States Consul at Asuncion, there has recently been considerable interest evinced by Argentine capitalists in kaolin in Paraguay, in which country there are numerous large deposits. The principal one is situated at Tobati, thirty miles from the Paraguay Central Railway, and is estimated to contain 7,800,000 cubic yards of kaolin. The kaolin of this deposit is said to be of a good quality, suitable for the manufacture of china, etc. As yet, however, no extensive investigations of the extent of the deposits or of the properties of the kaolin have been made. It is stated that a company, with a capital of about £500,000, will be formed in Argentina to extract the kaolin from the Tobati district and to manufacture products therefrom.

Russian Phonetics.—A special course in Russian phonetics and their application to class teaching will be delivered by Mr. M. V. Trofimov, B.A. (Petrograd), lecturer in Russian at University of London King's College. The course will consist of thirty hours, and will be held on Wednesdays from 5 to 7 p.m., beginning on Wednesday, November 8th, 1916. On each day one hour will be devoted to theory and a second to practical demonstration and discussion. The class is specially designed for those who teach or wish to teach the Russian language in England, whether themselves of Russian or English nationality. The fee is two guineas for the course of thirty hours.

Black Damp in Mines.—The United States Bureau of Mines, in pursuing investigations looking to greater safety in mining, has analysed samples of the air in many different coal mines in the United States, and has studied the analyses. The results of one phase of this study are presented in Bulletin 105, "Black Damp in Mines." This study shows how atmospheric air, after entering a coal mine, loses oxygen and gains carbon-dioxide, with resulting formation of so-called black damp. The report also discusses the effects of the constituents of black damp on men, on the burning of oil and acetylene lamps, and on the explosibility of methane. Copies of this Bulletin may be obtained free of charge by addressing the Bureau of Mines, Washington, D.C.

Japanese Cotton Trade.—Japan's exports of cotton yarn have shown a large increase since the latter part of last year. According to the *Japan Chronicle's* report of investigations made by the Spinning Association, exports of various cotton cloths during the first half of this year amounted in value to $23,415,072. This figure is unprecedentedly large, and shows an increase of $4,123,467 over the amount for the preceding six months, and $10,966,488 over that of the corresponding period last year. The highest rate of increase was seen in the exports to India, followed by Siberia, while the exports to the Philippines decreased by about one-half as compared with the preceding half-year.

Basket-making at Nice.—A school for teaching the art of basket-making (*École de Vannerie*) to disabled soldiers and other disoccupied persons has been opened at Nice. Although opened barely three months ago, it already numbers 79 pupils. It is contemplated opening branch schools in other parts of the Department of the Maritime Alps, in order to encourage the art as a home industry, and so eventually to free the country from dependence on German goods, which previous to the war flooded the French markets to the extent of 80 per cent. Vast tracts of marshy country and other suitable waste land might be utilised for osier growers if a demand were created for materials for basket-making.

London: Printed by William Clowes & Sons, Ltd., Duke Street, Stamford Street, S.E., and published for the Royal Society of Arts by G. Bell & Sons, Ltd., York House, Portugal Street, W.C., in the Parish of St. Clement Danes, in the City of Westminster.—November 3, 1916.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICES.

ARRANGEMENTS FOR THE SESSION.

The Opening Meeting of the One Hundred and Sixty-Third Session will be held at 4.30 p.m. on Wednesday, November 15th, when an address will be delivered by DUGALD CLERK, D.Sc., F.R.S., Chairman of the Council, on "The Stability of Great Britain."

The following arrangements have been made for the meetings before Christmas:—

ORDINARY MEETINGS.

Wednesday afternoons, at 4.30 p.m.:—

NOVEMBER 22.—LESLIE URQUHART, "The Economic Development of Russia and Britain's Share therein." The RIGHT HON. LORD CARNOCK, G.C.B., G.C.M.G., G.C.V.O., K.C.I.E., British Ambassador in Russia, 1906-1910, will preside.

NOVEMBER 29.—

DECEMBER 6.—C. M. WHITTAKER, B.Sc., "The Coal-Tar Colour Industry."

DECEMBER 13.—H. WILSON FOX, "The Development of Imperial Resources."

DECEMBER 20 (at 4 p.m.).—A. C. BENSON, C.V.O., Master of Magdalene College, Cambridge, "Classical and Scientific Education."

INDIAN SECTION.

Thursday afternoon, at 4.30 p.m.:—

DECEMBER 14.—JOHN ALTON TODD, B.L., Professor of Economics, University College, Nottingham, "The World's Cotton Supply and India's Share in it." The RIGHT HON. LORD EMMOTT, P.C., G.C.M.G., will preside.

Papers to be read after Christmas:—

LAWRENCE CHUBB, Secretary to the Commons and Footpaths Preservation Society, "Highways and Footpaths."

W. A. CRAIGIE, M.A., LL.D., Joint Editor of the Oxford English Dictionary, "The Lexicography of the Arts and Sciences."

JAMES HARRIS VICKERY, LL.B., "German Business Methods."

CAPTAIN PHILIPPE MILLET, Colonial Editor of *Le Temps*, "The Problems of French North Africa."

OCTAVIUS C. BEALE, "British Arts and Crafts after the War."

COLONEL SIR THOMAS H. HOLDICH, R.E., K.C.M.G., K.C.I.E., C.B., D.Sc., "Between the Tigris and the Indus. The Ben-i-Israel."

SURGEON-GENERAL SIR C. PARDEY LUKIS, K.C.S.I., K.H.S., M.D., F.R.C.S., President, Scientific Advisory Board, Indian Research Fund Association, "Opportunities for Original Research in Medicine in India."

SIR C. ARTHUR PEARSON, Bt., Chairman, Blinded Soldiers and Sailors Care Committee, Address on "The Blind Sufferers from the War, and their future Employment."

JOSEPH PENNELL, "The Artistic Aspects of War Work."

F. A. HOCKING, B.Sc., Pharmaceutist to the London Hospital, "The War and our Supply of Drugs."

INDIAN SECTION.

Thursday afternoons, at 4.30 p.m.:—

January 18, February 15, March 15, April 19, May 17.

COLONIAL SECTION.

Tuesday afternoons, at 4.30 p.m.:—

January 30, February 27, March 27, May 1.

HOWARD LECTURES.

Monday afternoons, at 5 p.m.:—

JOHN S. S. BRAME, Professor of Chemistry, Royal Naval College, Greenwich, "Coal and its Economic Utilisation." Three Lectures.

LECTURE I.—NOVEMBER 27.—The economic importance of coal—Enhanced importance in war time—Coal: the munition of war—The movement for economy—The output of coal and consumption

for various purposes—Duration of supplies and economical considerations in relation to other countries—Other alternative sources of energy.

Lecture II.—December 4.—Recent developments in knowledge of composition of coal—Coal as a heating agent—As source of power—For domestic heating, etc.—The by-products from coal distillation, their relation to industry, and particularly as raw materials for munitions of war.

Lecture III.—December 11.—Directions in which economy may be realised—Economy in production—The utilisation of small and low-grade coal Improvements by suitable preparation for market—Economy in use—By-product recovery—Economies possible from centralised systems of power generation: from extended use of carbonised coal, including gas—Low temperature carbonising schemes.

William Ripper, D.Eng., D.Sc., Professor of Engineering, University of Sheffield, "Works Organisation and Efficiency." Three Lectures.

April 23, 30, May 7.

Cantor Lectures.

Monday afternoons, at 4.30 p.m. :—

Professor A. Beresford Pite, F.R.I.B.A., Royal College of Art, South Kensington, "Town Planning and Civic Architecture." Four Lectures.

January 29, February 5, 12, 19.

Juvenile Lectures.

Wednesday afternoons, January 3 and 10, at 3 p.m. :—

Alan A. Campbell Swinton, F.R.S., "Electricity and its Applications." Two Lectures.

FOTHERGILL LECTURES.

The Fothergill Lectures on "Surveying, Past and Present," by Edward A. Reeves, F.R.A.S., F.R.G.S., Map Curator and Instructor in Surveying to the Royal Geographical Society, have been reprinted from the *Journal*, and the pamphlet (price one shilling) can be obtained on application to the Secretary, Royal Society of Arts, John Street, Adelphi, London, W.C.

A full list of the Lectures which have been published separately, and are still on sale, can also be obtained on application.

MECHANICAL MILKING.

In reference to the statement on this subject in Engineering Notes in the *Journal* of October 27th, Sir Philip Magnus put a question on November 2nd, to the Secretary to the Board of Agriculture, asking whether attention had been called to the alleged advantages of substituting the mechanical milking of cows for hand milking; if so, whether the Board had considered the practicability of the proposal; and whether he was aware of the effect of the adopting of mechanical milking in removing many difficulties with which railway companies had to contend and in facilitating the carriage of milk by earlier morning trains.

Mr. Acland, in reply, said:—"The Board have for years given close attention to this subject, and are well aware of the advantages to be derived through the use of milking machines under suitable conditions. Farmers generally are also pretty well aware of the advantages and disadvantages of the machine compared to hand milking, though there is a good deal of difference of opinion as to what is the best machine. Trials of different machines have been conducted under the Board's auspices at farms attached to agricultural colleges, and wide inquiry has been made as to the results of the use of machines in practice. Many farmers having large and medium-sized herds are finding it an advantage to instal machines at the present time, but generally there is not much saving of time effected by their use, and therefore the point as to catching earlier trains which the hon. member raises does not arise."

It may be added that mechanical milking is largely employed in Holland, and that it has been found very useful in Australia and America. In this country opinion as to its value is divided. Some dairy farmers have been very successful with it, but others, after trying it, have abandoned its use. It does not entirely supersede hand milking, as the udder is not quite emptied and has to be "stripped" by hand. It also appears to affect the teats, in some cases at all events.

ARTS AND CRAFTS.

The Arts and Crafts Exhibition at Burlington House (Second Notice).

The present Arts and Crafts Exhibition shows a healthy blending of old and new ideals. The Committee have arranged a small but interesting retrospective room, the President of the Society has written a spirited preface to the catalogue which compares certainly to no disadvantage with similar forewords in the earlier catalogues, and the old custom of holding lectures in the galleries has been revived under the rather more modern guise of papers followed by discussion. On the other hand, the grouping of a portion of the exhibits under such headings as Domus, University, Ecclesiastic, Municipal, Hall of Heroes, is quite a new departure, and so is the practice of allowing different schools of art to be responsible for a certain amount of space. The plan tried some years ago (on one occasion only) of allowing some members of the Society to

group their own exhibits together has this year been extended so that certain artists, or bands of artists, are responsible for the decoration and furnishing of what are practically small rooms. With regard to the effect of the exhibition as a whole, it would be difficult to say too much for the general architectural and decorative planning of Ecclesiastic, with its chapels decorated by Mr. Wilson, Mr. Louis Davis and others, and held together by its general scheme of decoration and by the frieze around the dome contributed by Mr. C. W. Whall. The appearance again of the Hall of Heroes is fine, with its walls adorned with paintings by well-known artists, its dainty figures by Sir G. Frampton in the apse and its general air of spaciousness and grandeur; but when one passes on to the neighbouring rooms one is tempted to wonder whether the feeling of roominess which is so delightful in the large hall has not been rather dearly bought at the expense of the overcrowded rooms on either side of it. University, which contains not only Mr. W. Rothenstein's fine decoration, "designed as a memorial to members of the English universities who have served in the war," but also a large composition by Mr. Augustus John, suffers rather from being used to house a somewhat miscellaneous collection of exhibits—not all of which accord very well with the title of the gallery. The little room in which are shown the work of the students of the embroidery class at the Royal College of Art, if not very remarkable, houses a pleasing and homogeneous little collection of work, but the exhibit of the Birmingham school hardly seems to justify its existence. There is some good student metalwork and some embroidery which is creditable as the work of girls of fifteen and sixteen, but there seems no particular reason for showing it at an exhibition at Burlington House.

Jewellery and Metalwork.—When we turn to the individual works, the jewellery and small metalwork are amongst the most interesting exhibits, and this is due in no small measure to the President's own work. Mr. Wilson's jewellery is always individual, distinguished and planned with real decorative feeling. He shows a whole caseful of jewellery and some specimens of silversmithing as well, amongst which a beautiful silver chafing-dish is worthy of special notice. Mr. Stabler, again, is represented by a good set of his wonderfully fine champlevé enamel, and some silverwork. The mace for Westminster Cathedral, however, which is his most important exhibit of enamel and metalwork combined, is rather unnecessarily heavy looking, even for a mace, though there is some excellent workmanship in it. Mr. Paul Cooper has some distinctive jewellery, some of it recalling Scandinavian enamelwork, and some beautiful silverwork and shagreen. Mr. C. R. Ashbee's exhibits include a good silver porringer, whilst some of Mr. Edward Spencer's work shows a happy combination of silver and ivory. Mr. James Cromar Watt's cup with cover in silver, enamel moonstone and crystal is rather Eastern in feeling and on quite different lines from most of the silverwork. Mr. and Mrs. Gaskin have sent some good jewellery, and Miss Kirkman, Miss Ramsay and a number of other women are adequately represented. On the whole both the metalwork and jewellery reach a very high level. There is little struggling after originality at all costs, and yet the work of the different craftsmen is easy to distinguish. The jewellers, too, for the most part have ceased to rely too exclusively on the colour and beauty of their stones, and are seeking to provide at the least beautiful and fitting setting—in many cases ornament only dependent in a minor degree on stones and enamel.

Textiles.—The embroidery is at once very interesting and a trifle disappointing. There is quite a good deal which is fresh up to a certain point, very little which shows much real originality. The most striking piece of work is Miss Newill's banner for the Birmingham Church Congress, which represents S. Martin dividing his cloak with the beggar. This is well and boldly schemed. Its main outlines are well pronounced and to be seen from a distance (a very important matter in a banner), and the workmanship bears the closest investigation. There is not a very great quantity of large embroidery, and some at least of what there is hardly justifies itself—it could have been done at any rate almost as well by machine as by hand; but there is some beautiful cutwork, a little good lace and a fair sprinkling of samplers Needlework pictures are fairly well represented. A good deal of the design harks back to the sixteenth, seventeenth and eighteenth centuries, and there are some good examples of embroidery in black or black and some colour on white in the old style. Mrs. E. W. Newberry's work, which is amongst the most beautiful in the exhibition, is inspired by Eastern originals. Her cushions, mainly in terra-cotta and black on unbleached coloured linen, suggest the old work which comes from the Greek islands, and her tablecloth worked in silk of many colours in plait stitch of some sort which covers the entire ground suggests that it had a fine piece of Eastern embroidery for its model. Mrs. W. Sickert's dalmatic is a bold piece of work which was shown at Ghent. There is a great deal of tasteful stitchery of a simple kind adapted to the ornamentation of clothes—some of it following more or less the fashions of the day, some adorning jerkins or tunics rather suggestive of the Balkans. A little elaborate weaving is shown and some tapestry, but the woven fabrics in the main consist of simple hand-woven stuffs remarkable on the whole for their beautiful colouring.

Amongst these may be mentioned Miss Mairet's work and Miss Inez Skrine's handwoven silk and mercerised cotton bedspreads, one in rose and gold, the other in blue and green, in which good use has been made of extra shuttles at the ends.

Writing, Illumination and Book Production.—The writing and illumination and allied crafts are mainly shown in one room, though Mrs. Sydney Cockerell's beautiful illuminations—the finest work of the kind in the exhibition—are on view in the retrospective room. There are not so many rolls of honour and war memorials as might have been expected, but Mr. Graily Hewitt exhibits—as well as a number of beautifully-written books and the Consecration prayer in gilt on parchment in the form of an altar cross—the roll of honour for St. Stephen's Club. Mrs. Louise Powell shows some good illumination, and Mr. Allan Vigers' frieze in a neighbouring room is wonderfully reminiscent of his illumination work. Mr. Kruger shows some good designs for printing and Mr. Noël Rooke an interesting certificate. The finest bookbindings are by Miss Katharine Adams, some of them quite old friends. The Doves Press and other printers have sent excellent examples of their typography, but there is not very much which bears on book production for the world at large.

Woodwork, Pottery and Design.—Furniture is one of the features of the exhibition. Mr. Gimson's chair in walnut and bone, designed as a study for a set to be executed in ebony and ivory for S. Andrew's Chapel in Westminster Cathedral, is interesting and unusual. Mr. Romney Green's walnut adjustable chair with folding table is good to look at and suggests the height of comfort and practicality. Mr. Laurence Turner's mirrors, especially the one in ebony inlaid with mother-of-pearl and ivory, are real works of art. There are not very many toys, but Mr. Macdonald Gill's animal alphabet blocks ought to rejoice the heart of any child.

The pottery includes a good show of Martin stoneware and some of Mrs. Stabler's charming little figures, as well as some cases of painted work by various people all very much of the same type. There is some beautiful lustre by the Pilkington Tile and Pottery Co.—amongst it some wonderful pieces of colour—but it is not very well shown. Messrs. Powell's case of glass is delightfully refined and delicate.

Designs for wallpapers, textiles and the like are rather to seek. Either the Society has looked coldly upon such work or the designers have not felt encouraged to send. Amongst those that are shown may be mentioned Mr. Horace Warner's Jay birds, which is attractive without being too obtrusive, and Mr. Edgar Pattison's Warsaw which, though rather aggressive in colour, is well designed and in its way interesting.

NOTES ON BOOKS.

La Science Française. Paris: Ministère de l'Instruction publique et des Beaux-Arts. 1915.

The French Ministry of Public Instruction contributed to the San Francisco Exhibition a Scientific Library of books ancient and modern, intended to illustrate the share taken by France in the development of science. This collection of scientific books is illustrated by the present publication, which is meant to summarise the work with which the collection dealt.

The term science covers in France a wider scope than in this country, where it is generally considered to include only those branches of natural knowledge to which the work of the Royal Society is specially devoted. These two volumes, therefore, besides including mathematics, astronomy, physics, chemistry, geology, biology, medicine, and geography, contain articles on philosophy in general (by M. Henri Bergson), sociology, the science of education, archæology, history, art, and economics. For the most part natural science proper is included in the first volume, while the second volume treats not only many of the subjects above mentioned, but also contains chapters on English, Italian, Spanish, and French literature as studied in France.

The chapter "Les études anglaises," by M. Émile Legouis, is extremely interesting; but it hardly does justice to the influence exercised in former years on French literature by that of England. While English writers of the seventeenth century were to a very large extent influenced, or even dominated, by their French contemporaries and predecessors, it should be remembered that in the eighteenth century the current flowed in the opposite direction. During the whole century the published writings of French philosophers, important as they were, were in fact but the development of ideas started by English philosophers. That this was so was probably due to a large extent to Voltaire, who while he was in England studied Newton's "Principia," and indeed introduced our great English mathematician to France. Voltaire's philosophy, too, was almost wholly based on Locke's teaching, though it owed something also to the writings of Hobbes. Rousseau also learned much from the former philosopher, though he was to a much greater extent a follower of Hobbes, while Montesquieu's model in his "Esprit des Lois" was the English Constitution—hence indeed its popularity in England. Voltaire's followers, Diderot and d'Alembert, learned much from England. D'Alembert in his Discours Préliminaire to the "Encyclopédie" founded his description of human knowledge

on Bacon; while Palissot, one of the adversaries of the "Encyclopédie," characterised the whole work as a "servilement copié de Bacon." Théry also says, "C'est le Novum Organum de Bacon qui inspira a Diderot ses Pensées sur l'Interprétation de la Nature." Condillac carried Locke's doctrines on to pure materialism; indeed it is not too much to say that the doctrines which led eventually to the French Revolution had their entire source and origin in the ideas which originally started and developed in the freer atmosphere of this country.

Other English writers also, nearer the end of the eighteenth century, for instance Gibbon and Adam Smith, had a considerable influence in France, and were greatly studied in that country. The whole question, however, is too large a one for discussion in a chapter on the "Study of English Literature in France," and perhaps it was hardly to be expected that M. Legouis should have given much attention to it.

Taking the book on the whole, it is an extremely interesting and valuable synopsis of the work which Frenchmen have done towards the advancement of human knowledge, and the idea of its publication was a very happy one.

DYEING IN GERMANY AND AMERICA. By S. H. Higgins, M.Sc. Second Edition. Manchester: At the University Press; London: Longmans, Green & Co. 5*s*. net.

The first edition of this book was issued in 1907 as "a Report . . . on the results of a Tour in the United States of America and Germany in 1905–1906," and the author's intention was to give a general survey of the dyeing and allied industries of these countries. Although no further visit has been paid to either of these countries, the author's subsequent nine years' experience as a demonstrator in the Dyehouse of the Manchester School of Technology and as a works chemist and manager has enabled him to add materially to what appeared in the first edition, and the work now serves as a very complete and compendious text-book which should prove useful, not only to the technical student, but also to the general reader who desires to obtain some knowledge of the dyeing industry.

The question of producing dyes in this country has been so acute since the outbreak of the war that most readers will turn at once to the last chapter, in which Mr. Higgins discusses the present situation. He appears to take a sane and moderate view of it. Although the aniline dye industry had passed into the hands of Germany, he points out that this is only a relatively small part of the total chemical industry of any country, and he claims that, with the exception of synthetic dye-stuffs, synthetic drugs, and fine chemicals, the English chemical industry has held its own. "As for the German colour industry," he writes, "I have long contended that it has too often provided food for those Britishers who are always stating that we are falling behind in the industrial race, and the fact that this industry is again brought to our notice only serves to point to the paucity of more suitable material to brood over. Even though the dividends declared by the German colour-works are high, it must be remembered that there are still many English chemical concerns which are the envy of German manufacturers."

Of course it would be foolish to attempt to belittle the importance of the German industry. Mr. Higgins does full justice to this, and he sums up the various reasons for its value very shrewdly. It has been a great industrial asset to Germany, he writes, "because it has become the mother of many new industries, such as synthetic pharmaceutical products, anhydrosulphuric acid, and liquid chlorine; because the industry has been a great object-lesson to the Germans in showing the advantage derived from the application of science to industry; because it has reacted in producing a more general appreciation of technical education; and because it has been an important factor in inducing the Government and local authorities to render assistance in fostering various industries."

Whether the German dye industry will ever recover the position which it occupied before the war remains to be seen. Steps have been taken by several other countries, notably Great Britain, France, the United States of America, Russia, and Japan to render themselves independent in this respect of the German factories; and it seems highly improbable that the world at large will ever again permit itself to suffer from the monopoly of a people whose commercial methods are now seen to be but little better than its barbarous methods of carrying on war.

GENERAL NOTES.

BELGIAN WOUNDED AND PRISONERS OF WAR.—The Belgian Committee of the "Oeuvre Internationale pour Blessés et Prisonniers de Guerre," propose to hold at Breda (Holland) an exhibition of paintings and drawings for the benefit of prisoners of war in Germany. Prizes will be offered, varying in value from 500 francs and a gold medal to 75 francs and a bronze medal; and the paintings and drawings will become the property of the Committee, who will dispose of them by sale or lottery for the benefit of the Belgian wounded and prisoners of war. All taking part in the competition must send in their work to the Committee, 17, Willemstraat, Breda, Holland, before January 1st, 1917.

VICTORIA AND ALBERT MUSEUM.—A collection of Chinese porcelain, chiefly of the latter part of the Ming dynasty (1368-1643), lent by the Rev. J. F. Bloxam, has been placed on exhibition in the Victoria and Albert Museum. Three cases contain "blue and white," illustrating the rich and varied qualities of colour attained in this class of ware by the Chinese potters of the sixteenth century. The intense "Mohammedan blue" of the reign of Chia Ching (1522-1566), composed in part of cobalt imported from Western Asia, is seen at its best on a large bulbous bowl with figure-subjects in panels, on a square-bodied bottle with gourd-shaped neck charmingly painted with groups of children in garden scenes, and on several covered boxes of various shapes. The beauty of these is equalled by that of the finest porcelain of the reign of Wan Li, approximately synchronising with the lifetime of Shakespeare; the blue is of a soft dark hue verging on indigo, under a bluish-toned glaze of wonderful silky smoothness. Examples of this Wan Li blue are two small plates with the figure of Shou-lao, god of longevity, seated in a landscape surrounded by various attributes; another plate, exquisitely painted with a bird on a peach-tree, should also be noticed. A cylindrical brush-pot with figure subjects exemplifies the light greyish-blue imitated by the Japanese potters of Hirado, which is recorded to have characterised the porcelain of the reign of Hsüan Tê (1426-1435). Another rare piece is a bottle with a formal design of lotus-flowers and Arabic inscriptions, made for Moslem use, dating in all likelihood from the time of Chêng Tê (1506-1521), whose name it bears.

NEWFOUNDLAND SEALING.—The Newfoundland sealing season of 1916, which has just ended, was financially the most successful experienced for years. The catch numbered 243,000, according to *United Empire*, and the value to the fishermen is returned at £200,000. In consequence of the war, and the absence of men to handle the ships, the number of vessels engaged was only twelve—the smallest number employed for many years; but this was counteracted by the large catch that was secured, as well as by the high prices prevailing for the proceeds of the fishery.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, NOVEMBER 13...London Society, at the ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 5 p.m. Mr. E. T. Hall, "Dulwich History and Romance."

Brewing, Institute of (London Section), Imperial Hotel, Russell-square, W.C., 7.30 p.m. Mr. S. O. Nevile, "The Formation of War Savings Associations in Breweries."

Surveyors' Institution, 12, Great George-street, S.W., 5 p.m. Address by the President.

East India Association, Caxton Hall, Westminster, S.W., 4.15 p.m. Mr. B. A. Collins, "Co-operation in India."

TUESDAY, NOVEMBER 14...Swiney Lectures, at the ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 5 p.m. Mr. J. S. Flett, "The Mineral Resources of Europe." (Lecture I.)

Asiatic Society, 22, Albemarle-street, W., 4 p.m. Mr. J. Kennedy, "The Gospels of the Infancy, the Lalita Vistara and the Vishnu Purâna: or, the Interchange of Legends between India and the West."

British Decorators, Institute of, Painters' Hall, Little Trinity-lane, E.C., 8 p.m. Mr. I. Beaumont, "My Six Months' Travels in Italy."

Photographic Society, 35, Russell-square, W.C., 7 p.m. Address by the President.

Anthropological Institute, in the Theatre of the Civil Service Commission, Burlington-gardens, W., 6 p.m. (Huxley Memorial Lecture.) Sir James G. Frazer, "Ancient Stories of a Great Flood."

Colonial Institute, Hotel Cecil, Strand, W.C., 8.30 p.m. Sir Rider Haggard, "Empire Land Settlement."

WEDNESDAY, NOVEMBER 15...ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 4.30 p.m. Opening Meeting of the 163rd Session. Address by Dr. Dugald Clerk, Chairman of the Council, on "The Stability of Great Britain."

Meteorological Society, 70, Victoria-street, S.W., 5 p.m. 1. Mr. C. E. P. Brooks, "A Meteorologist in China." 2. Lieut. A. E. M. Geddes, R.E., "The Storm of the 11th-13th November, 1915, in its Passage over the British Isles."

Microscopical Society, 20, Hanover-square, W., 8 p.m. 1. Dr. C. Singer, "The Microscopic Work of the Accademia dei Lincei." 2. Mr. S. C. Akehurst, "A New Tank and Pond-weed Holder for use with Greenough Immersion Objectives."

Literature, Royal Society of, 2, Bloomsbury-square, W.C., 5.15 p.m. Lecture by Professor Walter de la Mare.

THURSDAY, NOVEMBER 16...Swiney Lectures, at the ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 5 p.m. Mr. J. S. Flett, "The Mineral Resources of Europe." (Lecture II.)

Linnean Society, Burlington House, W., 5 p.m. 1. The General Secretary, "(*a*) Pedanios Dioscorides of Anazarba; his writings and his commentators; (*b*) The new cabinets for the Linnean herbarium." 2. Dr. A. B. Rendle, "A new Australian genus of Hydrocharidaceæ." 3. Mr. A. W. Waters, "Some collections of the littoral marine Fauna of the Cape Verde Islands, made by Cyril Crossland, M.A., in the summer of 1904.—Bryozoa."

Camera Club, 17, John-street, Adelphi, W.C., 8.15 p.m. Mr. F. Young, "The Camera-Pilgrim's Progress."

Historical Society, 22, Russell-square, W.C., 5 p.m. Mr. W. Foster, "The India Board."

Numismatic Society, 22, Albemarle-street, W., 6 p.m.

Mining and Metallurgy, Institution of, at the Geological Society, Burlington House, W., 5.30 p.m. Informal Meeting.

FRIDAY, NOVEMBER 17...Swiney Lectures, at the ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 5 p.m. Mr. J. S. Flett, "The Mineral Resources of Europe." (Lecture III.)

Mechanical Engineers, Institution of, at the Institution of Civil Engineers, Great George-street, S.W., 6 p.m. Report of the Hardness Tests Research Committee.

CONTRIBUTIONS TO THE READING-ROOM.

The Council have to acknowledge, with thanks to the Proprietors, the receipt of the following Transactions of Societies and other Periodicals.
